Dr. Thompson advises more caution, a longer consideration, a more careful weighing of symptoms and persistence in treatment before operating. I agree with him that this is good advice, and *should* be done, and I have no doubt *is* done, in all cases, before the operation is even thought of. *I agree to all this, but when shall we stop pursuing a course which produces no results; where shall we draw the line? Shall it be at three years, or five, seven or nine years of ineffectual treatment, when, in the meantime our patients are growing worse and the probability lessening that they can be finally cured by any means.* In the case to which the Doctor refers, he "stands hesitating" what to do, resisting the clamorous appeals of that poor suffering lady for an operation which offers a *fair* chance of cure, and doing nothing in the meantime which does her any good. How long will he think it wise or necessary to "hesitate?" How many *more* years must she suffer before he will consent to do what she and her husband, with a full, and clear understanding of the nature of the operation, its liability to kill her on the table, or within a week, or, if she gets over it, to fail of a cure; while on the hand so many others *have* been cured, that there is a fair prospect that she may be cured also? I saw the lady at his request and examined her carefully and took notes of her case. Her symptoms all date from a confinement about nine years ago. Her trouble,

to my mind, is ovarian and uterine. She has been treated about nine years; has been under the care of many physicians, some of them as long as two and three years at a time; she has had several surgical operations performed upon her anus, rectum and cervix uteri—the last by Dr. Thompson. She is worse to-day than at any time. She is a helpless wreck; a house-bound invalid; has "no pleasure in life," and is a constant care and expense to her husband and friends. The Doctor says he has *just* discovered that she has an acutely anti-flexed uterus, and thinks her symptoms may all be due to this condition and so "hesitates" to operate. I say give her three months treatment with stem pessaries or any other means, straighten her uterus, and fully satisfy himself as to whether this treatment will cure. Then call a consultation, and let the materia medica be exhausted for three months or six months more if she will stand it, and *then* if not cured, as I hope she may be; after ten years in all spent in useless treatment, I should say then remove her uterine appendages.

Dr. Thompson would not wait ten years or two years or six months before operating on any case in general surgery where there were so many indications that an operation would benefit his patient. He says he wants the most positive and unmistakable evidence that the ovaries are badly diseased before he thinks it right to operate. He perhaps forgets that the symptoms for which we sometimes operate are all produced by the periodic congestion and activity of the normal ovaries when the tubes or the uterus may be so diseased as to prevent menstruation. Indeed Batty's first case was in a patient who had a congenitally small and undeveloped uterus, and where the ovaries were normal and the pains of the "unrelieved menstrual molemen" had nearly produced insanity. Indeed he first named the operation "normal ovariectomy." Marriage was suggested by several speakers as a means of cure. This might do in some cases and probably has worked wonders for many. But in the case just referred to, marriage produced all her troubles. Many of these cases originate from an unfortunate labor or abortion. Who would marry such a girl as Dr. Hamilton operated on, or the lady whose sad case I narrated this evening—a lady having convulsions two weeks out of every month? Two of the ladies upon whom I operated were engaged to be married, and in consequence of their long continued and uncured troubles the engagements were broken off; but since their restoration to health by this operation, I hear some talk of the possibility of married bliss coming to them at an early day.

In another case, a patient upon whom I performed Tait's operation has been "married thirteen long weary years without ever having become pregnant." It is not fair to say these patients are "mutilated and unsexed." They were virtually unsexed by the disease before the operation, and the removal of the cause of all their pain and years of sickness has made them healthy, happy, and useful members of society.

Some cases fail to be cured, and some, very few, die as the immediate result of the operation. But I venture to say that there is not an operation in surgery to-day, as grave as this, which is attended by as

few fatal results or as few failures to cure. Dr. Thompson does not refuse to perform tracheotomy because so many cases operated on die, or fail of a cure. Surgeons do not refuse to cut off legs because some patients die who are operated on, or to cut out cancers when they must be in great doubt whether the disease will not return, and whether they are really doing their patient any good.

Dr. Busey in his eloquent address "endorsed Dr. Thompson's remarks," and as I have replied to those remarks, I need not repeat. This operation is opposed because it has not cured everyone upon whom it has been performed. Have its opponents cured everyone whom they have treated? I have no doubt they, in common with other good physicians, have had some failures, and perhaps some deaths, and yet they don't apply the logic of their arguments to themselves. They lose a patient in childbed perhaps, whose uterus they have washed out and who has taken large doses of quinine, antipyrin, etc., but the next case they have they treat in exactly the same way. They don't make eloquent speeches against "washing out the puerperal uterus in every case" with solutions of the bichloride of mercury, or some other antiseptic, because some have died notwithstanding its faithful use, and a few *because* of its too faithful use, of mercurial poisoning.

Operators are blamed because they do not show "permanent results." It would make this reply too long to go into the statistics of this subject, but there are numerous examples of as permanent results as can be shown from an operation performed for the first time in this country by Battey in 1872—only fourteen years ago; no one can say how these patients will be twenty years from now. Battey's case operated on fourteen years ago he *reports as cured*, and she remains *cured* up to the present time. That is as far back as we can go. Dr. Busey says the life of woman has not been prolonged by this operation. How can he know that? He intimates that more years have been lost than saved by it. He cannot demonstrate that, while I could say much on the opposite side of lives certainly saved in cases of myoma of the uterus, pyo- and hydro-salpinx, hæmorrhage, etc.; but we were especially discussing the propriety of this operation in cases of prolonged and aggravated hysteria and nervous diseases. I admit, and have always admitted, everybody admits, that there is less certainty of a cure in this class of cases than in those just referred to. So there is less success with any other mode of treatment, or they would not continue uncured for so many years and then *finally*, as a *last resort*, come to this operation. No one recommends it; no gynecologist would think of operating until his brother the general practitioner had had several years' opportunity to cure and *had failed*. I think some of the treatment these patients are subjected to and the "hesitating" and let-alone policy as dangerous as oöphorectomy. For instance, my patient came near a terrible death by falling into the fire, in one of her attacks of menstrual epilepsy, while the doctor was "hesitating" what medicine to give next. I think Dr. Hamilton's patient came near being poisoned several times with large doses of

chlpral. And I venture the hint, I don't know, of course, if it is true, but I fear it is, that as many of this class of cases, who have required most of a large family to hold them during their convulsions, and in one of my cases a good part of the neighborhood, and this continuing a week or two out of every month for several years, have died from the effects of overdosing with morphine, chloral or chloroform, as ever died from the effects of the removal of the uterine appendages.

Drs. Smith and Busey say "this operation is becoming too popular, too many operations are being performed, and that unless a halt is called no woman with nervous diseases will be safe; that the profession ought to call a halt." It may be true, and I think it is, that men have tried to do more with this operation than they have succeeded in accomplishing in some cases. So they have with the cervix operation and with many others. Notes of warning have gone up against Emmet's operation, which the best gynecologists of the world have united in calling "the greatest improvement of the age," and yet it is done too often, by rash and inexperienced men and in inappropriate cases; harm has been done and perhaps a score of women killed by it. If what some say is true, sterility has been produced by it. And yet trachelorrhaphy has its undisputed field, so has oöphorectomy. I do not recommend it, as would be inferred from this debate, for the cure of all nervous troubles. I don't want to castrate all women who have painful menstruation or hysteria, but I do say that occasionally a case occurs, which has been under treatment of various and many kinds for many years, where everything else seems to have been faithfully tried and *failed*, which becomes finally a candidate for castration.

The cases are rare, but they exist, and I am sure I am right when I say, consider it as a *last resort*, do everything else *first*, be years about it if you like, three years or ten, but if you *then fail*, and they are getting worse and desire it, operate, or turn them over to some one else who *will operate*, and give them this chance. If I had the time, I would like to speak of the fashion of considering these operations failures if the fullest effect desired is not secured at once, as if by miracle. The change of life is produced by it, artificially, but it must be remembered that this change comes about slowly, when in health even, and those who have operated most, say that they do not consider that they have failed, until at least two years have gone by since the operation, and then, nerve centres which have acquired the habit of exploding in these dreadful convulsions which have been going on for years, do not at once cease to act in this way, and a complete cure cannot immediately occur when the prime cause of the trouble has been removed.

I saw a case of epilepsy which was originally caused by the presence of a tapeworm, continue for a year after I had secured its expulsion—after this time the cure was perfect. The opposition to this operation shown by Emmet and others, when my paper on this subject was read to the American Gynecological Society last year, was referred to.

I reported *four* operations as the basis of my paper, and *all* I had then seen fit to perform, while Dr. Baker, in saying it should not be done too often, referred to *eight* or more cases recently done by himself, and Dr. Lusk; who recommended so much caution, wrote me, and I have his letter now, in which he says that he did this operation twice in the first week after the Society adjourned. Dr. Wilson, of Baltimore, said in that discussion that "he would say only a few words in addition to what had been said on Dr. Johnson's paper, as he had expressed his views most fully and accurately." See American Gynecological Society Trans., p. 138, vol. x, and again on p. 131. Dr. Sutton said, "It is hardly necessary to compliment Dr. Johnson on so good a paper as this one, so full of practical detail and practical suggestion, and one proving the great merit of the treatment of the cases which he has given in detail," and in closing his speech he said, on page 132, "I congratulate Dr. Johnson upon the success which he has obtained in these cases and I bid him God-speed in his good work." Dr. Emmet, as is well known, does not approve of this operation for dysmenorrhœa or nervous ailments. He said on page 145 of that discussion, however: "I think it has a large and useful field in other cases."

I was pleased that Dr. Busey in his remarks virtually approved of my operation, after an examination of the specimens, and that he disclaimed any reflections. I do the same most heartily, and in this reply, to be read by the Secretary after I have gone abroad, I am mainly on the defensive in closing the debate.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, July 16, 1886.

THE VICE-PRESIDENT, HENRY T. BYFORD, M.D.,
IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

DISCUSSION OF DR. F. E. WAXHAM'S PAPER ON OCCLUSION OF THE OS UTERI AS AN IMPEDIMENT TO LABOR, WITH A REPORT OF TWO CASES.

(Read at the May meeting.)

DR. W. W. JAGGARD said: From the very clear description of Dr. Waxham's case, I infer the condition was that described by Nägele under the term, *conglutination orificii*, an uncommon complication of labor, but seldom indicating incision. Usually, pressure of the finger is sufficient to open the os.

A more serious condition is that described by Schmitt, under the term *conglutination organica*. The cervical canal is obliterated to a variable extent. I had a case, illustrating this condition, under my observation in Professor Spaethe's words during the winter of 1882. The lower half of the cervical canal was obliterated. Radial incisions were made around the *os externum*, and the canal was dilated with the index finger. Forceps were subsequently applied. The case was reported in the *Medical News*.

DR. JOHN BARTLETT said: I have nothing of interest to offer directly pertinent to the present discus-

sion. But I have rather recently attended a case which I deem so nearly akin to those reported by Dr. Waxham as to justify me in mentioning it.

Mrs. Anderson, 37 years old, came under my notice about three years ago. Five years since, she felt a burning pain in the nose and about the womb. At the same time her menstruation increased in quantity until in the course of a year, it became profuse. Because of these difficulties, she sought relief from a quack. For the purpose of removing a cancer, which this pretender diagnosed, a most violent caustic was put into the nostrils and applied to the womb. One year afterwards the tissues injured by the corrosive had healed; a violent uterine pain remained, and the flow had again become excessive. She applied to Dr. A. R. Jackson, who made an operation for the relief of the *atresia vaginæ* which he found existing. Although the operation was thorough, contraction recurred; so that when she was admitted into the Woman's Hospital in 1883, her condition was probably about the same as it was prior to Dr. Jackson's treatment. Dr. Mary H. Thompson operated upon the patient, opening thoroughly to the *os uteri*. Contractions, however, very soon reformed in the vagina; in October, 1885, her condition was serious. Her pulse was weak and frequent; neuralgic pains about the pelvis were nearly constant, and superadded to these older symptoms were those suggesting pregnancy. The uterus was enlarged and menstruation had ceased for three months. Of her condition at that time, Dr. Thompson writes: "The vagina was closed more perfectly than before. Not an opening could be seen in the occluding disc, which was only one inch from the *ostium vaginæ*. By examination through the rectum, it was ascertained that the uterus was enlarged, especially toward one side of the body." The distress of the patient, the apparently complete closure of the vagina, the nonappearance of the menses and the peculiar enlargement of the womb suggested either retained menstrual blood or some form of pregnancy. After a consultation, Dr. Thompson proceeded to open up the canal—at the time supposed to be perfectly occluded—between the uterus and vaginal *cul-de-sac*. In reality, a very small opening still existed; this was enlarged carefully by incision and distension until the *os uteri* was thought to be easily in communication with the remains of the vagina.

One month after the operation I was called upon to visit the patient. On the preceding night at a certain hour, most violent pains, as those of child-bearing, had come on, and had continued despite of anodynes, for some five hours. The pains had now at the same hour as the night before, returned with increased violence. Not to go into details, I will say that the symptoms pointed strongly to some form of pregnancy. In view of the serious character of the case, I called in consultation on the next day, Dr. R. G. Bogue. We left the patient still in doubt as to her true condition. During the following night, I was again summoned; the exact resemblance of the pains to those of labor, and the now recognized hardening of the swelling above the pubes during these pains, made it quite certain that pregnancy ex-

isted, and that the contractions would finally lead to the extrusion of the foetus from its sac *per vias naturales*, or otherwise. Upon careful examination, the vagina was found to be shut off about one inch from the *ostium* by a hard, firm and thick disc of cicatricial tissue. Toward one circumference the small opening detected and enlarged by Dr. Thompson a month before was recognized. By rectal examination, what seemed to be the *cervix uteri* was reached, three quarters of an inch beyond the upper face of the cicatricial disc. Connecting the disc and cervix was apparently a tube of tissue much smaller in circumference and thinner than proper vaginal walls. The pains continuing with regularity. Dr. Bogue and myself concluded to assist delivery. Slight incisions by means of the bistoury were made in the circumference of the opening in the cicatricial disc, a metallic dilator was then introduced, and when some dilatation had been effected, a modified Barnes dilator of very small size was inserted. Within an hour, by the occasional use of the knife and the continual tension of dilators, the disc opening admitted for a little distance the end of the finger into the remnant of the vaginal tube, above the disc. By the point of the finger pressed firmly onward, could now be recognized a hard body which was taken for the *cervix uteri*. With a little more dilatation of the disc opening, it was perceived that the hard body was the foetus, and that the *os uteri* was healthy and dilating in a normal manner, the membranes being unruptured. As soon as the opposing disc opening was expanded to a size presumed to be sufficient to permit of the passage of the head, the membranes were ruptured. It was then discovered that the shoulder presented; by aid of suitable instruments the child was turned and in the somewhat too vigorous efforts at delivery the body parted from the head, the latter remaining *in utero*. This accident in such a case, with an extra, entirely rigid *os* precluding free procedure through the *os uteri*, ordinarily would be regarded as unfortunate, I looked upon it as a favorable step toward delivery, confident that by means of a suitable vectis the head could be easily scooped through both of the opposing ora. In fact, the head was readily so delivered, and the placenta falling over the *os uteri* was removed with the same instrument. One of the symptoms that confused the diagnosis on the first day of the appearance of labor pains was the unusually large, rapidly attained size of the supra-pubic tumor. This symptom was now explained, for an examination to determine if the patient was entirely "cleared" revealed the presence of a second foetus presenting by the head. The vectis was applied and the foetus at once withdrawn, as was also in like manner the second placenta.

The labor revealed the true anatomy of the injured parts. The patient desired that the passage through the disc should be kept open, but inasmuch as the *os uteri* was almost immediately behind it, it was deemed useless and harmful to make the attempt. Within three months the dilated opening in the disc had contracted to a size but little greater than that observed before the miscarriage.

DR. F. E. WAXHAM said: I would simply allude

to the great resemblance in the case coming under my care, between the uterine tissue and the foetal membranes, especially in those cases in which there is but a small amount of amniotic fluid, and I can see how very easy it would be to do permanent injury to the mother by rupturing the uterine tissue by a pencil or some other sharp-pointed instrument, when, perhaps, by more extended and careful examination, it would be found that simple dilation would be sufficient. In the case reported, the knowledge that the amniotic fluid had been escaping for several hours was sufficient evidence to me that there was an *os*, and it was also proof that the tissues presenting were not membranes, but the uterine tissue. But the great trouble was to discover the *os*, and I assure you, it was difficult indeed. The *os* was present in the center of the presenting mass, and yet we could not discover it. It was impossible for me to do so, and it was only after a continued, careful and searching examination that Dr. Nelson was enabled to detect the very slight dimple which was present.

DISCUSSION OF DR. HENRY T. BYFORD'S PAPER,
ENTITLED "A STUDY OF THE CAUSE AND
TREATMENT OF PELVIC HÆMATOCELES."

(Read at the June Meeting.)

DR. T. D. FITCH said: I have had very limited experience with operative procedure in this class of cases. As a rule, I feel like praising the bridge that has carried me safely over. My usual treatment has been the expectant plan, or trusting to resorption of the clot. Resorption occurs in other tissues of the body, the leg or arm, where you would not think of opening the cavity and turning out the clot. It would be a very bad principle in surgery, I think. My experience has not been sufficient to condemn the operation entirely, but I feel like trusting to the safer plan of the expectant treatment. I have never operated in more than two or three cases, and would not have operated in them had not there been a mistake in diagnosis. One of these cases was a lady at Jefferson, who gave a history of cellulitis. There was softening and fluctuation in the tumor presenting. I was called in consultation by the attending physician. The symptoms were those of cellulitis, resulting in abscess. The aspirator was used and a very small amount of pus was drawn off, and then a larger amount of disintegrated blood. All was drawn of that could be, and the woman recovered, no bad results following the aspiration. No drainage was instituted, and no scooping out of the blood clot was performed; there was no special treatment except on general principles, and the vaginal injections of antiseptic fluids. The opening was not enlarged, the sac was not injected, nor washed out. The opening made by the aspirator needle probably closed up so that no air was admitted, and no decomposition or blood-poisoning occurred.

Another case was one in which I assisted in an operation for supposed extra-uterine pregnancy. Two distinguished Fellows of this Society were present and concurred in the diagnosis. It was decided to open the tumor through the vagina with the galvanocautery knife, and when this was opened, there

poured out of it a gelatinous fluid, as white, and as clear and pure as could be; it looked to me very much like soft boiled rice. It was a clear white, and perfectly inodorous. The sac was washed out with antiseptic fluids, and the patient treated on general principles; I think no drainage was used. The sac was not scooped out; nothing was turned out except the tablespoonful or two of gelatinous fluid, of which I spoke.

Another case I might mention, in which the attending physician and myself (I was called in consultation) diagnosticated an abscess; opened it with the aspirator, and found that it was an hæmatocele. I believe the expectant plan of treatment is preferable to operative interference. I think a larger percentage of cases would recover under this treatment.

DR. JOHN BARTLETT said: I will take occasion to refer to a fatal accident that once came under my observation, which tends to show the necessity for the greatest care in opening cavities, *per vaginam*, whether resulting from hæmatocele or cellulitis. A patient was greatly reduced by long continued pelvic abscesses. It seemed to be one of those cases in which an operator is called upon to make a determined attempt to reach, evacuate and curette a chain of abscesses found to exist within the pelvis. Several collections of matter were opened, and it was supposed that the object of the operative procedure had been happily accomplished. The final washing of the cavity with carbolized water was in progress when suddenly, the patient fell into a profound collapse; respiration ceasing and pulsation at the wrist failing. This condition was regarded as an accident from ether. Every effort at restoration was unavailing till a Faradic current was passed through the phrenic nerves at proper respiratory intervals. The patient then gradually rallied, and the danger was thought to have ceased. On the following morning the carbolized injection was repeated by an assistant; a fatal collapse immediately ensued. Post-mortem examination revealed a small opening through the roof of the pelvis, and the presence in the peritoneal cavity of the injected fluid. If the Society will pardon a digression, before closing I will take occasion to refer to a symptom of hæmatocele, which would seem to be as rare as it is suggestive. In one case, associated with this condition, I observed the whole surface of the abdomen below the navel, to present an ecchymotic appearance as from the extravasation of blood after an injury. The patient was alarmed at the "black and blue" appearance, regarding it as a sign of "mortification." It existed for weeks and disappeared, *pari passu*, with the pelvic extravasation.

DR. W. W. JAGGARD thought the ruptured cyst of extra-uterine pregnancy a more frequent cause of retro-uterine hæmatocele than the text-books would lead one to believe. Gallard has emphasized the importance of the operation of this etiological factor. He¹ makes a statement to the effect that independently of traumatism, almost all hæmatoceles are caused by the ruptured cyst of extra-uterine pregnancy. Such a broad statement naturally provoked salutary

criticism. More recently, Veit,² of Berlin, has collected 146 cases of hæmatocele, of which forty cases, or 28 per centum were probably due to the ruptured cyst of ectopic gestation. Veit's estimate does not appear extravagant.

He would like to inquire of the author of the paper, what was the indication in the case reported for operative interference? The indication had probably been stated, but through inattention, he did not remember it. A small non-suppurating, retro-uterine hæmatocele of six months' standing was not, *per se*, an indication for any operative interference.

Any discussion of the surgical treatment of retro-uterine hæmatoceles, would be incomplete without some mention of Dr. A. Martin's plan of treatment in cases of extra-peritoneal hæmatoma. Laparotomy is performed, eventration of the intestines effected, the sac incised, evacuated and curetted, and subsequently united by sutures, drainage is maintained *per vaginam*. In Martin's hands, this operation has been perfectly successful in six cases.

DR. C. T. PARKES said: I do not think I have anything new to offer on the question of treatment of hæmatocele. My experience embraces only three cases. The first was a lady whom Dr. Fitch saw with me about a week after the initial symptoms, which present themselves in these troubles, had appeared, and we concluded to make an opening through the *cul-de-sac* of Douglas. I used the Paquelin cautery for the purpose of opening up the mass, which was not very extensive. The principal symptom which led us to think it was necessary to resort to interference, was the evidence of the presence of probable suppuration. The lady had been having slight chills and some corresponding rise of temperature, and we thought it best to be certain whether or no the mass had decomposed and broken down, so we opened it with the cautery, and quite a quantity of grumous, broken down blood, with clots came out. The lady was relieved of her pain and distress. We introduced a drainage tube, and through this tube passed a large catheter as long as the opening would permit, and washed out the cavity every day and followed it up for a long while, with a diminution in the size of the mass, until it got so that it was merely perceptible above the pubes, then the chills came on again more severely, and after suffering for a month or six weeks she finally died of septicemia. In that case I was satisfied from the fact of being able to fill the cavity apparently, under the force of hydrostatic pressure, and then have something give way, and the fluid rapidly disappear, that we had a series of cavities which were opening into each other. I think if I had such a case to manage now I should do differently. I should use thorough antiseptic precautions, and care at present; such treatment was not then deemed necessary. The next case, a very interesting one, happened last winter; I saw the lady four or five weeks after she was taken ill. She was taken as though she were going to have a miscarriage after having missed menstruation twice, and when I saw her she was in an extreme condition of collapse; upon examining the abdomen, it was found full of

¹ Leçons Cliniques des Maladies des Femmes. Paris, 1873. P. 635.

² Die Eileiterschwangerschaft. Stuttgart, 1884. P. 14.

something, dull on percussion, resonant above, and to the sides; on digital examination the ordinary signs of hæmatocele were present. This woman was in such a weak condition that I could not bring myself to the idea of interfering, and tried to support her and wait for events. I attended her two weeks, while she varied from one condition to another, all the time life hanging by a thread. In the third week, on examining her abdomen, I thought I detected fluctuation, and in two or three days was certain of it. I aspirated in the *linea alba* midway between umbilicus and pubes, and at first withdrew a quart of blood, but, although I was satisfied there was more there, I did not repeat the aspiration that day. Two days afterwards I aspirated again, and withdrew two quarts. She began to improve from that moment; I merely put her on tonics and supporting treatment; this was in February. I saw her about a month ago, and she was going about the house the same as any one else. The third case was a little later in the same year, a lady who had been bleeding a little for some time, with the presence of signs of conception of two months' date. I made an examination, and was satisfied that I detected to the right of the uterus a mass as large as one's fist, easily reached by manipulation internally and externally, tense to the touch, and elastic. I diagnosed a probable hæmatocele, kept her quietly in bed, but did nothing special for her. The occurrence of this tumor was accompanied by extreme shock, prostration, pallor of the body and symptoms of collapse. She has now entirely recovered without any interference whatever. That last case led me to think of some of the reports I have read about surgeons being called to see a patient in collapse, finding she has flowed a little, with a history of probable pregnancy, making an examination, and discovering a little tumor, diagnosing extra-uterine pregnancy, using electricity and curing the patient. It seems to me there may be a possibility of there being a mistake in some of these cases of extra-uterine pregnancy that are cured so readily by the use of electricity. They are becoming very frequent. I must say, that it was a very difficult matter for me to decide in this case, whether it was extra-uterine foetation or hæmatocele, still I am satisfied that it was an hæmatocele.

DR. H. T. BYFORD said: Before closing the discussion, I would like to add the following case to the series reported in the paper:

Case VI.—Mary H., a German servant girl, 25 years old, was taken sick with pains about the lower abdomen, nine months ago. The attack, which came on after a menstrual period, kept her in bed little of the time, but did not pass off. In six weeks, her menses came on and lasted two weeks. The bleeding ceased for a few days, then returned and had continued, in varying quantity, until stopped by ergot about a week before I saw her. Vesical irritation was an almost constant symptom. Up to that time, she had tried to attend to her work, but then gave up her place. She told me, a little over a month ago, when I first saw her, that she had felt worse since taking the medicine. The great pelvic tenderness subsided rapidly under the "absolute rest"

treatment, and in less than a week afterwards, I was able, without paining her, to completely circumdigitate a large boggy or semi-elastic tumor in the right broad ligament, extending behind the uterus from a level with the internal os upwards, and reaching into the left broad ligament, where it felt harder and nodulated. The uterus was anteflexed, displaced anteriorly, and to the left (leaving only room enough between the cervix and the pubes for the index finger,) and intimately attached to the surrounding mass. The probe entered three inches, turning forwards. After keeping off her feet, although not in bed, using hot douches, iodine applications to the abdomen, iron internally, and having glycerine plugs applied about every three days for three weeks, the tumor had become harder, somewhat nodulated in places, and perceptibly smaller. She had felt quite well again until the last few days, when she undertook to resume her domestic duties.

This case shows well the positive benefit of rest, and the positive harm that is sure to result from want of it. Its history is similar to the history of many such tumors which go on to suppuration, but which, with proper treatment, would have been promptly absorbed.

The unfortunate case related by Dr. Bartlett bears witness to the dangers of the curette in pelvic hæmatocèles, and is probably one among many somewhat similar ones that have not been reported. The necessity of a large opening, perfect drainage and great antiseptic precaution is vividly shown by one of the cases recited by Dr. Parkes. His view as to the liability to the formation of pus pockets is corroborated by the sudden discharge of half an ounce or more of pus on March 26, in the case of Mary St. —, followed by the rapid sinking of the uterus back into a natural position. This pus pocket, had the operation *not* been performed, would probably have formed and pointed upwards in the direction of the least resistance, and would have become an abdominal abscess, and a serious thing to manage. I quite agree with Dr. Parkes that simple hæmatoma and hæmatocele are too often thought to result from extra-uterine pregnancy, and think it is partly the result of Gallard's theory that all non-traumatic cases are extra-uterine pregnancies, a theory which has done its good and has had its days. The intensity and persistence of the local symptoms, the passage of the decidua, and the past or present characteristic symptoms of the pregnant condition should usually prevent such a mistake.

I think with Dr. Jaggard that Bandl would have us operate too early; I only claimed that Bandl's views were a great advance in the therapeutics of pelvic effusions, in that, while recognizing the dangers of early interference, he does not allow the fear of inducing septicemia to intimidate him into waiting until septicemia has already accomplished its mischievous, and perhaps fatal work. The reason why Bandl's latest views have had so little apparent effect upon the profession, is that they have only been before the profession at large for a few months. I had come to the conclusion that with our present knowledge of antiseptics we need not be frightened out of

opening up these accumulations, and had acted upon it, before I knew of Bandl's views; and so had many others whose veneration for long established authority had not overpowered their individual judgment.

A. Martin's method of operating for hæmatocoeles and hæmatoma is *one* method, but that it is *the* method cannot be maintained upon scientific grounds so as to convince the profession; nor has it as yet been so proved by its success. As to the frequent bunglesomeness of operations *per vaginam* and *per rectum*, there is scarcely to be found an opportunity for the bungler like the performance of laparotomy for pelvic disease. I doubt if I exaggerate in saying that half of the abdominal sections are done in a bungling manner, especially when compared to those of Martin and a few others.

In my paper I advocate the expectant plan of treatment, and have used it, and so far succeeded with it, in all of this series of cases except one. That case was operated upon because the conditions for a cure without an operation were not attainable; because even if attainable, they would have taken too much time to restore the patient to usefulness; and because if properly done, the operation in such a case is almost devoid of danger. I regard it as a good illustration of when we may operate in case the expectant plan does not afford relief. In case VI, Mary H., which I have just reported, I shall use every effort to do without surgical interference, because the interior of the sac cannot be easily and safely reached.

Protheroe Smith, M.D., M.R.C.P., of London, was then elected Honorary Fellow of the Society.

MISCELLANEOUS.

CHARLESTON PHYSICIANS IN GREAT NEED.—We are permitted to present the following extract from a private letter from one of Charleston's best known physicians to a medical gentleman in this city:

"We are distressed," he writes, "almost beyond endurance. Our women and children are our sources of anxious solicitude. May God protect them in the open field, tenting in the night air! My entire family—wife and four children, the oldest eleven years of age—are out of house and home, like hundreds of other sufferers."

We think little more need be said to show the necessity of speedy aid for the sufferers among our own brethren in Charleston. There are no doubt many cases of individual want among medical men and their families, for while their services are in demand, and they are busied in attending to those suffering from injuries and the results of exposure, yet they are seldom paid, at least in cash. Their families are homeless and must be provided for, but food and shelter are not to be obtained without ready money in such times, and ready money the physician but rarely obtains.

We therefore appeal to our readers throughout the country to help their brethren in South Carolina in this their hour of need. We are accustomed, by our very calling, to help others when in distress, and let

it not be said that we are indifferent to the sufferings of those in our own ranks. Now is the time to help them, and he who gives quickly gives twice.—*N. Y. Medical Record*, Sept. 11, 1886.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Clinical Medicine, Pathology and Hygiene of this Branch of the Massachusetts Medical Society will meet on the second Wednesday of each month after October 13. It is a noticeable feature of its meetings that marked attention is paid to hygiene and public health. At the meeting on June 8 Dr. D. A. Sargent, of Harvard, read an exhaustive paper on "The Effects of Military Drill on Boys," which will be published in the next issue of THE JOURNAL.

DR. THOMAS ALEXANDER MCBRIDE, one of the most brilliant young physicians of New York, died at sea, on August 31, of acute Bright's disease, while returning home from Carlsbad, where he had spent most of the summer under treatment for Bright's disease.

DR. CHARLES DUDLEY HOMANS, of Boston, died at Mt. Desert, on September 1, in his sixty-first year. His death is thought to have been due to disease contracted in an operation two years ago.

CREMATION AND ROMANISM.—The Roman Holy Office has forbidden Roman Catholics to belong to cremation societies.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 4, 1886, TO SEPTEMBER 10, 1886.

Major P. Middleton, Surgeon, assigned to duty at St. Francis Barracks, St. Augustine, Fla., as Post Surgeon. (S. O. 126, Div. of the Atlantic, Sept. 2, 1886.)

Capt. L. A. La Garde, Asst. Surgeon, upon departure of Third Infantry from Ft. Ellis, M. T., to proceed to Camp Sheridan, Mammoth Hot Springs, Wyo. Ter., and report to the commanding officer for duty, relieving Asst. Surgeon Pilcher. (S. O. 87, Dept. Dak., Aug. 27, 1886.)

First Lieut. Wm. J. Wakeman, Asst. Surgeon, granted leave of absence for one month, with permission to apply for three months' extension, to take effect when his services can be spared in the Dept. of the Platte. (S. O. 207, A. G. O., Sept. 6, 1886.)

First Lieut. James E. Pilcher, Asst. Surgeon, when relieved by Asst. Surgeon La Garde from duty at Camp Sheridan, to return to his proper station, Ft. Custer, M. T. (S. O. 87, Dept. of Dakota, Aug. 27, 1886.)

First Lieut. Phil. G. Wales, Asst. Surgeon, granted leave of absence for one month, with permission to apply for an extension to Nov. 5, 1886. (S. O. 70, Div. of the Pacific, Aug. 31, 1886.)

First Lieut. Wm. B. Banister, Asst. Surgeon (recently appointed), to report to the commanding general Dept. of Arizona for assignment to duty. (S. O. 208, A. G. O., Sept. 7, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING SEPTEMBER 11, 1886.

Woodruff, C. E., Asst. Surgeon, ordered to receiving ship "Vermont," Oct. 4, 1886.

Atlee, L. W., Asst. Surgeon, detached from the "Vermont" and ordered to the "Quinnebaug," per steamer of 25th inst.

Bogert, E. S. Medical Inspector; N. McP. Ferebee, Surgeon; C. Biddle, P. A. Surgeon; H. B. Scott, Asst. Surgeon, detached from the "Trenton" and placed on waiting orders.

VENOUS BLOOD TUMORS OF THE CRANIUM

in Communication with the Intra-Cranial Venous Circulation, Especially the Sinuses of the Dura Mater.

BY WM. M. MASTIN, M.D.,
OF MOBILE, ALA.
(Continued from page 320.)

III.—TRAUMATIC CLASS.

My researches in the traumatic group have been rewarded by the gathering together of several well authenticated and important records.

One of the most typical, as well as the earliest, instances, is that related by Percival Pott* ("Chirurgical Works," first Amer. from last London edit., vol. i, p. 132, Phila., 1819; also French edition, t. 1, p. 151, 1760):

A boy, 8 years of age, son of a Jew merchant of this city, received a blow on his head with a stick. This made him giddy for a few minutes, but there was no bleeding, no external wound, and but little pain, and he concealed the fact of there being a swelling over that portion of his head until it was discovered by his barber. In the centre of the top of his head was a tumor almost the size of a walnut; indolent, had a dull kind of pulsation, and palpably contained fluid. In the presence of Serjeant Amyand and Mr. Shipton the tumor was divided with a knife and a quantity of blood discharged; but when the swelling was emptied it was found that the blood continued to flow, plainly not from the scalp wound, but from the bottom of the cavity. Examination now showed that the sagittal suture was fractured, and that a portion of the displaced fragment of bone was forced into the sinus, and by the sides of which the blood issued forth. Attempts to extract this fragment failed. By advice of the consultants, a small perforation was made on one side of the suture, but through this the point of the elevator could not be introduced so as to remove the broken piece. and so the trephine was applied on the other side of the suture, but with like result. At last it was decided to risk the hazard of wounding the sinus (which was, indeed, already wounded by the broken bone), and enclose the suture within the circle of the trephine. This was done, but the button of bone came

away in pieces, and left the original perforating fragment still piercing the sinus. This fragment being withdrawn by means of forceps, a flux of blood followed, but a dossil of dry lint controlled it. The patient recovered.

There are very many cases similar, if not exactly analogous, to this case, to be found in surgical literature; and among the most striking of which are those mentioned by Guthrie (Commentaries on Surgery, etc., p. 349, Amer. ed.), and M. Mouton (Mem. Royal Acad. Surg. of France, Sydenham Edition, p. 8).

M. Azam (Dupont, op. cit., p. 20) reports two cases of this accident which came under his observation, as follows:

C., age 22; miller, robust; entered the Hôpital Saint-André, service of M. Hirigoyen, Nov. 11, 1850. Situated on top of the frontal region, a little to the right of median line, was a tumor of the dimensions of a large nut. It was irregularly round, manifest fluctuation, but no discoloration of skin. Gentle pressure with the palm of the hand reduces it completely in two or three minutes, after which the skin remains empty and flaccid, and is also very thin and soft. Hence one can easily recognize an irregularly circular depression across it, with salient and unequal edges. The patient reduces it easily himself, and it disappears when the head is thrown backward and reappears with the forward inclination. The forward posture cannot be maintained for any length of time on account of vertigo, which accompanies this position. No bruit or pulsation, but seems a little more tense during the respiratory movements. I have thought that I perceived an obscure blowing sound in the tract of the superior longitudinal sinus when tumor was rapidly reduced by the patient, but my confrères could not verify it. No pain, and were it not for the deformity with the vertigo whilst bending forward, he would not be inconvenienced by its presence.

As to its origin he reported that, at the age of 15 years old, he was kicked by a horse in the frontal region. Did not lose consciousness, and even continued to follow his occupation—it being several days thereafter before he discovered this tumor, which has always presented its present appearance. He had consulted another physician some time previously, who made an exploratory puncture, which was followed by a jet of blood. This was easily arrested. Nov. 20, M. Hirigoyen punctured it with a lancet.

* Reported in previous paper.

† Reported in my first article.

Blood spirted out, having all the characters of venous blood. A probe introduced now discovered a depression in the bone and some roughnesses, although the bone is not denuded, but covered by a thick, soft membrane. No orifice of communication with interior of skull is discoverable, but such must exist, and is probably with the superior longitudinal sinus. Hæmorrhage easily controlled, and skin wound healed rapidly. Pressure over tumor was employed for twenty days without result, and the patient left the hospital in an unchanged condition. Saw him twice afterwards, the last time in 1857, and tumor in same condition. The avoidance of any operation, and the use of local pressure, was advised.

The next is the second case¹⁰ of M. Azam (Dupont, loc. cit.):

Jeanne T., of the *Bourg-sur-Gironde*, age 60 years, consulted the 'Charity Committee' of the Medical Society of Bordeaux in March, 1854, about a tumor situated in the frontal region. She stated that about eighteen months previously, whilst at work in the field, she stepped upon a rake, which flying up, the end of the handle struck her with considerable force on the forehead. The pain was intense, but she did not lose consciousness. The apparent contusion was relieved by ordinary measures without medical attention. Twenty to twenty-five days afterwards she recognized the existence of a tumor at point of contusion. This was soft, size of a small nut, and hardened and increased in volume when she lowered her head. No headache. Did not consult a physician until after three months had elapsed, at which time the skin covering the tumor becoming thinner and of a violet color, she consulted M. Gaignerat, of Bourg, who punctured it, and, according to her statement, it bled most profusely, but a bit of English taffeta sufficed to staunch it. She presented herself now before the Medical Society. At this time the tumor, situated on the median frontal line, near hair margin, was about the size of the half of an ordinary nut; soft and fluctuating; slightly violaceous in color; without pulsation or bruit, and conveying the sensation of a skin pouch containing a spongy substance. It becomes tense when the head is bowed down or lowered, and a continuance of this position causes dizziness. It softens and slowly diminishes under pressure by the hand or fingers. It is very evident that the fluid passes into the skull. After reduction of tumor there remains under the skin a soft tissue which prevents any close examination of the underlying bone. Punctured it with a small trocar; only a small quantity of venous blood escaped. Manipulating the canula in different directions showed that the tumor was not formed of a single pouch, but of a spongy tissue composed of large cells. This explains the slowness with which the fluid trickled out, and which, also, evidently passed through a narrow passage in the bone into the skull cavity. I could not discern the opening, nor did I recognize any rugosities or denudation of the bone.

The annexed case¹¹ of M. Hutin, which occurred

at the Hôpital des Invalides, is reported by Dr. Gustave Dufour (*Compt. rend. et Mém. de la Soc. de Biol.*, t. III, p. 155, 1851):

Achille Maximilien, Marquis de W., Comte d'I., born 1770, at Paris; entered infantry service in 1792. In 1799, in charging a redoubt in the Piedmont, he received a blow from the butt-end of a musket on right side of forehead about 3 cm. from median line. He remained unconscious for twenty-four hours. When he regained his senses he was told by the surgeon in attendance that there was a fracture of the skull, and the lesion was very grave. There was no wound of the integument, but a deep depression under the skin was quite perceptible to the touch. During the next year he was an inmate of different hospitals, and received divers forms of treatment, especially local pressure. The ultimate result of the wound was an infirmity which incapacitated him from following the profession of arms. When he leaned forward with head inclined towards the ground, he would feel a swelling form on the site of the wound, having the volume of a nut, of a violet color, and which would disappear spontaneously when he again assumed the upright position. In 1814 he gained admittance to the Hôpital des Invalides, and in 1847 M. Hutin, then becoming surgeon-in-chief, was peculiarly interested in his case, and added himself the following notes to the history of the case: 'Cicatrix not apparent; osseous depression very marked. The condition is, doubtless, the result of absorption of the diploë and the approximation of the two tables of the frontal bone. The pouch is small, formed at the expense of the skin, and is not apparent when the soldier is standing, sitting, or reclining on his back; but when he bends forward with the head lowered, the pouch makes its appearance and attains the volume of half an egg. It is livid in color; is formed, evidently, as are cysts in contused parts, and is dependent on a communication with the superior longitudinal or some other sinus.'

I learned that this old man, notwithstanding his age of 81 years, was in perfect mental and physical health. October 28, 1851. Seized with erysipelas of neck and thorax, complicated with chronic bronchitis, and died November 3.

Necropsy—Head.—No visible traces of erysipelatous action. Normal in size and contour. On forehead, 2 cm. below hair margin, and to right of median line, is a cutaneous space about 2 cm. in diameter, which is rendered distinct from surrounding skin by its rosy color, and this corresponds to a clearly outlined osseous depression beneath. Lowering the head now fails to produce the phenomenon which was so easily brought about during life. *Brain.*—Sound and without traces of old or recent apoplectic clots; white and gray substance distinct; vascular network of pia mater moderately injected, but without infiltration, and is easily separated and detached from the cerebral convolutions—even directly under the wound. The visceral layer of the arachnoid, however, on the right side, 3 cm. from the middle line, is glued down to its parietal layer and also adherent to the dura mater, and any traction exerted upon these adhesions causes a few drops of

¹⁰ Reported in my first paper

¹¹ Reported in my previous paper.

blood to ooze out into its (arachnoid) cavity. The dura mater is also easily separated from the entire surface of the bone except at this locality of 3 cm. from the median line, where it is adherent to the osseous wall. Opposite to this attachment the bone is perforated by several small openings. Injection of water and insufflation of air into the superior longitudinal sinus demonstrates the existence of a pathological communication of the sinus with the blood pouch above. The calibre of the sinus is somewhat increased, and filled by a long, reddish, fibrinous clot. Skin over tumor thinned, and sends out from its inner fibro-muscular surface attenuated fibrinous prolongations which attach themselves circularly to the periosteum on the circumference of the bone depression, and which depression is lined by a bit of cellular periosteum, and is 5 cm. in breadth by $2\frac{1}{2}$ cm. in height. The circumference of the depression is formed by a notable thickness of compact bone tissue, but its centre is very thin and spongy. The floor of the depression is also divided, by a jutting out of compact structure, into two smaller depressions: the left one extends a little beyond the middle line of forehead, is rugose, and is sprinkled with little dark openings; the other on right side is more extensive, and is riddled with minute apertures—entirely deprived of its vascular element (diploë) and corresponds to the thinnest of the cutaneous cavity, at which point both skin and bone are semi-translucent. The frontal suture plainly seen above and below the osseous lesion, but especially apparent on the altered surface. Finally, the tegumentary coverings are thinned, being deprived of all muscular and adipose tissue, and composed only of skin re-enforced by a delicate lining of fibrous tissue.

Hutin reports another case¹² (*Mém. de Médecine Mil.*, t. xiv, p. 232, 2e Série, 1854):

K., born in 1771; entered military service in 1790; received at the battle of Jena, Oct. 14, 1806, two sabre wounds on the head—the first on superior and middle of forehead, the second on top of the head. Did not lose consciousness; fragments of bone extracted; recovery after about nine or ten months without any grave symptoms.

Forty years passed without his being troubled by any serious sickness; only suffered from severe headache. In March, 1846, while intoxicated, he fell into a bed of rocks, fracturing thigh and ribs. A pleuropneumonia was not tardy in developing; and in ten days thereafter he was also attacked with erysipelas, which was epidemic in the wards. Delirium; parotid abscess. March 24. Carries hand frequently towards summit of head to the right of the most prominent scar. Pressure here discloses circumscribed fluctuation and pain which did not exist previously. Diagnosing an abscess, a small incision was made into it, but only blood escaped. There was a blood-pouch containing a black, semi-coagulable liquid, poured out between the osseous vault and the pericranium, thus detaching the latter. Attempts to detect a fissure failed. The day following the dressings were soaked with blood; attempts to find fissure still futile;

extended incision, which brought to view a slow, continuous oozing of venous blood from the depths of the bony wall and to inner side of the wound. This was without pulsation and uninfluenced by the respiration. A delicate blunt probe pressed upon this point readily passed on into the skull through a small opening which was covered over to about three-quarters of its extent by the soft tissues. Dry charpie and bandage arrested hæmorrhage.

Autopsy.—Scalp puffed up and much injected from erysipelatous inflammation. Cicatrix on frontal bone adherent to the remains of the frontal suture, with marked depression of the integument. At 2 cm. beyond the fronto-parietal suture and within $1\frac{1}{2}$ cm. of the sagittal, commence the other adhesions belonging to anterior region of the second cicatrix, and which are equally resisting but of limited extent. Below these is the pouch which was incised during life. This pouch (subpericranial) is about 4 cm. in extent from before backwards and 2 cm. from right to left. On removal of skull-cap all was found normal except a trivial injection of the arachnoid, one or two points in the brain, and a small quantity of serum in the ventricles. Dura easily detached over almost entire vault, except at a point corresponding to the wound of the vertex, and on each side of the closed sagittal suture, where it adhered closely to the parietes, but without any visible scar. At a point corresponding to the external angle of the wound the dura mater intimately united with external tissues through a fissure in right parietal bone. The unclosed opening of the bone was about 2 mm. in width by 1 cm. long. Longitudinal sinus contained a small quantity of coagulated blood, which was partially dislodged by a stream of water—after which was visible a very pronounced projection in the sinus, passing in a line from behind forward and from right to left, and corresponding exactly to the external cicatrix. This projection was caused by a depressed thick bone-splinter depending from the internal table, and was the result, evidently, of the sabre blow—being partially detached and thus remaining fixed for many years. This spicula terminated in a spine which had perforated the sinus, and passing through into the lumen maintained patulous an opening in its walls about 4 mm. in size. Through this opening a small quantity of blood had escaped from the sinus, and which, poured out between the bone and dura, formed in this locality an oblong pouch of 3×2 cm. in diameter; but on the outside of the skull it had diffused itself between the bone and the periosteum, forming the collection which had been mistaken and opened for an abscess. This external effusion had passed through an opening existing in left parietal, $1\frac{1}{2}$ cm. in front of and to the right of the sharp end of the fragment, and resulting from the non-occlusion of the bone divided by the sabre blow. Hence there was a direct communication between the superior longitudinal sinus and the wound in the integument, for in this fracture there were no adhesions between the meninges and the pericranium as existed through the anterior fracture. The perforation in the superior longitudinal sinus is a little to right of median line.

Stromeyer refers to two examples. The first (Ueber

¹² Reported in my previous paper.

Sinus Pericranii, *Deutsche Klinik*, Bd. 11, S. 160, April 13, 1850) is transcribed below:

A boy, 6 years of age. He sustained a fall on his head from a considerable height in his second year, resulting in a depression of the right parietal bone, which extended along the greater part of the sagittal suture. The point of greatest depression was $2\frac{1}{2}$ lines. The entire depressed portion was covered by a blood-pouch of $2\frac{1}{2}$ inches square, which when filled was raised about 3 lines. On complete emptying the bone was felt, and the outer table was evidently poorly formed. Turgescence of the tumor is favored by each circumstance which is likely to produce congestion of the head, namely: crying, coughing, dependent position of the head, compression of jugular veins, etc. When child was quiet no fluid was discernible in the pouch.

The second case, of more recent date (*Maximen der Kriegsheilkunst*, note, S. 362, 1861), is thus briefly mentioned:

A cavalryman in 1859 was dismissed from the army on account of a blood-cyst located on the frontal bone. When distended with blood it was the size of a pigeon-egg.

The cause of the growth is not stated in this instance, but on account of the profession of the patient, together with the connection in which it is referred to, I have been led to consider it as an example of the form due to direct injury, and thus class it as such.

There are, in addition, cases belonging to the traumatic division, mentioned by Schellmann ("Ueber Verletzungen der Hirnsinus," *Geissen, Inaug. Dissert.*), and quoted by Bergmann (*Deutsche Chirurgie*, Lief. 30, S. 365, 1880).

ETIOLOGY.

The two principal varieties of this lesion recognized by M. Dupont were these: First, when the tumor communicated with the sinus of the dura mater through normal skull-openings or canals, as varicose venæ emissaria passing through their respective foramina; and second, in which this communication with the intra-cranial venous circulation was effected by means of abnormal passages. This latter class might be due to fracture of the cranium and wound of the sinus; perhaps to a non-traumatic or spontaneous perforation of these structures; and, finally, to an ulceration of the osseous tissue and a vein in the situation where such a vein pierces the skull in its course to the sinus.

M. Dufour suggests another condition, that is, in which the extra-cranial growth communicates with the sinus, either directly or indirectly through the medium of the diploë circulation. He considers this variety to be especially anticipated in persons of advanced years, in whom the diploë veins are greatly developed and frequently dilated into venous expansions or lacunæ.

The etiological classification adopted by Herman Demme is as follows: (1) Rupture of the external cranial veins, without scalp wound, resulting in cysts which may communicate in various ways with the sinus. Thus, a vein emptying into the sinus may

become torn, and, forming an epicranial or aponeurotic blood-collection, after the manner of traumatic aneurism, communicate with the sinus by this means; especially in the case of the large parietal veins which penetrate the bone through their foramina located on either side of the posterior portion of the sagittal suture. It may occasionally happen, also, that, under the pressure of the extravasated blood, bone resorption takes place, leading to opening of the veins of the diploë and through these to a communication with the deeper venous blood conduit of the dura. Again, the injury producing such an external blood collection may itself excite absorption and perforation in the position of a Pacchionian fossa or depression, and by this method intercommunication between the sac and the sinus system be established. (2) Varices of the external cranial (emissary) veins forming cysts which unite directly, through their relative openings, with the corresponding sinus. (3) Extra-cranial venous cysts resulting from enlargement and dilatation of the sinus itself. These are produced either by gradual absorption and breaking through of the cranial parietes, or they are pushed forward and protrude through a normal or preëxisting opening, like, for example, a fontanelle.

In closing a brief but interesting article on this character of formations, MM. Follin and Duplay declare that with the information before them they can admit only two varieties, namely: First, tumors produced by traumatic ruptures of the sinus; second, tumors resulting from atrophy and perforation of the bone in the region of the sinus or of the Pacchionian cavities. They add, however, that it may be possible, although an exception of extreme rarity, for tumors of this nature to be produced by a varicose dilatation of an emissary vein of the sinus. But, they continue, "we may be permitted to express some doubts as to the existence of this variety."

Bruns describes two forms of varices of the extra-cranial veins communicating with the dural circulation, under the description of (1) varix verus circumscriptus, and (2) varix verus cirsoideus.

Stromeyer believes that these lesions are usually produced by a rupture of an emissary vein, resulting in blood extravasation and formation of a limiting sac beneath the pericranium.

The theory of osseous atrophy—rarefying osteitis—first formulated and advocated, I believe, by Simon Duplay, is supported by Legouest and Servier, Azam, Follin and Duplay, and many others. The initial step in this process is claimed to be found in, (1) a trivial or even unnoticed traumatism, in the form of a contusion; (2) in the erosive action of the Pacchionian granulations alone; or (3) in both the first and second combined—the one being dependent upon the other. The final rupture of the rarefied osseous point may be accomplished either spontaneously, or caused by some slight shock or blow.

These general etiological outlines, as applied to the several groups separately, call for a more complete elaboration.

A. *Congenital Group*.—The points and theories to be examined relative to the etiology of the congenital cases, mentioned in the order of their seeming

prominence, are as follows: (a) Aneurismal or varicose dilatation of one or more emissaria Santorini; (b) Localized morbid processes in the structure of the sinus wall—a phlebectasia or true varix of the sinus; (c) Pathological enlargement and dilatation of the venæ diploicæ; (d) Certain hereditary vices, such as syphilis and struma; (e) Developmental arrests, as want of closure of a fontanelle, abnormal fontanelles, etc.

a. Notwithstanding the questionable opinion expressed by some authors as to the rôle played by varicose venæ emissaria in the production of this form of sanguineous tumor, the preponderance of general evidence, clinical and anatomical, is most decidedly in favor of such a morbid association, and therefore I must claim conspicuous recognition for it in this position. In clinical proof of this union the cases of Moreau, Mersemann, Acland, Michaud, Stromeyer and Verneuil bear ample testimony; and hence not only dispel any serious doubt as to the etiological office of such varicosities, but even accord to this factor a high rank in the causal list of the present collection of congenital cases. In four of the cases intelligent and carefully conducted post-mortem sections, with surgical examination in the fifth, demonstrated the real character of the lesion.

b. Diseased processes in the sinus-wall, producing hernial protrusion, or true ectasia, of the sinus itself, is upheld by the recorded examples of Demme and Foucteau, and probably that of Flint, in two of which a necropsy disclosed the extent and nature of the tissues involved. In Demme's patient the microscope was employed in verifying the post-mortem appearances, and in the other (Foucteau's) one or more of the coats of the sinus was clearly recognized by the unaided vision as entering into the composition of the sac.

Francke (*Lehrbuch der Chirurgie*, Bd. 11, S. 49), expresses the belief that such blood-pouches formed at the expense of the sinus wall, can occur only in monstrosities and non-viable children; but the above instances, especially that of Demme, are fair evidence of the incorrectness of his views and statement.

Furthermore, Velpeau (*Gaz. des Hôpitaux*, t. viii, 2e Série, p. 87, 1846) mentions having seen in two instances (presumably congenital), extra-cranial blood-tumors caused by a phlebectasia or hernia of the dural sinus; once near the anterior fontanelle, and a second time in the region of the occipital boss.

c. Disease and enlargement of the diploic vessels is represented by the patient of Francke (and several others), in whom there was a blood tumor identical, apparently, with a frontal diploic vein, and associated with congenital resorption or absence of a portion of the outer table.

d. Hereditary syphilis or the rickety diathesis occasionally finds expression in the production of craniotabes, where areas or spots of softened and thinned osseous structure take place in the cranial walls, only requiring some slight internal or external pressure to convert them into veritable skull perforations. Although this condition is but seldom observed congenitally, occurring principally in syphilitic infants during the first year subsequent to birth, yet it is

worthy of note that this sometimes does happen; that the inner cranial aspect is usually the primary seat of attack; and that they are generally observed occupying the posterior parts of the parietal bones—about the position where one form of this venous tumor is most frequent; and, too, in which neighborhood the Pacchionian bodies most abound.

Parallel with this observation the so-called gelatiniform degeneration of the outer table of the skull (Parrot) must be referred to, as offering points for consideration in this study.

e. The influence of certain developmental arrests suggests a field for inquiry.

These may be shown in want of closure of the normal fontanelles, thus facilitating hernial protrusion of the dural sinuses; and in abnormal fontanelles, as absence of ossification in the ossa Wormiana. Against the latter, however, in those instances where the growth is situated centrally and anteriorly on the head, may be urged their extreme infrequency in the median part of the cranial vault.

Another condition having a possible, if not probable, relationship to the etiology of the congenital class, is to be found in traumatism from head pressure during parturition.

A wound or rupture of the sinus may occur at birth, as stated by Bergmann (*Deutsche Chirurgie*, Lief., 30, 1880), when the overlapping of the cranial plates, in the line of their sutures, exceeds a certain limit—an occurrence that, in spite of the great changes in shape and size to which the foetal skull is subjected in a narrow pelvis, must be considered rare. He mentions also that Litzmann (*Ueber den Einfluss des engen Beckens auf die Geburt im Allgemeinen*, in *Volkmann's Sammlung Klin. Vorträge*, Nr. 23, S. 191, 1871), saw the *sinus longitudinalis* twice torn during labor in cases of generally contracted and flattened pelves, where the pressure from the promontory upon the already compressed head was so great as to force the sharp serrated edge of the sagittal suture through its tense coverings. Both children died shortly after birth.

Similar cases are reported by Michaelis ("Das enge Becken, noch eignen Beobachtungen herausgegeben von Litzmann, Kiel, 1865), Weber (*Beiträge z. pathol. Anat. der Neugeborenen*, Lief. 1, Kiel, 1851), Olshausen (*Deutsche Klinik*, S. 365, 1864) and C. Hennig (*Die Kopfblutgeschwulst*, in Gerhardt's "Handbuch der Kinderkrankheiten," Bd. 11, S. 54). Again, the same injury of the *transverse sinuses* was met with by Weber (loc. cit.) and Breisky (*Prager Vierteljahrsschrift*, Bd. 63, S. 178).

Under such circumstances where there is a limited wound of the sinus, particularly if the external tissues or scalp escape implication, it is easy to appreciate how this character of tumor can be thus originated.

Finally, it should be noted that in all the clinical cases belonging to the congenital group which were positively determined by post-mortem dissection (varicose venæ emissaria, ectasia of the sinus, and dilatation of the diploic veins), the lesion had its origin, apparently, in a morbid action of the vein-wall itself, namely: a venous hypertrophy and phlebectasia.

B. *Spontaneous Group*.—The several explanations

proposed as to the origin of the spontaneous group may be summed up in the subjoined arrangement: (a) Absorptive or erosive action of the Pacchionian glands; (b) An obscure form of osseous resorption, or rarefying osteitis; (c) Varicosities of the venæ emissaria; (d) Localized morbid processes in the sinus wall, producing bone absorption, and consequent hernial protrusion of the sinus; and (e) Certain constitutional or systemic vices.

a, b and c. As previously referred to, two forms of osseous implication were recognized, that is, bone resorption dependent upon two separate and distinct causes, namely: an osseous atrophy resulting from the absorptive or erosive action of the glandulæ Pacchioni, and a rarefying osteitis due to some remote contusion. Careful investigation, however, has determined me to include the two forms under the single title of *rarefying osteitis*, since it is very probable that the osteitic changes ascribed to the action of the Pacchionian granulations are very similar to, if not identical with, those resulting from bone contusion, especially as the history of a blow or fall is often associated with the special individual action claimed for these glandular bodies.

Furthermore, the bone resorption resulting from localized diseased processes in the structure of the sinus itself, followed by a true sinus varix or ectasia, is, doubtless, closely allied to the above forms of osteitis, and, hence, this should be comprehended, also, under the single form mentioned. Therefore in the following remarks I shall speak of one variety of osteitis only as produced by the three above named factors. The hypothesis of a rarefying osteitis with spontaneous perforation in the so-called spontaneous cases was suggested by M. Simon Duplay (vide Duplay, also Follin et Duplay), who formulated his theory upon the researches of Trolard upon the venous system of the skull and brain. This author (*Recherches sur l'Anatomie du Système Veineux du Crâne et de l'Encéphale, Archives Gén. de Méd.*, t. 1, Mars, 1870) described as situated on the lateral parts of the superior longitudinal sinus, certain areolar venous spaces or *locs sanguins*¹³ corresponding to the forea glandulares, limited on one side by the osseous surface, and which, bathed by the venous blood, communicate freely with the superior longitudinal sinus and the venous canals of the diploë.

A brief résumé of the theory advocated by Duplay is as follows: The osseous lesion is the first degree or stage of the morbid formation. The bone is subjected to a blow or fall—a contusion—which produces a partial localized atrophy of the skull. This atrophy of the cranial bone is not extremely rare, occurring at all ages, and often taking place in limited areas or spots, particularly on the lateral parts of the superior longitudinal sinus over the fossæ lodging the Pacchionian glands, and in which, also, are these spaces or *locs sanguins* communicating freely with the sinus, and upon which anatomical disposition the theory is based. Thus, taking one of these points, atrophy is developed consequent upon a trivial blow and pro-

gresses steadily, reducing the bone to an exceedingly thin lamina, until spontaneous perforation is produced, or perhaps more frequently, a slight secondary contusion or shock may supply the rupturing force, and an opening into one of these venous spaces or lacunæ is effected. By this means intercommunication with the sinus is established, venous blood escapes and is effused beneath the periosteum, the tissues are floated up, and this type of blood-tumors of the cranial vault is the result. "It is thus, probably, that one would be able to explain the relation ascertained to exist in nearly all cases between the development of the tumor and the previous action of a blow or fall."

This theory of a rarefying osteitis in spontaneous cases is accepted in full by Legouest and Servier; and these authors even apply it to a more extended field than that claimed by Duplay, since they assume that the same theory is applicable to the pathogeny of analogous tumors developed in other portions of the cranium—first when occurring over the mastoid cells or the frontal sinus, a pneumocele resulting; or, second, even the diploic structure may become involved. In explanation of the latter involvement they refer to the existence in the diploë of ramifying cavities, lined with the internal venous coat (intima), communicating as freely with the dural sinus as with the extra-cranial circulation. These diploic canals constitute, especially in old persons, a continuous system which unites abruptly with four or five principal confluent passing to the cavernous sinus, the ophthalmic vein, the middle meningeal vein either directly or through the intermediary of the posterior condyloid vein. It results, therefore, that the wear of the cranial table opposite to these confluent may give rise to the development of a sanguineous tumor in communication with the intra-cranial venous circulation without the longitudinal sinus being perforated.

M. Azam believes that traumatism is always the point of departure of a rarefying osteitis; and Dufour also considers the abnormal communication to be caused by an obscure form of osteitis, followed by interstitial resorption of bone, the probable consequence of a trivial contusion.

Many authors rather question the possible rôle ascribed to the Pacchionian granulations of producing atrophy and skull perforation, among whom may be mentioned Meyer, of Hamburg (*Virchow's Archives*, Bd. xix, p. 171), whose rich experience in this field of inquiry entitles his opinion to consideration. Notwithstanding very elaborate investigation and examination of these bodies he has failed to encounter a single instance in which the forea glandulores of the calvarium extended to actual perforation.

But, on the other hand, some writers advocate this theory, giving it decided preference over any other, as shown by the opinion of Dr. Gross (*System of Surgery*), who asserts that "the most common cause of the abnormal communication is spontaneous, progressive absorption of the osseous tissue corresponding with the Pacchionian depressions, when, under the influence of slight traumatism, the blood escapes beneath the pericranium."

Again, as a direct example of this character of

¹³ These structures were described, prior to the publication of Trolard, by Cruveilhier, Luschka, Henle and Meyer. They are designated as *lacuna lateralis sinus* by Key and Retzius, and have received also from Browning the euphonious term of *Parasinoidal spaces*.

perforation accompanied by a rupturing force or shock, the following case mentioned by Demme will be found of special interest and importance:

A robust man falling from a high building scaffold received numerous severe injuries which proved fatal in ten hours. At the autopsy there was discovered a large blood effusion extending over the posterior part of the sagittal suture, and which was found to be, for the most part, beneath the periosteum. After carefully washing the clot there was shown to exist, on the left side of the sagittal suture, a sharp-edged opening the size of a cherry stone, through which protruded a Pacchionian granulation covered over by coagulated blood. On removal of the skull-cap a second coagulum was observed interwoven with the meshwork of the large Siegel sinus, and which (the sinus) communicated directly with the extra-cranial hæmatoma through this resorptive opening of the Pacchionian gland. My examination left no doubt in the matter that the intra-cranial hæmorrhage arose from a rupture of one of the numerous venous vessels tearing through the fibrous walls of the sinus.

In further support of these views I may refer to those obscure alterations and perforations occasionally met with in the petrous portion of the temporal bone, sometimes opening the tympanic cavity, which, according to Luschka, like the *fora glandulores* of the calvarium, are not improbably the result of pressure exerted by these villous-like vegetations.

Typical examples of this pathological process (rarefying osteitis) are furnished by the cases of Bruns, Hecker, Dubois, Giralès, and Duplay, for, although not positively demonstrated to exist by post-mortem sections, they have the history of a contusion followed after a delayed period by the appearance of the tumor, together with the subjective symptoms to be anticipated under such circumstances.

The cases of Bruns, Dubois, and Duplay were regarded as being connected with the sinus either immediately or through the medium of the diploic canals. But all the symptoms seem to indicate to my mind, that Bruns's case was associated with the veins of the diploë, whilst those of Dubois, Giralès and Duplay were, doubtless, in direct communication with the sinus.

On the other hand, the patient described by Hecker was suffering clearly from a blood-pouch first communicating with the diploë and then leading to the sinus—the result of extensive cranial loss. Hecker explains the origin and formation of this case (*varix spurius circumscriptus venæ diploicæ frontalis*) about in this wise: In consequence of a fall on the head in infancy a separation of the outer cranial table was produced with tearing of the diploic vessels, which is easily explained from the thinness of the external table and the great vascularity of the infantile skull. The blood escaped now from the diploic veins into the adjacent cellular tissue under the skin, and as the repair of the vein-rupture (perhaps on account of anatomical conditions) was not effected, the hæmorrhagic effusion continued until the cellular tissue became infiltrated and, as it were, consolidated. Now, however, this consolidation forming a barrier against further bleeding, a pouch with well-defined walls was finally formed, which, gradually but more or less com-

pletely filled with blood, emptied its contents, by means of the supra-orbital foramen, into the external cranial veins, especially the *vena supraorbitalis*. Osseous absorption rapidly supervened, and the tumor reached its present limits.

Hernia or ectasia of the sinus is shown in only one instance, namely, the specimen of the Jacobi. There is considerable doubt expressed, however, by several authors, whether it was of congenital or spontaneous formation, but both Bruns and Demme are decided in their opinion as to its being spontaneous. Here, also, as before suggested, it is more than probable that osseous atrophy was the active element in causing the skull opening.

c. Varicosities of the renal emissaria is exemplified in the cases of Melchiori and Andrews, in both of which necropsies disclosed the morbid changes.

Dr. Andrews gives this solution of his case: A small vein penetrated the skull (occipital emissary vein) communicating with the torcular Herophili and the scalp, and the protracted determination of blood to the brain produced enlargement and distension of the torcular,—this emissary vein also receiving a proportional increase in its calibre. Like the continued drop wearing a stone, so the oft-repeated *vis a tergo* expansion wore the bone, producing the pulsating tumor (in thus dilating the vein) and the large foramen in the skull.

In regard to spontaneously arising single or *circumscribed* dilatations of the external cranial veins, Bruns (Op. cit., p. 191) expresses the opinion that they are extraordinarily infrequent. This assertion is based upon his personal experience of two cases, with one other which he had found recorded.

e. Constitutional and systemic vices—more especially syphilis and struma—deserve notice as occupying a possible causal position. Such is manifested in those osseous changes already referred to in the congenital group; but in this category there should be included, also, any systemic condition predisposing to bone alteration or degeneration. Furthermore, it is quite possible that, in cases of rarefying osteitis, there is often some constitutional condition—a predisposition—which renders the osseous tissue peculiarly susceptible to the taking on or lighting up of this atrophic process upon the reception of a contusing force. Suggestive of this is the case of MM. Nèlaton and Richard, in which the growth was not discovered until after a severe illness of the patient.

C. *Traumatic Group*.—Direct traumatism is the essential element to be recognized in the etiology of this class, and the necessary conclusion deduced therefrom is that, in all traumatic cases fracture is, practically, invariably present, wounding the sinus-wall by, (i) either depressed fragments or detached spiculæ, as in any comminuted fracture; (ii) by punctured fractures, the instrument used in such fractures also penetrating the underlying sinus; (iii) by the separated sharp edges of the fractured bone, especially if the line of fracture passes across the suture to which the sinus is attached; (iv) the sinus may be torn through by a disjunction or separation of the sutures over the sinus, particularly the sagittal suture.

There is, however, another method by which this lesion may be possibly caused where fracture is not a necessary accompaniment, namely, rupture or tearing of the sinus without fracture or suture-separation, produced by certain decided changes in the form of the cranium resulting from heavy blows inflicted by some broad, flat instrument (Bergmann). I have no record of an example so produced, but the injury demands notice as standing in the category of possible factors.

From this character of injury experience shows that the transverse sinuses tear more frequently than the longitudinal, which is explicable not only on the ground of their anatomical location and connections, rendering them much more fixed and unyielding than the latter, but also in the fact that the cause resides, perhaps, in the direction of the rupturing forces, which commonly operate from above and behind. Thereby the cranium is compressed from above downwards, but expanded laterally,—an expansion which must cause great stretching of the transverse sinuses, and, as seen, a giving way, occasionally, of their walls.

On the other hand, rupture of the torcular Herophili is, of all the sinuses situated directly beneath the cranial walls, the most rarely met with. It should be noted, also, that in the analysis of the seven traumatic cases, six are characterized by the absence of external or integumentary wound, and in only one is the fracture open or compound. Hence this preponderance of subcutaneous or simple over compound fractures in association with this injury, must be mentioned as a point of special interest. It is necessary to remark, however, that investigation has shown that laceration of the sinus from cranial fracture with depressed bone-splinters, without simultaneous scalp wound, is comparatively rare. Nevertheless, in one of Stromeyer's cases it is important to refer to the fact that it was a child who had his right parietal bone depressed, from a blow the result of a fall; without cutaneous wound, furnishing another instance of injury of the sinus from a simple fracture.

(To be concluded.)

THE THERAPEUTIC ACTION OF THE OIL OF TURPENTINE IN THE MORE PAINFUL AFFECTIONS OF THE DIGESTIVE ORGANS OF INFANTS AND YOUNG CHILDREN.

BY BEDFORD BROWN, M.D.,

OF ALEXANDRIA, VA.,

MEMBER OF THE BOARD OF MEDICAL EXAMINERS OF THE STATE OF VIRGINIA.

In the therapeutic management of the more painful and grave affections of the alimentary canal of infants, and in those of a harmless character attended with suffering, I have for some years past been testing the virtues of the oil of turpentine as a curative agent. The use of the turpentine in this class of affections has given me much satisfaction.

The diseases of the digestive organs of infants, we

are all aware, are among the most intractable and fatal which come under our observation and treatment.

If by any agency these painful and destructive diseases, which cause so much suffering to these helpless little creatures, and anxiety to relations, can be relieved or mitigated, I believe the profession is entitled to a knowledge of it. While I appreciate the fact that the therapeutic properties and application of this well-known remedy to the treatment of certain adult affections are clearly comprehended by the profession, I am equally aware that its value as a remedial agent in a large class of diseases of the mucous surface of the alimentary canal of early life, is probably not understood. Who in our profession does not witness annual visitations, during every hot season, of those inflammatory affections, often epidemically, a large proportion of which prove fatal regardless of the use of opiates, astringents, alkalies, mercury, and bismuth? In my own experience the oil of turpentine often fills a place here which no other remedy does. The therapeutic action of the turpentine on the diseased mucous membrane of the intestinal canal is of a multiform character. It is eminently soothing to the irritated and inflamed membrane, and seems to promptly arrest that rapid exfoliation of epithelium which, during the inflammatory process, is progressing at an unusual rate of rapidity. If it be really true that this agent is capable of correcting this sloughing process in intestinal inflammation, it is an important point gained in the therapeutics of this class of diseases. I think that experience will fully sustain the opinion that the agent is really reparative in its action.

The action of turpentine on the tongue is doubtless largely typical of that on the mucous surface of the digestive organs. On the *dry, cracked, red, contracted* and imperfectly nourished tongue of fevers the direct effect of the agent is to increase and regulate the circulation of the organ, to reestablish the secretions and restore nervous function, so that in place of the former condition the organ becomes moist and pliable, assuming its natural complexion and softness. We have reason to believe that in that numerous class of diseases of the digestive tube of an inflammatory character, accompanied with fever, the condition of the tongue actually in part represents the state of the mucous membrane of the gastro-intestinal canal, and the action of the turpentine on the one indicates to a certain extent its remedial influence on the other. The oil of turpentine in common with the other essential properties and products of wood tar, is manifestly antifermentative, antiputrefactive, deodorant, and antiseptic. In this respect, apart from its peculiar powers in healing inflammation of mucous membrane, it becomes an important agent in correcting fermentative and putrefactive action in the contents of the intestinal canal, which plays so conspicuous a part in the causation of disease in infantile life. The action of turpentine on the circulation, and indeed on the process of blood formation, is positively of a restorative character. This peculiar therapeutic property is clearly demonstrated through the remarkable influence of the remedy in restoring the circulation in purpura

simplex and purpura hæmorrhagia, and in correcting the tendency to those affections. In both of these diseases there are certainly blood stasis and blood depreciation. This fact, which has been repeatedly demonstrated in the practice of myself and others, indicates the decided influence of the agent over certain abnormal irregularities of the capillary circulation, and at once directs our attention to its adaptability in relieving engorgements and healing inflammations of the mucous membranes. Its remarkable influence also in arresting hæmorrhage of the stomach and intestines constitutes another evidence of decided action in regulating the circulation of those membranes. Whether this hæmostatic power is due to some astringency or to some peculiar influence on the vital conditions of the blood, as in the case of purpura, is difficult to decide.

The action of the drug in these diseases of the mucous membranes is not confined to its influence over the capillary circulation, but extends to the organic system of nerves and the secretions. In other words, it exerts a positive influence on the vital operations of the epithelial cell itself. When the digestive juices of the salivary gland, the stomach, pancreas and intestines are imperfectly secreted, as they too often are, all food, instead of being digested, being exposed to a temperature of 100°, is at once subjected to the laws of chemistry and, undergoing rapid fermentation and putrefaction, gives rise to various deleterious products of an acrid and gaseous nature, which produce an endless train of morbid actions in the alimentary canal of the infant.

I am fully impressed with the belief that the oil of turpentine acts as a stimulant to the salivary, stomachic, pancreatic and intestinal secretions, and in this way becomes a promoter of the digestive operations. In that condition of the system indicated by a dry, red, glazed, or brown tongue, we may rest assured that the processes of digestion and assimilation are wellnigh suspended for the want of the appropriate secretions. If the turpentine can restore the secretions of the mouth and restore the tongue to its normal state, the digestive process has already received an important impetus. There is probably no stage of human existence more subject to those painful, protracted and deleterious sequences of indigestion from defective secretions of the digestive fluids, than that of infancy.

The dry, inflamed, and aphthous mouth of the infant suffering from chronic mucous disease, when all healthy secretion is in great part suspended, calls imperatively for the use of some agent which has the power to restore these absolutely necessary factors of digestion. The almost invariable improvement which follows the use of the turpentine in the digestion of infants suffering from intestinal and gastric affections, leads to the rational conclusion that it exerts a general influence in promoting the flow of the various juices concerned in the act of digestion. Under the use of this agent the process of digestion is certainly facilitated, becoming more easy, comfortable, and more free of pain, while the abnormal products arising from indigestion are decidedly diminished, if not entirely prevented.

Mention has been made of the antifermentative and antiputrescent active, as well as the antiseptic properties of turpentine. The presence of these properties is clearly indicated in its decided agency in preventing and arresting the evolution of offensive intestinal gases and tympanites. Probably in our study and treatment of the intestinal diseases of infants we have not heretofore attached sufficient importance to those septic influences arising from the acts of fermentation and putrefaction in the contents of the canal. In such cases we are too prone to trust alone to the agency of opiates, alkalies, and astringents. Fermentative action and its peculiar products in the contents of the digestive organs of the ill-fed, ill-nourished infant suffering from dyspepsia is the bane of infantile existence. These products consist of the various acrid and irritating animal and vegetable acids as the lactic, butyric, and acetic.

The gases evolved from fermentation and putrefaction are the carbonic acid, carburetted and sulphuretted hydrogen, and the ammoniacal. The hourly contact of these deleterious and poisonous agents with the imperfectly developed epithelial coats of the infantile digestive organs must prove destructive of its organization and cause erosion, with its extensive morbid consequences.

Following these general remarks on the use of the oil of turpentine in the intestinal affections of infancy, it is proper to state in detail the special diseases to which it is applicable.

Gastralgia.—All infants are liable to transient attacks of painful colic, arising from temporary distension from accumulation of gas in the stomach, or from the presence of acids. But artificially fed infants more particularly are occasionally subject to a violent, protracted and intensely painful form of gastralgia in which appetite and digestion are suspended, accompanied with rapid reduction of flesh and strength, sufficiently to endanger life. Vomiting may or may not be present. There may be slight diarrhœa or constipation. The affection is invariably attended with wasting of the tissues and suspension of development, anxious and contracted facies, but no fever except in advanced stages, when gastritis or duodenitis may be developed. Pain is the great and absorbing feature of the disease, which is a never-ending source of suffering to the little patient, and a source of perplexity to friends.

The disease may appear at a very early age. It does not appear to be associated with any organic lesion. It does not partake of the intermittent character of ordinary colic. But the pain is almost constant and unceasing, without relief from opiates. The abdominal walls are usually retracted. The shrill penetrating cry of these little sufferers may often be heard, to the dismay and distress of all, pervading the entire house, day and night, except when under the influence of opium. On one occasion a feeble, emaciated little infant was brought to my office suffering with this affection, for treatment. Such were the shrill and distressing screams of the little creature, the wasted and piteous expression, that all transient callers were compelled to leave the room. The mother was robust and apparently in a vigorous

state of health, and afforded an abundant supply of nourishment.

I think in this case the child was suffering from an aggravated form of acidulous dyspepsia, with simple irritation of the gastric and duodenal mucous membranes. In two or three months this wretched little sufferer, under the turpentine treatment, combined with a few simple anodyne and alkaline remedies, was converted into a rosy, fat, merry, healthy infant. I have found the following formula a useful remedy in this class of cases:

R Mucilag. acac..... ℥ss
Sodæ bicarb..... xgrs
Chloroformi..... xgtt
Ol. terebinth..... 3ss M

Sig.—A teaspoonful every two or three hours to an infant of six months.

Intestinal Catarrh of Infancy.—Catarrhal inflammation of the lower ileum, cæcum, and colon, is well known to be one of the most frequent and fatal diseases of infants during our hot seasons. The inveterate dyspepsia of the artificially fed infant, subsisting on cow's milk, arrow root, and other farinaceous food during dentition, united with the depressing influence of heat, constitute the most fruitful source of intestinal catarrh. The enormous amount of lactic, butyric and acetic acids generated in the stomach and intestines of those dyspeptic infants subsisting on these particular articles of diet, act as corrosives and destructive agents on the delicate epithelium. Thus a constant process is going on in those cases of exfoliation of epithelium and erosion of the submucous coats of the large intestine. The succeeding steps are engorgement, inflammation, ulceration, and softening.

Only about one-fourth of the entire number of artificially fed infants digest cow's milk perfectly. The remainder either digest it indifferently, or not at all. They, the latter, must pass through the lactic acid stage, with its attendant dyspepsia, pain, discomfort, more or less protracted intestinal catarrh, with its peculiar type of low fever, which resembles in many respects, in a striking manner, typhoid fever. The mouth and tongue are dry, red, and aphthous. The skin is dry, parched, and shrivelled. The pulse is quick and the temperature high at night. The abdomen is usually distended and tender on pressure. The intestinal discharges are muco-sanguinous and often frequent. The emaciation is always great. This, which is in ordinary termed the chronic diarrhoea of infancy, with its attendant pain, low fever, and emaciation, is a scene so often witnessed that we are prone to take a superficial view of these cases without penetrating further into the true pathological principles involved. I believe that genuine typhoid is not a more perfect example of septic fever than the form under consideration. Not only the intestinal contents, while in a state of fermentation and putrefaction, afford septic material for absorption, but the debris of broken down and sloughing tissue from softening and ulceration, furnish also materials for infecting the blood, and the production of true septicæmia. Hence in these cases we have to deal with a disease far more complicated than a simple

diarrhoea. We have here an example of a local lesion and septic fever united.

The excess of lactic acid is also responsible for the presence in these cases of that inveterate form of intertrigo, which aids in impairing the general health. The acid here acts as a destructive agent on the delicate cuticle, leaving the cutis exposed and inflamed. In other words, the cuticle is destroyed by contact with the corrosive acids in identically the same manner that the epithelial coat of the intestine is from the same causes.

Infantile life is the acid stage of human existence, as old age constitutes the alkaline period. In infancy we are called upon to contend with the effects of acid development and action, while in old age the enemy that besets its course is of an alkaline character, in the form of ammonia. To repair the damages resulting from catarrhal inflammation of the intestines, restore lost epithelium, reestablish suspended secretion, heal erosion of mucous membrane, the turpentine performs a good part.

Dysentery of Infancy.—In the primary stages of acute dysentery, when the symptoms are violent and accompanied with much fever, tenesmus and pain, the acute features may be much modified by the use of minute doses of mercury (mild chloride), ipecac, and bicarbonate of soda, followed by the tartrate of soda and potash in sufficient quantity to clear the intestinal tract effectually. This procedure relieves the intense engorgement of the mucous membrane of the large intestines promptly before disorganization begins, and diminishes inflammatory action, and improves the state of the secretions. The powers of digestion and the febrile conditions are also benefited by the proceeding. The following formula may then be resorted to with infinite benefit:

R Mucilag. acac..... ℥i
Ol. terebinth..... ℥ss
Ol. resini..... ℥ss
Aq. menth. pip..... ℥iij M

Sig.—A teaspoonful to a child of six months every 3 hours.

In connection with this treatment, anodyne enemata, composed of tinct. opium and mucilage, should be resorted to, to allay pain and procure sleep. In the advanced stages of this affection, when the fever assumes a depressed type, the general system begins to suffer seriously from emaciation and constant fever, when the tongue becomes red and dry, indicating great general prostration and a tendency to disorganization of the mucous membrane involved in the inflammation, in my experience the turpentine is among the best agents for arresting this state of affairs, and turning the tide in the direction of health and of reestablishing a reparative process.

In some cases in the stages of disorganization I have combined the oil of turpentine with the oil of yellow sandal-wood with positive benefit. It may be found also advantageous to combine the turpentine with other agents of an anodyne, alkaline, astringent or antiseptic character.

The local anæsthetic or anodyne influence of the oil of turpentine on the gastro-intestinal mucous membrane is very considerable, which adds greatly

to its value as a remedial agent in the treatment of this class of affections.

Enteritis of Infancy.—While simple, uncomplicated enteritis is not a frequent disease of infancy, yet it occurs occasionally, and is always of serious import at this tender age. Enteritis is manifested by the presence of slight fever, moderate diarrhoea, prostration, and paroxysms of violent spasmodic, nauseating and depressing pains in the abdomen, occurring particularly one or two hours after taking nourishment. During these attacks the pulse becomes frequent and feeble, the surface and extremities cold and often livid. Relief only comes after the passage of the contents of the intestines through the diseased duodenum, jejunum and ileum. The severe paroxysms of pain do not occur usually until the contents of the stomach have escaped from the organ into the small intestines.

Enteritis is invariably accompanied with loss of appetite and impaired digestion. Nausea and vomiting in a more or less degree are usually present. Consequently the tendency to emaciation and reduction of strength are marked. In the treatment of this affection I have found the following formula more useful than any other:

R	Mucilag. acac.	f3i
	Aq. menth. pip.	3ss
	Ol. terebinth.	gttxii
	Tinct. belladon.	gttx
	Aq. calcis.	3iss
	Tinct. opii. deod.	gttx M

Sig.—A teaspoonful for an infant one year old every three or four hours.

As an adjuvant to the turpentine treatment in the painful affections of the intestines and stomach of infants, the belladonna has given me much satisfaction, and more particularly when the discharges are frequent.

Unclassified Painful Functional Affections of the Stomach and Intestines of Infants.—Infants which subsist on cow's milk and vegetable food principally, are liable to frequent attacks of pain and discomfort from irritations of the alimentary canal arising from imperfect, slow and tedious digestion, which may interfere seriously with the health and growth of the subject. These attacks may be purely of a functional character, or partake of a mild catarrhal nature, with slight fever. The intestinal discharges in these cases usually present an unhealthy appearance and are often extremely offensive, indicating a state of fermentation and putrefaction. The stimulant and carminative virtues of the turpentine, united with its antiseptic and anodyne properties, render the remedy peculiarly appropriate to this class of cases, particularly when combined with lime water and minute doses of carbolic acid.

In the class of cases treated of in this paper the oil of turpentine, as a remedial agent, is not presented as a *sine qua non*, but as a valuable agent to fill a place, and as an effective means of coöperating with other treatment for the relief of the many aggravated, painful and difficult affections of the gastro-intestinal canal of infants.

TRANSPLANTATION OF CONJUNCTIVA FROM THE RABBIT.¹

BY EUGENE SMITH, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOTOLOGY IN DETROIT COLLEGE OF MEDICINE.

It is not my intention to go into the history of transplantation of conjunctiva from rabbit to man, but simply to report a successful case, and the method followed. Allow me to premise, however, by saying that in the winter of 1873-4 I saw De Wecker, of Paris, make the operation wherein he placed the conjunctiva, after removal from the rabbit, on a microscope slide over a tumbler of hot water to keep it moist and warm before transplanting.

In 1881, at the International Medical Congress in London, which I had the honor to attend as a delegate from this Association, Dr. Dufour, of Lausanne, reported several cases, in two of which he adopted the method followed by De Wecker. The same year—1881—it was my good fortune to assist Dr. Wolfe, of Glasgow, in a successful case, in which, instead of using hot water, he placed the conjunctiva to be transplanted on the back of his hand, transporting it in that way to the patient's eye. This method was so simple in comparison that it is the one I have since adopted in two cases, only one of which was a success.

Mr. S. F., æt. 26, was burned in the right eye with molten iron in September, 1885. He consulted me several weeks after the injury, at which time the upper and lower lids were attached to the inner half of the eyeball, the cornea being covered at its inner two-thirds. There was still a great deal of inflammatory reaction, and I advised postponement of operative procedure.

On January 25, 1886, about five months after the injury, I transplanted conjunctiva after the method of Wolfe, as described by him in the *Annales d'Oculistique* for September-October, 1881, in his report of the case in which I assisted. My operation was made in the presence of the class of the Detroit College of Medicine.

It is not an easy task to remove so thin a membrane as the conjunctiva and transplant it. The moment it is dissected it rolls upon itself and it is nearly impossible to recognize the epithelial surface again. Sutures even do not prevent this tendency to roll up. For the purpose of recognizing the epithelial surface, three or four sutures are placed in the conjunctiva before it is dissected from the rabbit, the suture being long and the needles left *in situ* for use in grafting. Dr. Wolfe suggested and practices placing the conjunctiva on the back of the left hand, where it adheres and dries after being spread out. A little warm water suffices to moisten the conjunctiva and make its removal from the hand easy, when the eye is made ready for its reception.

The difficulty in holding the lid everted is overcome by passing three sutures through the border of the lid, with the ends of which the lid is controlled and kept in the required position. By this means

¹ Read in the Section on Ophthalmology, Otology and Laryngology, at the Thirty-Seventh Annual Meeting of the American Medical Association.

the annoyance of having the lid fly back just at the critical moment is avoided. From four to six sutures are all that are necessary to maintain the graft in position. In my case I tied the sutures so tight that they came out the third or fourth day without assistance. This is my habit with conjunctival sutures in general.

For the success of this case I feel indebted to Dr. Wolfe, and I have no doubt that if his precepts be followed by others more successful cases will be reported, and the operation become one of the regularly recognized operations, rather than a curiosity in ophthalmic surgery.

219 West Fort Street, Detroit, Mich.

CHLOROFORM AS AN ANÆSTHETIC.

BY T. J. HUTTON, M.D.,

OF FERGUS FALLS, MINN.

FORMERLY RESIDENT PHYSICIAN IN THE LONG ISLAND COLLEGE HOSPITAL, AND IN THE BRIGHAM HALL ASYLUM.

While interne in the Long Island College Hospital fifteen years ago I had many excellent tutors; taken all in all the faculty as a whole seemed to me the personification of wisdom and professional enthusiasm. On one point, however, there was a serious breach of harmony: one used chloroform, one ether, another a mixture of the two, with or without alcohol, etc. On entering upon private practice, I chose chloroform as my anæsthetic, and have now used it exclusively for fifteen years. Never, except in consultations, when I always defer to the preference of counsel, have I used any other anæsthetic than chloroform.

In discussing this subject there are three questions which should be answered: 1. How often have I administered chloroform to complete insensibility? 2. Under what limitations? 3. With what results?

1. I have administered chloroform to the surgical degree of anæsthesia about three thousand times; I have not kept a record of the cases, but I am sure that this rather falls short of than exceeds the truth.

In the Schuylkill, Pennsylvania, coal region, where I spent the four and a half years subsequent to leaving hospital, the Fates and their congeners the Molly Maguires held high carnival. Mining accidents, errailing all degrees of mutilation, were of almost hourly occurrence; and bullet wounds were sufficiently frequent to keep one quite in practice in that interesting department of surgery. It was not a rare occurrence to administer an anæsthetic to two or three patients daily. Although eleven years have passed since I left that interesting field of labor, I can still distinctly recall single days in which I had three serious accidents to treat, each requiring an anæsthetic. During those four and a half years I must have administered chloroform at least fifteen hundred times; in the past eleven years certainly no less.

2. Under what limitations? I do not administer chloroform to every one; and a rule from which I rarely deviate is to administer from a dram to an ounce of brandy, or whiskey, a few minutes in advance—according to the age of the patient. I do not administer it to persons with serious organic ailments, nor to

scrawny individuals whose midgety stock of vitality is taxed to its utmost in normal respiration. Whole forenoons are not spent in stethoscopic determinations of heart lesions; a rapid survey of the *tout ensemble*—heart, pulse, tongue, general appearance and recent history, determines the fitness or unfitness for chloroform. All subjects must by no means be free from flaw, but granted the necessary soundness, it is used for both sexes, for all ages, for all manner of operations. A child a few weeks old was operated on twice under chloroform, first for cleft palate, again for hare-lip. A woman aged 66, subject to violent attacks of hystero-epilepsy, was reduced to insensibility by chloroform at least a score of times. It is always administered in the second stage of labor—to partial or complete insensibility, as the case may require—except in rapid or painless labors, or that the patient object. I remember but three who persistently objected, and all who took it once demanded it in subsequent deliveries. In a case of convulsions before labor in a primipara, bleeding, croton oil and sedatives failing to arrest them, four pounds of chloroform, administered alternately during four days and nights, stopped them. Convulsions began Monday; stopped Thursday. On the following Sunday a large healthy child was born. Mother and child doing well. I shall not wonder if this case prove unique in the quantity of chloroform administered. There are some further limitations to its use, which some may consider trifling, and perhaps unworthy of mention, but which I regard as the key to this question: *First*, I use Squibb's chloroform exclusively. Notwithstanding my familiarity with chloroform in general, I would still feel extremely chary were I compelled to use any other manufacture. *Secondly*, I will not administer it with a patient's head elevated. Dentists have offered greatest seductions in this direction. Sent for by them I go to find patient all ready, *sitting high up in chair*. "You must place patient on lounge with head low as body or I shall not administer it" is my invariable, inflexible charge. Once a little lady sat thus waiting, who, though free from heart or other organic lesion, was as impressible as mercury—as electric as the famous fish. Her pulse ran 122. "Not for a million dollars, Mrs. C., would I give you chloroform," I said, and after a glass of stiff port the extracting proceeded without anæsthetics. *Thirdly*, I will only administer it on my "rag," which is extemporized in five seconds on the spot. A piece of old sheet or shirt about $2\frac{1}{2} \times 3$ inches and four or six folds in thickness is saturated with chloroform. After the stimulant is given this is held for the first whiff or two about four inches from the nose, then advanced to three, two, or one inch, and curved towards the nose, is so held until insensibility is obtained. It need scarcely be written that the patient's clothing, particularly the neck-gear, must be abundantly loose, and that a quiet, trustful, passive condition must be enjoined on the part of the patient; "now close your eyes—breathe in long and gently." Covering the back of the rag with a piece of pasteboard saves chloroform by preventing evaporation; and it will be readily seen that our rag permits of a free admixture

of air with the chloroform inhaled. Pure air in abundance is admitted to the operating room, and it is kept pure by admitting none but those whose services are absolutely necessary. *Fourthly*, with one hand I administer the chloroform and with the other I hold the pulse. Any change is instantly noted and I act accordingly—desist or push to completion. *Fifthly*, when the thermometer is 90° or more in the shade I will not give chloroform to the degree of insensibility if the operation can possibly be postponed, for reasons to be stated under *Results*.

Sixthly, in many intelligent families where I had administered it in their presence, where the indication remained longer than I could myself remain, I entrusted the administering of chloroform to friends of patients. This has happened time and again, in all manner of convulsive troubles, the four pounds already referred to being among the number. As to the number of times I have given chloroform to the degree of partial insensibility, or that it has been administered by my patients' friends to this degree under the strict precautionary rules already cited, I cannot state the number; but it was certainly used a *very great* number of times. Why should it not have been when I have always assured doubting, intelligent people that "used as I direct, it is safe as water." A recent article would indicate that some one has administered it internally almost as freely as water—teaspoonful doses oft repeated; but of its internal effects I know very little. I have prescribed it internally only in the form of spirits of chloroform; this only a dozen or score of times in lesser convulsive affections of middle age, and always with satisfactory results.

Finally, *with what results have I used chloroform as an anæsthetic?* What success? what failures? what major or minor accidents? I have always scrupulously and religiously adhered to the precautions mentioned. I have never had a death occur directly or remotely chargeable to the effects of this anæsthetic. Never was there any alarming accident. Never did the heart fail, necessitating resuscitation. Never was an operation interrupted or its administration suspended because of systemic failure. In four instances the patient would not go under, *i. e.*, could not be rendered insensible. This is the sum of all the singular or noteworthy phenomena that I have observed. Two of these four patients were females. I saw them a year or two apart, and it was so long ago that while I remember distinctly the main circumstances, I forget the details. The other two were healthy young men—Germans, in their prime. Both were traumatics. One had his fingers torn by machinery; the other had shot off a thumb. All four rebellious patients were seen in very hot weather, when the mercury stood 90° to 100° in the shade.

I know that generalizing is always dangerous, more especially when based on meagre data; yet I dare to believe that these failures to anæsthetize were due to a peculiar condition of the blood and nervous centres induced by the extremely high temperature. This view is confirmed by the fact that by waiting until the evening hour these patients "went under" chloroform kindly and promptly.

To my mind ether could never fill the place of chloroform. The huge quantity of ether required drains finances for freightage. Its louder all-pervading odor in the operating-room is no argument in its favor. No more are the silly colloquies, the vomiting, genital irritations, and erotic séances. Moreover, time is valuable to most practitioners; all can not well afford the indefinite time required for etherization.

Finally, as to safety—the greatest of all considerations—I have, in consultations, seen two deaths occur under ether, one directly chargeable to it, the other indirectly, whereas, as already stated, *I have never witnessed any ill results from chloroform.*

Fergus Falls, Minn., Aug. 12, 1886.

OCCLUSION OF VAGINA WITH RETENTION OF MENSES.¹

BY J. W. MEEK, M.D.,

OF CAMDEN, ARK.

My object in reporting the following case is simply to make a contribution to the history of a rare and sometimes serious affection.

I was called in November, 1885, to see a young lady, aged 15½ years, who was suffering with complete retention of urine, of thirty-six hours duration. This was my first professional acquaintance with the case. The retention was promptly relieved with a catheter. Two days afterward retention again occurred, and was again relieved. I now sought more minutely into the case, and learned that she had never menstruated but twice, first six months, and last three months prior to this time. Each menstruation was preceded by weight in loins, bearing-down pains, and partial retention of urine. After a week's duration of above symptoms a sudden *gush* of menstrual fluid gave immediate relief.

I made a thorough vaginal examination, and at the depth of about one inch from the ostium vaginæ I found a tense, elastic membrane, bulging downwards, with a sensation of fluctuation above it, completely obstructing the vagina. The nature of the case was clearly made out. A pyriform tumor could be felt over the hypogastrium. The fluid, at the previous menstruations, had evidently ruptured the dam each time, but it had been each time after menstruation very neatly repaired.

Realizing the danger that sometimes attends operations for the relief of these affections, I proceeded cautiously as follows: The large needle of an aspirator, detached from the aspirator, was thrust through the obstruction and permitted to remain there for several hours. About one pint of tarry fluid slowly passed through the needle. The needle was then withdrawn and the remainder of the fluid was permitted to flow through the orifice made by the needle. Ten days afterwards no trace of the orifice made by the needle could be seen, and an operation was commenced for the permanent relief of the condition. The patient was placed in the lithotomy position, and the labia separated with retractors. A small

¹ Read before the State Medical Society of Arkansas, April 29, 1886.

opening with a pair of scissors was cautiously made in the centre of the obstructing membrane. About one ounce of foetid menstrual fluid was discharged. The opening made by the needle had closed before giving exit to the entire collection. I thought it best to again defer any extensive operation lest the wounding of the soft parts too severely might lead to the absorption of poison from the remaining fluid, which by this time had become septic. The fluid was washed away with warm water and patient kept in bed.

Two weeks later the operation was completed as follows: Through the opening previously made a Caros female urethral dilator was introduced and expanded until the membrane was put on the stretch. Incisions were now made with a hernia knife at several points. A small bivalve speculum was then introduced and widely expanded. The entire obstruction gave way, and the only dressing applied was lint saturated with glycerine.

Since then she has enjoyed excellent health, and I feel sure is now prepared to discharge all the duties and functions of womanhood.

As I said in the outset, operations of this kind are, though very simple, sometimes attended with serious consequences. Sims, in his "Uterine Surgery," advises against making a free incision, and Holmes says that all operations performed for the relief of these obstructions, after an accumulation of the menses has taken place, are attended with peculiar danger. To account for the phenomena sometimes following operations on these parts, he offers the following:

1. That the retained fluid, on the admission of air, is peculiarly liable to undergo decomposition and may thus lead to metritis, peritonitis, and death.

2. That when the hyperdistension of the uterus is relieved suddenly, contraction of that organ may set up and the fluid forced backwards into the Fallopian tubes may rupture the same.

Rupture of these tubes may also take place before any operation has been performed.

Post-mortem examinations have verified the above. In view of these facts, an early puncture, permitting the fluid to gradually pass away, is imperatively demanded.

As to the cause of the closure of the vagina in the case narrated, I can only say that it was clearly acquired. The membrane was of a cicatricial nature, apparently formed by union of the anterior and posterior vaginal walls. The mother informed me that the child had once suffered from seat worms (*oxyuris vermicularis*), and that these were known on one occasion to migrate into the vagina, giving rise to considerable leucorrhœa.

MEDICAL PROGRESS.

INTRA-VEINUS INJECTION OF SALT SOLUTIONS.—In a paper read before the Boston Society for Medical Improvement, on April 5, DR. F. B. HARRING-

TON says: The effort to prevent death, which threatened as a result of the loss of blood, led at an early period in the history of medicine to transfusion. The use of the blood of animals and of blood which has not been defibrinated has been abandoned as dangerous. The blood of distinct species seem to possess toxic influences, and undefibrinated blood of the same species is dangerous, because of the occurrence of clots. Excellent results have been obtained by the use of defibrinated blood, but it is always difficult and sometimes impossible to obtain sufficient human blood for transfusion. This has led to the use of various substitutes for blood such as milk, egg albumen, peptones and the like. These although of value possess some elements of danger. The intravenous injection of salt solutions was extensively practised in the cholera epidemic of 1832-33. It was again used in later epidemics. It produced marked temporary improvement, but did not effect the final result.

Within late years it has been found by experiments on animals, that those dying from loss of blood could be resuscitated by the injection of solutions of common salt. Salt solution is an indifferent fluid, and the beneficial effect is supposed to be due to the increase in volume given to the blood remaining in the system after bleeding. In progressive anæmia life may continue, although the red corpuscles are reduced to less than one-tenth of the normal number; a reduction greater than would ever occur from hæmorrhage. When the red corpuscles remaining after severe bleeding are brought into circulation by a harmless medium the danger of death is diminished. Moreover the increased volume of the current gives the heart something to contract upon and its action becomes slower and stronger.

Ott, as the result of recent experiments, claims that the beneficial action of blood transfusion in acute anæmia may be explained only by the introduction of a certain amount of fluid into the circulation. The theory of the "transplantation" of blood by means of transfusion he believes is untenable, being disproved by experiments. Maydl, on the other hand, in his experiments on dogs was able to save more animals by defibrinated blood than by salt solution. He says we must recognize two forms of death from hæmorrhage. In one there is anæmia of the nerve centres, although blood enough to sustain life still remains in the body. In these cases stimulation, position, and auto-transfusion are usually sufficient to prevent death. In rare cases the injection of salt solution may be necessary. Death in the second form is due, he believes, to such a loss of blood that there are not enough of the normal constituents of the blood left to sustain life. In this case the transfusion of blood becomes necessary; or salt infusion may be immediately performed, to be followed in a short time by the transfusion of defibrinated blood.

Ott and Maydl thus differ in their estimation of the value of blood transfusion, yet both agree as to the value and the lack of danger in the careful use of salt solution. The difficulty of obtaining a proper quantity of defibrinated blood at short notice, and

the ease with which saline solutions can be made, certainly predispose in favor of the latter.

In 1883, Dr. Bull collected and tabulated nineteen cases in which salt solution had been used as a substitute for transfusion. This table is presented with ten new cases which I have collected.

Schwarz's solution is a saline solution made slightly alkaline by sodic hydrate.

To sum up, we have one case (3) of iodoform poisoning, three cases (14, 15, 16,) of poisoning from illuminating gas. These four cases recovered. There were four cases of collapse. Two (21, 29) from peritonitis, one (28) from septicæmia, one (23) from shock. These cases showed temporary improvement, but all died. One case (2) of incomplete removal of uterine carcinoma after temporary improvement, died; one case (5) died on the following day from amyloid degeneration of the remaining kidney, the other having been removed; one case (6) recovered from the hæmorrhage, but death followed in six days from septicæmia: One case (7) recovered, but died in three weeks from peritonitis, one case (10) died in three hours, the result of a second hæmorrhage from a gastric ulcer; one case (17) of nephrectomy after temporary improvement died in twelve hours; one case (24) recovered from the hæmorrhage and died in five days of peritonitis. Of the above-mentioned fifteen cases, four recovered. The others died from some cause other than the hæmorrhage. There remain fourteen cases of which thirteen made complete recovery. One case (25) died immediately. If correctly reported the injection of over sixty-six ounces in fifteen minutes must be looked upon as a dangerous proceeding. It is the only case favorable for the operation, in which there was no improvement.

Experience has shown us that the system will bear the loss of very large amounts of blood. Maydl found that dogs would sometimes bear the loss of two-thirds of the blood volume and recover without transfusion or intra-venous injection being performed.

To determine when intra-venous injection is demanded is a question of judgment of the patient's peril, and not a question merely of the amount of blood lost. All ordinary means should first be tried. If these fail the salt-solution may be necessary. The best form of solution is made as follows:

Sodic Chloride.....	6 ʒiss.
Sodic Bicarbonate.....	1 gr. xv.
Aqua Distillata.....	1000 oil +

Care should be taken that the solution be perfectly free from débris. Water that has been boiled and filtered or pure water that has been filtered will answer the purpose. The solution should be warmed and kept at a temperature between 100° and 104° F. A reservoir with a rubber tubing and a canula of small size make the best injection apparatus. No air should be allowed to enter the current. The solution should enter the circulation at a low pressure and its effect on the heart should be carefully watched. Gravity pressure is safer than a syringe. An elevation of one and one-half to three feet is sufficient. The amount used must depend upon the effect upon the circulation, but may be from one to four pints. If a vein can be found in the arm it may be used.

This can usually be accomplished if a ligature is placed above the arm above the elbow and the blood in the forearm is pushed toward the elbow, by the hand or by bandaging. If the vein cannot be found, the artery may be used. The salt-solution should not be allowed to enter the circulation too rapidly, lest the heart be overpowered. The simplicity of the operation, its great efficacy in cases of simple acute anæmia and the lack of danger in its careful use makes it the duty of every practitioner to be prepared to make trial of this means of saving life when the necessity arises.—*Boston Medical and Surgical Journal*, May 27, 1886.

ERGOT IN THE THIRD STAGE OF LABOR.—DR. V. M. REICHARD, of Maryland, says in regard to "Ergot in the third Stage of Labor, and its Influence in Preventing Septicæmia." It is an agent of the greatest utility in the third stage, and especially in the post-placental period. Those authors who are most chary about giving ergot advise its use when the head is about passing the vulva. This, however, may cause trouble. With an adherent placenta—and there are some men who find these cases are not extremely rare—the drug may cause such severe contraction as to interfere seriously with the operator or indeed imprison the placenta within the uterine cavity. The safest rule by far is not to give ergot until the placenta is in the vagina or escaping from the mouth of the womb. Given at this time and in full and sustained doses, too much cannot be said in its favor. It lessens or prevents after pains; it hastens involution to a marked degree; and it reduces to a minimum the dangers of septic absorption. In this latter direction I conceive lies its greatest usefulness. The situations most favorable for the absorption of septic organisms are the denuded placental site and the occluding thrombi in the mouths of the uterine sinuses. By securing firm contraction or hypercontraction both these dangers are met. The uterine cavity being emptied thoroughly and kept almost entirely in a state of tonic contraction, the discharges are carried out at once, the placental site is reduced to the smallest size, and the thrombi have the serum forced out, thus diminishing their value as propagating media for septic organisms.

The facts bear out these assertions. I have found that women who are thus treated with ergot do better than those who are not. The temperature scarcely rises above the normal, and they are in better condition at the end of the lying-in period. In a recent case in which the placenta was remarkably adherent, all judicious efforts failed to remove the entire placenta. The injury to the uterine surface by prolonging further the efforts at removal was judged to be greater than the danger of leaving behind a piece of placenta. The woman was given a drachm of ergot every four hours. In twenty-four hours the lochia were very offensive, and on the third day a goodly-sized piece of placenta was discharged in a putrid state. At no time was the woman's condition at all serious. I do not wish to be understood as saying that every effort should not be made to remove the entire placenta. But what I do say is that ergot will so seal

the uterine absorbing surfaces that a putrid piece of placenta may be retained and no bad results follow. Whether it be only a coincidence or the effect of a cause, opinions may differ; but I am sure that since giving ergot to every woman immediately after the expulsion of the placenta my cases do a great deal better than before I commenced to give it.

To sum up: Ergot should not be given until the placenta is under entire control; then should be given several doses in quick succession until the womb is well contracted and low down; and after this a drachm every four hours. The rapidly-repeated doses may cause vomiting, but I have never seen any bad results follow this. On the other hand, the womb seems to contract more forcibly.—*Philadelphia Medical Times*, September 4, 1886.

TREPHINING IN HÆMORRHAGE FROM THE MIDDLE MENINGEAL ARTERY.—In the past three years, Krönlein has opened the cranial cavity for hæmorrhage from the middle meningeal artery and resulting hæmatoma in four cases where neither wound of the skin, nor fracture of the skull existed.

The diagnosis was correctly made in every case. In each instance there was found a marked supra-dural extravasation in the region of the arteria meningea media. Two patients recovered. Cerebral hæmatoma may be (a) diffuse, or (b) circumscribed. Of the latter (b), Krönlein makes the following classification according to the seat of hæmorrhage:

First. Hæmatoma media, or tempero-parietale, of the middle cerebral fossa (a region supplied by the trunk and anterior or posterior division of the arteria meningia media) due to hæmorrhage from the anterior branch of the anterior division.

Second. Hæmatoma posterius, or parieto-occipitale—parietal eminence—due to hæmorrhage from rupture of the posterior branch.

Third. Hæmatoma antierius, or fronto-parietale—frontal eminence.

The tempero-parietal region is the most common seat of injury (a) from the vulnerability of the region, (b) from the size and number of vessels, it being the seat of the trunk and the main branches. All hæmatoma are accessible at the anterior inferior angle of the parietal bone, with the exception of the circumscribed ones of the parieto-occipital region. If the hæmatoma is not found here, the parieto-occipital region must be explored, and the point for trephining is under the parietal eminence. Krönlein's indications for surgical interference are symptoms of cerebral compression, and his rule for locating the points for operation are as follows:

1. A line called the horizontal line of the skull, namely, one passing from the infra-orbital border to the external auditory meatus.

2. A horizontal line parallel with the above, and projected backward from the supra-orbital ridge. Both points of operation are in this line.

(a). The anterior; three to four cm. posterior to the zygomatic (ext. angular) process of the frontal bone.

(b). The posterior; at the point of intersection of the above horizontal lines, and one projected vertically, from a point just posterior to the mastoid process.

Krönlein claims that a double operation is indicated not only in cases where a single perforation fails to find the seat of extravasation, but also in cases of diffuse hæmatoma, since the clot can be more completely removed, and also a better opportunity afforded for drainage, should such be necessary.—*Boston Medical and Surgical Journal*, Aug. 26, 1886.

BROMIDE OF ARSENIC IN DIABETES.—MOOCK (*France Mid.*, Feb. 25, 1886); reports the case of a woman æt. 54 years, who had probably had diabetes about four years, and who also had phthisis in the stage of cavity. She was much troubled with valvæ pruritus. Small doses of bromide of arsenic were given, together with iodoform, and in two weeks the pruritus had entirely disappeared and the chest symptoms were much ameliorated. At first she was given gluten-bread, but afterward was allowed ordinary bread toasted. The improvement continued for two months, at the end of which the sugar passed had been reduced to not much more than one-twentieth of the original quantity, and the chest symptoms were quite checked, although a cavity, of course, remained. DR. N. S. DAVIS, JR. (*THE JOURNAL*, May 8, 1886) has reported excellent results with bromide of arsenic in conjunction with a strict anti-diabetic diet.—*New York Medical Journal*, September 18, 1886.

INTRAPERITONEAL INJECTIONS IN ACUTE HÆMORRHAGE.—RÜTGERS records the case of a woman who, as a result of post-partum hæmorrhage, was in a state of profound collapse, and whose veins, after ligature, did not swell, so that no indication for the site of an intravenous injection was obtainable.

A solution of sodium chloride 90 grains, sodium hydrate 5 grains, and distilled water 34 fluid-ounces, was accordingly introduced into the abdominal cavity by means of a trocar. After three days, during which abdominal pain and subnormal temperature obtained, the general condition was excellent.

It is evident, from this experience, that the absence of swelling in veins after ligature is no sure sign of actual death, and it is suggested that the method described may replace that of hypodermatic injection of water in Asiatic cholera.—*Centralb. f. d. med. Wiss.*, Aug. 7, 1886.—*Medical News*, Sept. 18, 1886.

VIBURNUM PRUNIFOLIUM AS A PREVENTIVE OF ABORTION.—CHÉRON (*Gaz. de Gynécologie*, July, 1886) recommends the following:

Tincture of viburnum prunifolium.....	40 minims.
Elixir of garus, ¹	} each..... 1 ounce.
Simple syrup,	
Distilled water.....	2 ounces.

A tablespoonful every hour, or half hour, as required.—*N. Y. Med. Jour.*, Aug. 7, 1886.

ARTIFICIAL COCAINE.—MERCK, of Darmstadt, has succeeded in preparing an artificial cocaine which possesses all the properties of the natural product. Benzoic ecgonine is treated with methyl iodide and a certain quantity of methyl-alcohol at 100° C. Benzoic methyl-ecgonine is thus obtained, and this substance is cocaine.—*Phila. Med. Times*, Sept. 4, 1886.

¹ Consisting of the compound tincture of saffron and an aromatic. The former contains aloes, saffron, cinnamon, cloves, and nutmeg.

BRITISH MEDICAL ASSOCIATION—ANNUAL
MEETING IN BRIGHTON.

The recent annual meeting of the British Medical Association at Brighton, Eng., was regarded by those present as one of the largest and most interesting that had been held in many years. Brighton is not only one of the most attractive cities at all times, but is especially so in the summer on account of its admirable location fronting the open sea. It is fortunate, too, in having possession of the Royal Pavilion and its appendages, which were built and occupied as the royal residence by King George IV; in the richly decorated rooms of which all the meetings of the Association and its Sections were accommodated. The general arrangements or programme for the strictly scientific and professional work differed but little from that of the American Medical Association. From two to three hours of each day were occupied in the general meetings of the Association, and three hours of each of the second, third, and fourth days in the several Sections. A part of the first day was occupied by separate meetings of the Council for business purposes, leaving no time for the Sections to meet until the afternoon of the second day. A general programme was given to each member at the registration table, and the subsequent details of work for each day were posted on the bulletin boards in the morning. The general meetings on the first, second and third days were very well attended, but those of the fourth day attracted comparatively few. Even the interesting and important address on Public Medicine by Dr. Mapother, which was given at 10 o'clock A.M., was listened to by not more than 100 members; and the closing proceedings at 4 P.M.

commanded the attention of only about 150. The Sections of Medicine and Surgery attracted the largest attendance; those of Public Medicine and Obstetrics next; while the remaining Sections of Psychology, Pathology, Therapeutics, Ophthalmology and Otology were attended by only small audiences. The President of each Section delivered an address, not to the general body, but to the members of the Section over whom he presided, which evidently served to increase the number in attendance and to promote the interests of the Sections. The number of papers actually read in the several Sections was not large, but as a rule, bore marks of having been carefully prepared by their authors, and in some instances elicited discussions of much interest, while others were passed without comment. In all the particulars to which we have thus far alluded, the doings of the British Association both in the general sessions and in the Sections bore a close parallel to those of our own National Organization. In another respect the parallel also holds good, and that is, in the difficulty of hearing with any satisfaction either the reading of papers or the discussions regarding them, unless in immediate proximity to the reader or speaker. Very few of those who took an active part either in the general sessions or in the Sections were heard satisfactorily over the half of even a moderate-sized audience. And it is this, more than all other things together, that renders the audiences, especially in the Section rooms, uneasy on account of the frequent coming in and going out of individual members. The fault is seldom in the acoustic qualities of the room as is too frequently alleged, but in the reader or speaker himself. The truth is, there are comparatively few members of the medical profession who stand erect with free expansion of the chest, and read or speak with that clearness of voice and distinctness of enunciation which is necessary to make themselves heard with pleasure in every part of a fair-sized audience room.

The business management of the British Medical Association is entirely in the hands of the Council, composed at present of about seventy members, a part of whom are elected by the several Branches. This Council selects the places for annual meetings, nominates the officers, arranges the programmes, considers and reports on all matters of business or medical polity, and in submitting reports to the general body, selects the members to move their adoption and others to second the motion, and when these have made their speeches in advocacy of the measure, the time for anything in opposition is generally limited and placed at a disadvantage. Our readers

will remember that prior to the meeting of the American Medical Association in St. Louis last May, considerable discussion was carried on in the pages of this journal on the feasibility of adopting changes designed to approximate the business organization of that body more closely to that of the British Association; and at the St. Louis meeting a committee was appointed to consider and report on the subject at the next annual meeting. One of the prominent objects we had in view while attending the recent meeting of the British Medical Association at Brighton was to study its practical working, with especial reference to examples for imitation in improving our own National organization, and we shall soon devote a few editorial pages to that subject. We will only add here, that the social arrangements and opportunities at Brighton were brilliant in quality and prodigal in amount. At the opening on the first day the members of the Council were tendered an elegant reception and sumptuous lunch by the Mayor of Brighton; on the second evening the whole Association was tendered a brilliant *soirée* by the profession and corporation of Sussex, which includes Brighton; on the evening of the third day was the Annual Banquet in the Rotunda, attended by three hundred and sixty members and a large number of invited guests; in the early part of Wednesday evening the Association of Irish graduates and schools gave an elegant entertainment; and on Friday morning the British Temperance League gave to members of the Association a temperance breakfast, which was not less elegant and interesting than any of the entertainments that had preceded it. In addition to all the foregoing, invitations to small companies for lunches and dinners at the residences of members of the profession in Brighton, were numerous and cordial. The number of visitors from other countries in attendance was large, especially from this country and the British Provinces on our northern border, and all were treated with marked courtesy and kindness. On the afternoon of the third day, in a very full general meeting, the American visitors were kindly invited to present the subject of the International Medical Congress for 1887, which invitation was accepted. The explanations made, ending with a renewed cordial invitation to attend the Congress, were received with approval, and resolutions of thanks and acceptance were passed with genuine enthusiasm.

THE ANTAGONISM OF MALARIA AND SCIENCE.

Certain portions of the very interesting Address of DR. BILLINGS before the British Medical Association seem to have produced a chill of astonishment, fol-

lowed by a stage of true febrile excitement and other unpleasant phenomena attendant upon malarial attacks, in some of our malarially situated contemporaries. The *causa rigoris* was Dr. Billings's showing that in some parts of the South, and especially in the Mississippi Valley, malaria is very much more prevalent than in the Northern and North-eastern portions of the country, and then asserting that "malaria and science are antagonistic." "It was within the limits of this malarial shadow that the foundation of modern gynæcology was laid by Marion Sims, of abdominal surgery by McDowell, Battey and Gross, of an important part of the physiology of the nervous system by Campbell. Nevertheless, the rule holds good that malaria and science are antagonistic; the exceptions prove the rule."

Before discussing the weighty question as to this antagonism, it may be well to say that exceptions do not *prove* rules; an exception shows that a rule exists, but it cannot show the truth of a rule. For if one exception can prove the truth of a rule, two prove it more fully; and we are reduced to the absurdity of saying that the more exceptions there are to a rule the more hard and fast, and the more universal the rule. Such logic as this gets us into deep water at once.

The Address is illustrated by four maps showing the distribution of deaths from malaria, cancer, consumption and pneumonia, as compared with deaths from known causes in the United States (Census of 1880). Remembering that "malaria and science are antagonistic," the malarial map shows very clearly that the scientific strata in this country were very irregularly distributed six years ago, though the next census may show that recent "terrestrial upheavals" have shifted them somewhat. For example, according to the map the greater part of the science of the country in 1880 was not only west of the Alleghanies, but west of the Mississippi River. The only two States or Territories which were wholly scientific at that time are Utah and Nevada. There is a small scientific strip along the coast of California, sharply bounded on the East by the Central Pacific Railway, and higher up we find a surprisingly large piece occupying the western third of Washington Territory. Then there is an equally rich vein of science running down through Nebraska, Colorado and New Mexico—much better than can be found anywhere on the Atlantic coast. The map shows that very large portions of Dakota, Minnesota and Wisconsin are very much more scientific than the eastern half of Massachusetts, New York and Pennsylvania. Down among the mountains of east Tennessee, too, are large de-

posits of science, as also along the Western coast of Lake Michigan. In short, the map shows most conclusively that there is more science in Utah, New Mexico and Nevada than in all the Eastern portion of the United States north of the Potomac River. Arizona, Idaho, Montana and the Southern part of Illinois are shown to have as much science to the acre as littoral Massachusetts, Connecticut, New York or Pennsylvania. And as malaria seems to be on the increase in the North-eastern portion of the country there is some ground to fear that it will not be long before all the surviving science will flee in terror in the direction of the setting sun, leaving that portion of the country enveloped in a dense fog of malarial ignorance.

The first two maps show, what is not mentioned in the Address, that malaria is antagonistic to cancer; and from this we may draw a very logical conclusion: Malaria and science are antagonistic; malaria and cancer are antagonistic; *ergo*, cancer and science are synergistic, or co-adjuvant; and the more one thinks of it the more will he be convinced that this is what the talented reader of the Address intended to say. For in this case the cancer map would show that as there is more cancer so there must be more science east of the Alleghenies; and our esteemed confrères of the Mississippi Valley would probably have not been so much offended; especially as the Northern part of Louisiana has a very aristocratic death-rate from cancer. The map shows that in some parts of the country the malarial microbe devours the cancer cell with avidity—a true “Battle of Cells and Bacteria” (see *Virchow's Archiv*, Bd. CI, Hft. 1; *THE JOURNAL*, August 22, 1885). Reasoning on these lines, and looking at the Utah portion of the malarial map, one might be inclined to formulate some such law as “Malaria and polygamy are antagonistic;” for there is a great deal of polygamy in Utah, but very little malaria; and while there is much malaria in the Mississippi Valley there is no polygamy; and this is further borne out by the fact that while the Sultan of Turkey has many wives he is not subject to malaria. Now then, if malaria and science are antagonistic, malaria and polygamy antagonistic, malaria and cancer antagonistic, and cancer and science synergistic, does it not follow that polygamy and science are synergistic? Have we not here a key to the great problem of what to do with the Mormons? Let the Government send half a dozen bacterio-therapists to Utah, each armed with cultivations of the bacillus malarie.

But are malaria and science antagonistic? It is difficult to say how the question is to be settled.

From those who have not been “incidents of a miasmatic cataclysm” there may be a possible affirmative answer to the question; but can we think that they who have had chills and are liable to have others will send any other reply than a unanimous negative? Furthermore, the announcement that the malarial microbes may attack and devour the germs of science is a serious thing for the already scientific man; a matter of tremendous import. What geologist from the unmalarial districts of the North will venture to go and study the effects of the recent earthquake with the possibility staring him in the face of a horde of malarial bacilli attacking his geological germs, like a devastating army of Metschnikoff's phagocytes. And would not his local geological society be justified in expelling him from its ranks, or quarantining him on his return until a quinine war had been waged on the *bacilli malarie* which might be concealed about his person? This is a serious matter. Imagine the consequence of a member of the American Association for the Advancement of Science actually having a chill at one of the meetings! Or could there be a more dire disaster than such an occurrence in the Concord School of Philosophy? Nevertheless, we find scientific men going boldly to work to hunt up that malarial microbe, and some of our German and Italian confrères claim to have captured it. Can we believe they know their danger, or is it an example of the utter disregard of consequences which sometimes takes possession of scientific men? Men will often fearlessly run risks which may involve loss of life; but it is seldom that they will take the chances of being de-scientified.

Yet, if science and malaria are antagonistic there is still a gleam of hope—one way out of the difficulty; and but one. We regard it as fortunate in medicine when we find something antagonistic to something else which is dangerous; and if malaria be antagonistic to cancer, polygamy and science, the converse must be true. Here then we have a prophylactic indication; instead of planting eucalyptus trees, which must take some years to grow, instead of draining swampy lands, which requires a vast amount of money, let us transplant full-grown cancer patients, polygamists, and scientists to our malarial districts, in such numbers that the malarial microbes must inevitably be overcome and driven from the country. Let a great cry go up from the Mississippi Valley and other malarial districts for an influx of cancer patients from the North and North-east, and scientists from Idaho, Utah and Nevada. And if the remedies prove potent against the evil then we will see that science and malaria are really antagonistic; we will see how

great results may spring from incidental suggestions made in a foreign country; and we will also see

"How *Index*-learning turns no student pale,
Yet holds the eel of science by the tail."

DEATH OF DR. JAMES WAKLEY.

Medical men will sincerely regret the death of the editor of the *London Lancet*, which occurred on Monday, August 30, after a long and painful illness, from epithelioma of the mouth. For twenty-five years he has been known over the civilized world as the great editor of a great medical journal, as the upholder of medical right and the powerful foe of professional wrong-doing—and in all that time, with all his work, and latterly with all his sufferings, he was the friend of poor humanity. He was essentially a journalist, and the type of the great professional editor. The mantle of a great editor (his father) fell upon him, and he showed that he could wear it. Under his management *The Lancet* has grown until now it stands with only one equal. He was, if any man ever was, the friend of the young physician; quick to mark indications of worth, and to open a way for its development. The English public have reason to mourn his death, for he was ever the watchful guardian of public health, and especially of the health of the poor.

MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA.—A letter in the *New York Medical Journal* from DR. F. PEYRE PORCHER, of Charleston, S. C., states that the Medical College building has been so nearly destroyed by the recent earthquake, that an entire new roof will be required and at least the partial rebuilding of the walls, before it can be occupied again for teaching purposes. As the medical men of Charleston have suffered in common with other citizens, severe injuries to their own property, they need prompt assistance from their professional brethren, more especially to aid in restoring the Medical College to its former usefulness. We trust there are some members of the profession in this City who would cheerfully contribute something for this purpose. If so, we will unite with them in sending a remittance directly to the care of Dr. Porcher. "It is more blessed to give than to receive."

THE ILLINOIS COLLEGE OF PHARMACY.—This College will begin its courses of instruction on the first day of October. The instruction rooms, corner Lake and Dearborn streets, are furnished in the most substantial and complete manner. Four laboratories

have been provided, for analytical, synthetical, microscopical and pharmaceutical work. The capacity of these laboratories enables 150 students to receive instruction simultaneously, and there are individual accommodations for four such classes, or 600 students. The special laboratory for instruction in dispensing work is an important department introduced by this College.

SOCIETY PROCEEDINGS.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY
AND HYGIENE.

Stated Meeting, June 8, 1886.

DR. F. I. KNIGHT, CHAIRMAN.

ALBERT N. BLODGETT, M.D., SECRETARY.

The records of the meeting (on April 14, see *THE JOURNAL*, May 29, p. 600,) at which the subject of Military Drill was first discussed, were read and approved.

PROF. D. A. SARGENT read a paper on

THE EFFECTS OF MILITARY DRILL ON BOYS.

He called attention to the fact that the primary object of establishing the drill in our schools and colleges was a professional one—to give instruction in military tactics to young men, in order that they might be of service to the country or community in case of an emergency. The war not only gave an incentive to the practice of military drill, but it also furnished a great stimulus to all forms of physical exercise, and especially to athletic contests and games. Within the past few years, physical training has received a new impetus. A large number of school, college, and city gymnasias have been built, and athletic games have obtained a strong hold upon public attention. As the occasion which gave rise to a call to arms grows more remote, the real object of the drill loses its significance, and the advocates for its maintenance in the schools now claim for it superior advantages as a physical exercise. In the City of Boston, the committees to whom the subject of military drill in schools has been referred have placed considerable stress upon this point. In 1883 the committee reported as follows: "Your committee believe that the drill, as now carried on, proves to be not only the *best* for physical exercise for these schools, but that, at the same time, it inculcates a more manly spirit in the boys, invigorates their intellects, and makes them more graceful and gentlemanly in their bearing." In the report for 1874 there is a similar statement. In 1875 the committee state: "We trust that the drills will be kept up, believing that committees having them in charge will see that no form of gymnastics could be substituted from which the boys would derive such benefit." In 1880 the committee say: "The establishment of the military

drill is one of the few provisions made by the School Board for the physical training of the pupils under its charge, and no one who has observed the soldierly bearing of the members of our school battalions can have any doubt of its value as a means of securing a full and symmetrical development of the physique."

Notwithstanding the fact that half of the members of these committees were physicians, I shall beg to differ with them absolutely as to their conclusions concerning the physical effect of the military drill upon boys. In order that we may approach the discussion of this subject more intelligently, let us inquire briefly into the physiology of exercise, and consider some of the facts which observation and experience have determined. Exercise in its simplest sense may be defined as muscular movement produced by muscular contraction. According to the physiologists, "the property of contractility is inherent in the muscular substance, but in normal life the manifestation of this property is immediately determined through the influence of the nervous system. . . .

"A nervous impulse originating at the brain or spinal column travels along the nerves to their terminal expansions in the muscular fibres; on its arrival at the muscular fibre, the nervous impulse is converted into a muscle-impulse. . . . Between the reception of the nervous impulse and the initiation of the visible contractile movement an interval elapses, known as the 'latent period,' which (according to Helmholtz) is probably occupied by molecular changes in the fibre preparatory to its alteration in form. At the close of the latent period the muscle-impulse is succeeded by a wave of contraction. . . . The contraction of the individual fibres produces changes in form of the entire muscle, shortening the distance between its two extremities by increasing its thickness, and slightly reducing its bulk.

"In the voluntary muscles (according to Weber), each contraction is compound in character, being composed of a series of rapid contractions, due to an equally rapid succession of nerve-impulses."

During muscular contractions certain chemical changes take place in the muscle substance, although the exact nature of the metamorphosis is not known. It is known, however, that the blood escaping from muscles in action is much darker than the venous blood of muscles in repose, and that it contains a much greater proportion of carbonic acid. It is also known that a greater amount of oxygen is absorbed by the muscle during the period of contraction, and Gaskell's experiments have demonstrated that the flow of blood through muscle is increased at the time of its shortening. Thus we see that the simplest muscular movements involve a molecular change at the nerve-centre in which the movement originates, in the nerve-fibre that transmits the impulse in the muscle-fibres that contract, and in the blood-vessels that dilate in response to the stimulation. The experimental researches in the physiological laboratory on a single muscle have given us an epitome of what should take place throughout the system at large, in order to realize the best results from exercise.

The consecutive action and harmonious relation

of the nervous, muscular, and vascular systems must accompany every effort to improve the physique and render the individual energetic, healthy and strong. How to attain this three-fold result is the problem that the instructor of physical training has before him.

To select at once a system of exercise that will do no harm to anyone, and yet be beneficial to all, is a difficult task, yet we shall come nearer doing the greatest good to the greatest number if we follow what may be termed the physiological method. As near as I have been able to ascertain them, the essential requisites of a good exercise may be summed up in the following suggestions:

1. The person should be sufficiently interested in the exercise to give it his attention in order to secure the necessary volitional power to start the movement. Any exercise executed in a lifeless way is of little benefit to nerve or muscle in a healthy condition.

2. There should be a weight or resistance to overcome in order to bring out the working force of the muscle, the theory being that the muscles were not created merely to move the parts to which they are attached, but to do service and help man bear his burdens. In using a weight, the muscle gradually acquires the force with which it tries to contract.

3. The exercise must be performed with sufficient vigor and rapidity to engage the energetic contraction of the muscles employed. When this is done, old tissue is broken down, and its place is supplied with new material in increased quantity, thus augmenting the size and strength of the muscles. The rapidity of the movement puts a limit to the weight used, and the alternate contraction and relaxation of the muscles assists the circulation of the blood in the parts employed.

4. As many muscles as possible must be brought into action in order to secure a full-orbed and harmonious development of the whole body. One-sided development is usually attained by robbing some other part of its just share of the body's nutriment. It is apt to be accompanied by a functional disturbance of one or more of the vital organs, by inducing malformations of the thorax, or it is likely to lead to the straining of parts that are weak, by gauging their strength by parts that are strong.

5. A sufficient number of muscles should be called into action at one time to stimulate the action of the heart and lungs, and increase the circulation and respiration. This is one of the most important considerations to bear in mind in regard to exercise. The more muscles a person can use at one time, and the more rapid and extensive the movement, the greater the muscular consumption of oxygen and elimination of carbonic acid. In order to sustain this activity in the muscles, a greater amount of oxygen must be taken in, and a greater amount of carbon-di-oxide must be given off from the system. This is accomplished through the respiration. "If a man walks one mile an hour, he breathes twice as much air as when he lies down; if he walks four miles an hour, he breathes four times as much, if six miles an hour, seven times as much." He takes out of this inspired air an increased ratio of oxygen, and eliminates nearly the same proportion of carbonic di-oxide during expira-

tion. To keep up this increased respiratory activity and aid the heart in removing the waste material and hastening forward the new, the limbs and walls of the chest must be absolutely free from any ligatures or constructions. The slightest interference with the action of the respiratory muscles at this time embarrasses the functions of the lungs and heart. The chief advantage of exercises that give employment to many muscles at one time is that by increasing the respiration and quickening the circulation, they improve the health and strength of all parts of the body.

6. As a "latent period" precedes the contraction of a muscle, so a momentary period of rest should, as far as possible, precede movement in exercise. This is best secured where there is an alternation in the movements, as in walking, running, rowing, etc. All tetanized movements, such as holding weights, standing in a constricted position, etc., tend to impair the tone of the muscles by interfering with the nutrition of both muscles and nerves.

7. Observation. The exercises of the young should be of such a composite nature as to bring about the co-operation and co-ordination of the muscles. This involves principally the training of the central nerve system. All gymnastic sports and athletic games that require skill, dexterity, coolness, courage and presence of mind, are included in this list, and are exceedingly valuable to any system of physical training, as adjuncts in the development of character.

My principal objection to military drill as a physical exercise, is that it does not to any extent meet the physiological demands of the body as set forth in the seven observations just referred to. In other words, it is not of sufficient interest as a means of physical development to arouse any moral earnestness and enthusiasm on the part of the boys. The exercise of the manual is not performed with sufficient force and rapidity to engage the energetic contraction of the muscles employed. It is essentially a one-sided exercise, bringing into excessive action the elevators of the right scapula, the deltoid, biceps, flexors of the forearm, wrist and fingers of the right side, while the other muscles, excepting the legs on parade days, do not get sufficient employment to keep them in good condition. It does not increase the respiration and quicken the circulation to a sufficient extent to secure the constitutional benefits that should accrue from exercise.

During the drill the clothing is buttoned close around the chest, and natural respiration is hindered. The muscles are not alternately contracted and relaxed, but are tetanized or kept in a state of prolonged tension. This, as we have seen, not only impairs the tone of the muscles used, but it also puts an additional strain upon the brain and nervous system at a time when both should be as much relieved as possible. Finally, the mere exercise of the manual of arms does not give sufficient breadth and scope of movement to secure the co-operation of the muscles, and as a training for the central nerve system, it is of little or no value.

Coolness, courage, presence of mind, and that rapid and responsible exercise of judgment in emerg-

encies, so valuable to the man of business, as well as to the soldier, are not developed by the drill itself, though I will admit that other moral attributes, such as obedience, patience, fortitude, and forbearance, may be brought to a high degree of perfection. The community at large, have long entertained the idea that there was something about military drill that made young men erect, or, as the committee have been pleased to term it, giving them a graceful and manly bearing.

I dislike to take from the drill one of the strongest attributes that has commended it to parents and teachers, but unless I have been misled in my observations, there is nothing in the drill itself that tends to make one erect or graceful. On the other hand, I am prepared to maintain that it tends to make him stiff and angular in his movements, as well as to droop and round his shoulders.

As no two minds are alike, so no two bodies are alike. But growing out of this great diversity of shapes and sizes, there is a figure around which nature tends to range those of a certain age, height, or weight (according as either is taken for the standard). This is termed the mean or typical boy for a given age, height, etc. Any marked divergence from this standard is readily detected by a casual observer. My attention was long since called to what I think may be termed the prevailing weakness or defects in the school boy's and student's physique. There are a drooping of the head, flatness of the chest, narrowness of the waist, and an exaggeration of the normal or physiological curves of the spine, and I might add to this number, though it is not quite so common in boys as in girls, lateral curvature of the spine. These defects, I say, are so apparent, that it does not take a practised eye to detect them. They attract the attention at once of any one who cares to examine the figures.

The drooping of the head and flatness of the chest may be accounted for by the increased prevalence of myopia, tightness of clothing, and the pressure of the school desk or table on the lower ribs and sternum. The hollowness in the back is partly due to the fact that it is a compensating curve, but more probably attributable to the weakness of the trapezii, rhomboidii, serrati and latissimus dorsi muscles. The smallness of the waist is undoubtedly largely due to inheritance, and to the fact that the youth of the present day make very little use of the muscles of the waist and loins. Lateral curvature of the spine may be caused in many ways; by defective seats, bad positions in writing and drawing, standing for a long time on one leg, carrying weights, or using one arm more than another, etc.

Personally, I do not put particular stress upon these malformations, if they can be discovered in time. Nearly all of them can be corrected by judicious exercise. If allowed to increase, however, they invariably lead to spinal disease, or to some functional disturbance of the heart, stomach, or lungs, followed sooner or later by structural changes in these important organs.

Whatever the original cause of these physical defects may be, the immediate cause is a weakness of

the supporting muscles. After the body has once acquired a bias in the wrong direction many exercises otherwise beneficial are likely to be injurious. Among this number are horseback riding, rowing, lawn tennis and military drill. In order that you may see how the last named exercise can prove injurious to imperfectly developed boys I wish to call your attention to the elastic nature of muscular tissue. In order to be as brief as possible, I shall simply quote extracts from the experimental researches described by Rosenthal on this subject, in his admirable treatise on "Muscles and Nerves."

"A muscle dissected from the body is easily extended by a weight, and is extended in proportion as the weight attached is heavier." "The law of elasticity for inorganic bodies is: The tension is directly proportionate to the length of the body extended and to the amount of the extending weights; and that it is also proportionate in inverse ratio to the diameter of the extended body."

It has been found, however, that soft organic bodies, like muscles, are capable of far greater extension than are rigid, inorganic bodies, of equal length and diameter and under the application of equal weight. But the organic body also exhibits another peculiarity. If a weight is attached to a steel wire or some other similar body, the latter extends and retains its new length so long as the weight acts upon it; but as soon as the weight is removed the steel resumes its original length. It is not so in the case of inorganic bodies. When the weight is removed from an organic body it immediately becomes shorter, but does not entirely revert to its original length, it attains the latter very gradually and in the course of many hours. This phenomenon is known as the gradual extension of organic bodies. Muscle, in common with all soft bodies, exhibits another variation from the bearing of rigid bodies. That is, muscles are comparatively more extensible by light than by heavy weights. For instance, if the extension of a muscle when carrying ten grammes is five millimetres, when carrying a weight of twenty grammes it is not ten millimetres but only eight; when carrying thirty grammes it is only ten millimetres, and so on.

Another striking fact in connection with the physiology of the muscles has been brought out by the experiments of Weber. He has proven conclusively that muscle is further extended by the same weight when it is in a state of activity than when it is quiescent. Here again, we have the experiments of the physiological laboratory confirming the facts that have been brought under frequent observation in the gymnasium. We can now readily understand, how carrying the head forward would soon extend the muscles of the neck, how carrying a gun, though a light one, with the same arm for any length of time would gradually extend the muscles, and elongate the arm, droop the shoulder and crook the spine. This is, in fact, what military drill tends to do in all cases, and what it invariably does do when there is a bias in that direction, when the boy is tall and slender, or the muscles weak and flabby, and there is no effort made to correct the evil tendency.

If it is deemed advisable to make military drill a

department of school instruction, I see no reason why a system of corrective exercises cannot be introduced as an accompaniment. If, on the other hand, military discipline alone is required, this can easily be applied to a system of class gymnastics or free exercises, as shown in the schools of Germany. After taking the most favorable view possible of military drill as a physical exercise we are led to conclude that its constrained positions, and closely localized movements do not afford the essential requisites for developing the muscles, and improving the respiration and circulation, and thereby improving the general health and condition of the system. We must further conclude that in case of any malformation, local weakness or constitutional debility, the drill tends, by its strain upon the nerves and prolonged tension on the muscles to increase the defects rather than to relieve them.

Finally, if the ultimate object of the drill was to prepare young men for the life and duties of a soldier, we should be forced to conclude that the drill itself would still be defective as a means of developing the chief requisites for men in that profession. This defect, we are pleased to state, is recognized by the great military nations of Europe and measures are taken to give all the recruits from three to twelve months' gymnastic training to develop them as *men* before they are expected to conform to the requirements of the soldier.

PROF. HITCHCOCK, of Amherst College, was introduced, and said that he had but few remarks to add to what had been said. The subject of physical training is a broad one, and concerns all the pupils in all our schools. It is not the introduction of all forms of training that is needed, but of chosen and carefully adapted forms of exercise for the conditions arising in the individuals before us. A library has been said to be not a collection of books, but a selection of books; and so the features of physical training may be very different in relation to the special requirements of each person.

The average college boy is a rather hard animal to drive, and is apt to kick over the traces. He must be catered to in the laying out of irksome duties, so as to get as much pleasure with the labor as possible. Military drill is objectionable on account of the character of the exercise, and on account of the discipline. If we desire to make a mere automaton of a boy, to deprive him of his thinking faculties, to make him dependent on orders and directions of others, then military drill is a good thing. Is this system the right one? I think not. Every boy is examined in all the branches of his curriculum, and his progress is in accordance to carefully prescribed directions. The same should be true in relation to physical training as is true in relation to mental or moral training. Boys should not be turned into gymnasium as calves are turned into a pasture, but should be carefully overlooked and guided, in order that the very means for their physical benefit may not become an agent of harm, or positive danger.

GEN. HOBART MOORE, Instructor in Military Drill in the public schools of Boston, said that he had been much interested in the exhibition of the drill, and

not less amused. He would not be surprised to find curvature of the spine, or any other deformity resulting from the exercise of the drill as this was done before the audience. In actual practice, however, the evils represented and charged to the drill, are not observed. The statement has been made that the drill is confined to one side of the body. This is not so. The drill is made to embrace movements in exercise of both sides of the body, and the result of its employment is not a symmetrical development of the body of the boy. In addition to this, the actual practice of the drill is preceded by exercise in the "setting-up drill," so that every possible source of defective or restricted exercise is removed.

Gen. Moore stated that he has pupils in Harvard and in other schools, and is constantly receiving most encouraging reports from them as to the influence of the drill-movements, and their relation to the bodily health and well-being of the pupils. In all the schools where the drill has been introduced, the boys are anxious to join, and often it is necessary to refuse permission to ambitious youths on account either of the small size of the applicants, or on account of their years. The parents of boys often come to the school to beg permission for their boys to join in the drill. An experience of twenty-five years in the practical teaching of the drill has convinced him that it is not only not harmful, but it is of positive advantage both in relation to the physical development of the boy's constitution, and also in relation to the training of the mental and moral nature. If this were not so, the drill would long ago have been discarded from the curriculum of our public schools. The striking rarity of accidents in the exercises of the drill is another feature to recommend it. In relation to the boys who are excused from drill, the fact is that more boys are exempted from drill on account of the effects produced by the abuse of gymnastics, than from all other causes put together. The boys themselves always want to drill. Objection to the drill does not come from those interested in it, the boys themselves, but from those who have no actual information on the subject, who are striving to upset an institution which the experience of years has found to be productive of great good, and to be free from serious harm.

DR. J. P. REYNOLDS said that he was at one time in Frankfort, and had observed the enthusiasm with which physical culture is there carried out. It is strange that in a city one-fifth the size of Boston, so much can be done and is done, and in our own city we have nothing. The experience of seventy years in Prussia should teach us something. We have retreated a long way toward barbarism, by our apathy in regard to the physical welfare of our children, and by neglecting them we lay the foundation for lives of feebleness and incapacity. Nobody who has observed the people of Germany can have failed to notice how much stronger and robust the population as a rule is in that country, than is the fact here. We are, as a nation, becoming effeminate and weak. The lessons of other countries are without influence upon our dulled faculties, and we have to look forward to an increased deterioration in the stock of

health and vitality as the logical result of our stupidity. In Germany, even the son of the Emperor was not spared the entire *regime* of the course for physical training laid down for the preparation of recruits for the regular army. Every man must perform this duty to his physical system before he is considered capable of attempting the discharge of his duties towards his country.

DR. D. F. LINCOLN said that one important point had not been touched upon in the course of the present argument, and that is the fact that the girls need careful physical training as much as the boys, and that they have even less opportunity for exercise than have their more fortunate brothers. The people are not doing their whole duty by their children until they have given them the advantages of physical culture commensurate with their mental development.

DR. C. F. WITHINGTON, in closing the debate, spoke of the lateness of the hour, and said that he would not prolong the discussion, although there was much to be said. He observed that the exercises of this meeting had demonstrated that the simplest of apparatus could be made serviceable for a very comprehensive system of physical culture, and vastly improve upon the form of exercises now in vogue. There could be no question that the drill leaves much to be desired as a means of physical development, which could be supplied by the simpler and less expensive form of exercises connected with the courses of physical culture as shown at this meeting. When our school authorities have attended to the first requirements for physical culture of the whole body of pupils, male and female, then if there is any time or any money to spare let them think of supplementing the function of the State in the maintenance of a militia.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, September 2, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

INTUBATION OF THE LARYNX.

DR. E. E. MONTGOMERY exhibited a set of Dr. O'Dwyer's tubes, the gag, and the instruments for the insertion and removal of the tubes. He related the history of a case of laryngeal diphtheria in which they were successfully used to relieve asphyxia. In consequence of an over-dose of stimulant the tube was coughed out and had to be replaced, as the child could not have breathed without it. The doctor contrasted the difficulties of tracheotomy with the comparative ease of introduction of the tubes; and called attention to the want of success attending the former operation, as parents will not give an early consent to its performance. He had performed eleven tracheotomies before he had a single successful case, and as his first intubation case has been a success, he is strongly in favor of the new operation.

DR. M. PRICE reported a case of

REMOVAL OF THE OVARIES FOR UTERINE FIBROID.

The case is one of interstitial uterine fibroid; the

uterus being about the size of one at the third month of pregnancy, irregular in outline and nodular, and pelvic-bound. The ovaries were displaced backwards and incarcerated between the uterus and sacrum, making it difficult to remove them. The woman had been suffering four years, and a confirmed invalid during the the last one, unable to do any work. Her marital relations had been suspended for over a year, owing to the sickening pain attending any attempt at sexual intercourse. She had to walk with great care and lie on her stomach while resting or sleeping to prevent a throbbing and sickening pain in the pelvis. A rather exceptional and interesting feature of the case was the absence of profuse and irregular bleeding. Her menses were irregular, scant and pale. Her chief suffering was from engorgement of and pressure upon the ovaries. All kinds of treatment had been, persevered in for the last three years, and the patient grew worse. She demanded operative procedure for her relief, preferring the risk of death to her suffering. The ovaries were removed July 9, 1886. They were hypertrophied. They were found low down behind the uterus. They contained numerous pus pockets. The tubes were enlarged but did not contain pus. With the exception of a suture abscess she did perfectly well, and made a perfect recovery. She is now able to look after her domestic affairs and is free from pelvic pain and soreness. No examination of the condition of the uterus has been made since the operation.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

The Children of the Poor—Laparotomy for Gunshot Wound of Intestines—A New Infirmary for Children—New Jersey State Board of Health and Vital Statistics—Precautions Against Live-burial—False Death Certificates—Resignation of Dr. E. M. Moore.

During the past summer the city has done less than usual for the children of the poor, and consequently more work than ordinary has been thrown upon the private charities which interest themselves in the little ones. For the first time in a number of years the authorities failed to make the appropriation for the maintenance of a special summer corps of visiting physicians among the tenement-house population. This service has always been attended with very good results; one of its chief merits, perhaps, being the fact that incipient cases of diarrhoeal disease are frequently detected in children whose parents might otherwise have unthinkingly allowed the trouble to go on until it would have been too late for medical aid to be of any service. In consequence of this neglect of the authorities, the Children's Aid Society, which has always maintained a corps of visiting physicians, has had to materially increase the number of these this season. The work of the Children's Aid Society's physicians, however, differed

from that of those employed by the city in the fact that while the former only visit the tenement houses when summoned to see special cases of sickness among the children, the summer corps of the Health Department are required to visit the tenement districts systematically, and specially look up all cases of illness, prescribing for every sick child that they meet which is not already under medical treatment. The summer, however, has been a comparatively cool one, and as the death-rate among young children is always in a direct ratio to the heat when the latter is at all extreme, the infant mortality has not been as large as would otherwise have been the fact. Probably the largest number of deaths in the city occurred in the hot weather in the early part of July, when in one week there were reported 1111, of which no less than 683 occurred in children under five years of age.

The St. John's Guild has also been unusually active in its work, and has done a vast amount of good through its seaside nursery and the excursions of its floating hospital. It also has had a corps of summer physicians of its own this year, who have distributed a large number of tickets for these, and in consequence of the weather continuing warm in September, the trips of the floating hospital have been maintained later than usual. The expenses of each excursion amount to about \$250.

Quite late in the season the Charity Organization Society also bestirred itself in behalf of the sick children, and through Mr. Fairchild, Acting Secretary of the Treasury—who was formerly its President—obtained permission of the War Department to erect a sanitary tent on Bedloe's Island (where the Bartholdi statue of liberty stands) for the purpose of affording a few hours of fresh air from time to time for mothers with feeble infants.

Dr. W. T. Bull, who added so largely to his reputation by his successful laparotomy in a case of perforating gunshot wound of the abdomen, in which the intestines were pierced in several places, has now again repeated this success. The operation was performed at the Chambers Street Branch of the New York Hospital, upon a sailor who was shot with a pistol, the ball entering the abdomen two inches below and somewhat to the left of the umbilicus. On opening the cavity it was found that the small intestine was perforated in two places, and that the sigmoid flexure of the colon and the sigmoid mesocolon were also wounded. Much blood had been poured out, and the operation, which was undertaken within two hours after the receipt of the injury, lasted about an hour and a half. The recovery was rapid and satisfactory.

A new Infirmary is now in course of construction at the Five Points House of Industry, the erection of which has been rendered necessary by the passage by the Legislature, at its last session, of the law requiring the isolation of all children affected with contagious eye diseases. The corner-stone was laid a short time since with appropriate services, and in his remarks the Superintendent, Mr. Wm. Y. Barnard, spoke particularly of the bad name which the spot had always borne, not only since Dickens had por-

trayed it in his "American Notes," but even from early colonial periods. He told how, in early Dutch history, it was the scene of the murder of Indians, and how, in 1700, a number of slaves, suspected of planning an insurrection, were executed and their bodies burned there. As the city grew to be a great metropolis, many a murder had been committed within its bounds, until it was hardly safe to pass through even by day. The man who, forty years ago, had predicted a scene like this, he said, would have been deemed a lunatic. The first effort to work a reform was made in 1850, by the Rev. L. M. Pease and his wife, who were suspected, by the parents of the children they wished to aid, of planning to kidnap them, and all other sorts of evil designs. But they persevered in the good work, and out of their small beginnings grew the present noble House of Industry. The new Infirmary will be four stories in height, 25 feet wide, and 80 feet deep.

The State Board of Health of New Jersey has just issued a series of instructions to the local boards throughout the State which are of considerable importance. The State Board is determined to enforce, as far as possible, a compliance on the part of all physicians within its jurisdiction with the statutes requiring the prompt registration of births, and requests that the local boards shall use their best endeavors to secure evidence against those neglecting to do this. It also requests that a proposed system, by which a full and accurate report may be obtained of all houses; their condition and surroundings, in which contagious disease exists, or has existed, with a view to securing more positive evidence concerning the ownership, and the enforcement of appropriate sanitary improvements. The State Board urges, in addition, the appointment of a competent veterinary surgeon whose duty it shall be to visit and inspect every dairy at least twice in each year; a measure which is of special importance at the present time in consequence of the increasing prevalence of pleuropneumonia among cattle.

Some of the philanthropic citizens of Brooklyn have conceived a plan by which the fear of being buried alive, which has always seemed to haunt the minds of certain individuals, may be done away with. It is proposed to incorporate a company for the purpose of erecting edifices in the suburbs, probably in the vicinity of the large cemeteries, for the temporary reception of dead bodies. The coffins will be left open, and the bodies will be allowed to remain until evidences of decomposition have become apparent, or, to use somewhat of a Hibernicism, until they show signs of life. Means will be provided that if a person in any of the coffins should be alive and recover consciousness, he could immediately communicate with an attendant and receive the proper aid; though the exact manner in which the supposed corpse shall make known the fact of his resuscitation has not as yet been decided upon. Whether the proposed project will be practically carried out or not appears at present to be somewhat problematical; though the legal gentleman who has been engaged to secure the incorporation of the company states that within the next six months the scheme will be in working order.

It has been reported that some of the physicians in the lower part of the city have of late been induced, either from a sense of pity, for a money consideration, or the sake of currying favor, to make out false certificates of death in the case of individuals dying of phthisis who were insured in cheap life insurance companies, which reserve the right to pay only half the amount of the policy to the beneficiary in the event of the person insured dying of consumption. It is to be hoped, for the honor of the profession, that the number of such medical men is exceedingly small; though that the thing actually occurs sometimes seems evident from the fact that a reputable physician, who reported to the Bureau of Vital Statistics the fact that he was asked by an undertaker to make out such a false death certificate, is said to have remarked to a reporter who called to see him in reference to the circumstance: "I can't afford to talk about this matter unless the newspapers are willing to pay me to move out of this neighborhood."

Very great regret is felt at the resignation from the State Board of Health of Dr. E. M. Moore, which has recently been announced. Dr. Moore, who is one of the leading medical men of the State and the country, and last autumn was elected President of the New York State Medical Association, was one of the original members of the Board, and his wise counsels in its deliberations, and active labors in its behalf, will be very severely missed in the future. It is stated that, in addition to the too great tax which it imposed upon his time, one reason for his resignation was that he felt the Board to be too much hampered in its proposed plans on account of the lack of funds which he considered essential for carrying out its legitimate and proper work. P. B. P.

CURABILITY OF PHTHISIS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—During the past year several valuable articles and editorials have appeared in *THE JOURNAL* on this subject, and I desire to contribute the report of a case:

In 1852 Mr. John Tyler, of the firm of Williams & Tyler, merchant tailors of this place, consulted me for a cough which had been troubling him for nearly a year—latterly accompanied with hectic and night-sweats, and loss of flesh. Suspecting tubercle, I made a careful and very thorough physical exploration of his chest, and found incipient phthisis; a small cavity in the apex of his right lung. All the symptoms, rational and physical, warranted the diagnosis. My advice to Mr. Tyler was to give up his business at once, and go to Aiken, South Carolina, the St. Johns River, Florida, or San Antonio, Texas. His partner, being loth to give him up, persuaded him to go to Nashville and consult the late Dr. Jennings, whose age, experience, and reputation at that time placed him in the very fore-front of the profession in this State, if not in the entire South. Upon a thorough and very complete examination of his case, Dr. Jennings fully confirmed my diagnosis, and advised him to go to San Antonio, Texas, to buy him a wagon

and team, and work for a living, spending all the time possible in the open air.

He remained there eight years, and returned here a perfectly sound man, with full recovery of his average weight, and capacity for any amount of physical exertion without undue fatigue or shortness of breath. The stethoscope revealed a flat dulness, characteristic of chalky metamorphosis. Purchasing a farm in the country, he led an active life for twenty years.

In 1880, Mr. T. came into my office to be examined for membership in the Order of the Knights of Honor by my partner, Dr. B. J. Harlan, who is examining surgeon to the Order. I said nothing to Dr. Harlan about Mr. Tyler's medical history, as detailed above, but curiously awaited events. Dr. Harlan having made his usual examination, seemed not satisfied, but requested him to accompany him into an inner room, and strip himself for a more thorough and critical examination. Upon completing this he requested him to return next morning, as he was not quite ready to recommend him for membership. As soon as he left our office, Dr. Harlan explained to me that his difficulty in the case was an unaccountable opaqueness, so to speak, *in the top of his right lung*, and that if he had any history of phthisis, at any time, he would not hesitate to pronounce it a *dry cavity*.

I immediately recounted the previous history of the applicant, as imperfectly detailed above, he expressed himself perfectly satisfied, filled up his application, fully recommending him for membership. He was duly elected, and stands to-day a first-class risk of the Order. Permit me to say in conclusion, in all candor, that if this is really, as it seems to be, a case of *cured phthisis*, it is the only one that I am willing to report as such, out of a very large mixed practice of forty years. Yours very truly,

J. M. TOWLER, A.M., M.D.

Columbia, Tenn., July 16, 1886.

NEW INSTRUMENTS.

NEW IMPROVED COMBINED TROCAR AND CANULA AND ASPIRATING NEEDLE.

BY H. LANDIS GETZ, M.D.,

OF MARSHALLTOWN, IOWA.

I take pleasure in presenting and recommending to the profession a New *Improved Combined Trocar and Canula and Aspirating Needle*. The object of this instrument is to overcome the disadvantages of the common trocar and canula and common aspirating needle and yet to preserve the advantages and applicabilities of both, and at the same time combining the instruments in a neat and compact manner and at reasonable expense.

The advantages of the instrument will readily suggest themselves, and I will therefore give only a brief description and a few suggestions concerning its application.

With the instrument for general use there are four sizes of canulae—the smallest of which is a part of

the aspirating needle and is not larger in diameter than a common hypodermic needle or small, old style, aspirating needle—in which the cutting point cannot be removed after having entered the cavity. The other three sizes of canula are used, in general, as required by the varying cavities to be evacuated.

A, button which screws on trocar rod F, which is used as a handle and also prevents the trocar from passing too far through the canula. To rod F are attached the three largest sizes of trocar tips. H, one of the tips as screwed on the rod F. C, handle portion of canula to which are attached by screw-joint the larger sizes of canula and the smaller or aspirating size J. E represents the outlet from handle portion of canula. I, a short piece of glass tubing through which fluid is seen to pass. G, a reversible bulb which may be used for exhausting or injecting. B, cap attaching to C, by screw joint into which is placed a small rubber disk, cut from rubber bandage material, through which pass the exploring trocar, or the larger trocar rod. 4, one of the openings, of which there are several in the end of each canula, to allow the fluid to pass, which will aid in determining the entrance of the sac. J, exploring canula with trocar needle passed through it. This needle is of the same length as the parts J and H combined, and when J is used the needle is entered in the opening in B, passed through the small rubber disk and then passed on through C and J until the needle point projects about $\frac{1}{2}$ inch beyond the canula.

The exploring trocar being too small in calibre to admit of grooving or perforating it, is flattened upon one side in such a manner that when it is passed through the exploring canula a groove is formed between the needle and canula.

To use the instrument for exploring place impermeable rubber disc in cap B and screw tightly on to C and attach canula F to C. Now enter exploring trocar at opening in B and pass it through until the point emerges about $\frac{1}{8}$ inch at end of canula F. The instrument is now ready for use. After having entered the sac withdraw the needle until the point of it has passed the outlet E. The bulb G or an aspirating pump may or may not be attached to E as pleases the operator.

The exploration being completed and a more rapid evacuation being desired, the instrument is withdrawn, the needle removed and the exploring canula J de-

tached from C. J without trocar tip attached is now passed through opening of same rubber disc in B, and passed through until A comes in contact with B. Now screw on J such sized trocar tip as you desire and slip over a corresponding size of canula and screw the same on to C.

The instrument may now be used in the same manner as when used for exploring. The sac having been evacuated, the trocar point is pushed forward into the canula just beyond the attachment with C—the instrument still in the cavity, the bulb is now reversed, the trocar is again withdrawn past E and the cavity injected. The manner of again evacuating will readily suggest itself.

Should it be desirable to leave a drainage-tube within the sac, detach the handle portion of canula C from the canula proper, leaving the canula still in the sac, and pass the tube through canula into sac and now withdraw canula, leaving the tube dipping into the sac. The instrument is novel, neat, compact, inexpensive, and complete.

204 E. Main St., Marshalltown, Iowa, Sept. 1, 1886.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

AMERICAN PUBLIC HEALTH ASSOCIATION—RAILROAD RATES.—The fare from Chicago to Toronto is \$14. Delegates to the Convention of the American Public Health Association who pay full fare in going to Toronto will be returned from Toronto at one-third fare. Please be particular to take a certificate from the agent of whom you purchase your ticket from Chicago to Toronto, which certificate should be signed by the Secretary of your meeting at Toronto, certifying that you had been in attendance upon the convention. Upon the presentation of the certificate, thus certified to, to the ticket agent at Toronto, he will furnish you with a ticket for the return journey at one-third fare. Geo. H. Daniels, 205 La Salle St., Chicago.

THE VOLTA PRIZE.—*L'É Progrès Medical* (Aug. 7) reports that the French Minister of Education has just fixed the date of competition for the Volta Prize. It is of the value of £2000, and was instituted by a decree dated June 11, 1882, in favor of the author of

a discovery which shall render electricity economically useful in one of the following applications: As a source of heat, of light, of chemical action, of mechanical power as a means of transmission of despatches, or in the treatment of disease. The competition will remain open to June 30, 1887, and the prize will be awarded the following December. Scientists of all nations may compete. A commission, nominated by the Minister of Education, will be charged with the examination of the discovery specified by each competitor, with a view to determine if it fulfil the required conditions.—*Lancet*, August 14, 1886.

THE INTERNATIONAL MEDICAL CONGRESS to be held at Washington, in September, 1887, promises to be a great success. It is under the patronage of the President of the United States, the Secretary of State, the President of the Senate, and the Speaker of the House of Representatives. The president elect is Dr. N. S. Davis, Professor of the Principles and Practice of Medicine in Chicago College. The list of vice-presidents includes the following distinguished names: Mr. Richard Quain, Professor Annandale, Professor Burdon-Sanderson, Dr. Ricord of Paris, Grant Bey, Dr. Klein, Dr. Dujardin-Beaumetz, of Paris; Dr. Murrell, Professor von Hebra, of Vienna; Professor Unna, of Hamburg; Dr. C. D. F. Phillips, Professor von Mosengeil, of Bonn; Professor Sayre, of New York; the Baron H. Larrey, of Paris; Professor T. R. Fraser, of Edinburgh; the President of the American Medical Association, the Surgeon-General of the United States Army, and the Surgeon-General of the United States Navy.—*The Daily Telegraph*, (London.) August 20, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM SEPTEMBER 11, 1886, TO SEPTEMBER 17, 1886.

First Lieut. Philip G. Wales, Asst. Surgeon, resignation accepted by the President, to take effect Nov. 5, 1886. (S. O. 212, A. G. O., Sept. 11, 1886.)

First Lieut. F. V. Walker, Asst. Surgeon, assigned to temporary duty at Ft. Adams, R. I. (S. O. 131, Div. of the Atlantic, Sept. 8, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING SEPTEMBER 18, 1886.

Simons, M. H., P. A. Surgeon; E. Norfleet, P. A. Surgeon, detached from the "Alert" and placed on waiting orders. Bogert, E. S., Medical Inspector, ordered to Navy Yard, New York, Sept. 28, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED SEPTEMBER 18, 1886.

Austin, H. W., Surgeon, granted leave of absence for thirty days. Sept. 16, 1886.

Goldsborough, C. B., Surgeon, promoted and appointed Surgeon from Oct. 1, 1886. Sept. 9, 1886.

Yemans, H. W., P. A. Surgeon, granted leave of absence for ten days. Sept. 16, 1886.

Bevan, A. D., P. A. Surgeon, promoted and appointed P. A. Surgeon from Sept. 1, 1886. Sept. 7, 1886. Granted leave of absence for thirty days. Sept. 7, 1886.

Glennan, A. H., P. A. Surgeon, promoted and appointed P. A. Surgeon from Sept. 1, 1886. Sept. 7, 1886.

Norman, Seaton, Asst. Surgeon, to proceed to Vineyard Haven, Mass., for temporary duty. Sept. 9, 1886.

ADDRESSES.

ADDRESS IN DERMATOLOGY.¹

BY HENRY J. REYNOLDS, M.D.,

CHAIRMAN OF THE SECTION ON DERMATOLOGY ILLINOIS STATE MEDICAL SOCIETY; PROFESSOR OF DERMATOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO; PROFESSOR OF SKIN AND GENITO-URINARY DISEASES, CHICAGO POLICLINIC; DERMATOLOGIST TO THE WEST SIDE FREE DISPENSARY; GENITO-URINARY SURGEON TO THE HOSPITAL OF THE COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO, ETC.

In obedience to the usual custom my remarks will be confined to what has appeared in the light of progress, advancement, and new discoveries in dermatology during the past year. It is difficult, if not impossible to determine in a year's time whether certain advances and discoveries in this department, as in other departments of medical science, are really such or are only so-called. It would not, however, be speaking in very flattering terms of the intelligence of the writers of the vast array of literature that is yearly presented to the medical profession, nor to those who eagerly peruse the same, were we to assume that only a little in the direction of advancement had been presented. While, however, but comparatively little, perhaps, in this department has been presented during the past year that can in every respect be regarded as real advancement, yet very many important clinical facts and experiences have been presented, which, in addition to establishing new theories, serve the equally important purpose of tending to show the fallacy of old ones. Therefore, not presuming to present all that has appeared on record in this light during the past year, I shall ask your indulgence while I enumerate such as have come to my notice or been deemed worthy of mention, together with some personal remarks regarding the same, and leave the matter, as regards the determination of the truthfulness and value of the so-called advances, for further investigation and your wise judgment to decide.

NOMENCLATURE AND CLASSIFICATION.

At the annual meeting of the American Medical Association two years ago Dr. Duhring read a paper on "Dermatitis Herpetiformis."¹ Under this head the author embraces the *impetigo herpetiformis* of Hebra, that affection termed by some authorities *herpes gestationis*, and a number of other rare condi-

tions described by various writers under different names. He subdivides the disease into the erythematous, vesicular, bullous, and pustular varieties, according to the symptoms present. The propriety of thus grouping into one disease these various manifestations is still a matter of discussion among those making a special study of skin disease; and although the name and classification Dr. Duhring proposes are generally received with favor, the question as to whether these various conditions can justly be regarded as different manifestations of an individual disease remains yet to be settled.

A few other insignificant changes have been made in the classification of the American Dermatological Association.

ACNE.

In a paper read at the eighth annual meeting of the American Dermatological Association,² the use of sounds in the male urethra, as a supplementary measure in the treatment of acne, was proposed by Dr. Sherwell, of Brooklyn, who claimed the cure of two cases by this method. In support of the efficacy of this procedure in acne, may be found, in a paper read at the ninth annual meeting of the same Society,³ by Dr. LeGrand N. Denslow, of St. Paul, other cases of acne reported, in which the same treatment was resorted to with apparent benefit. Dr. Denslow also reports, in the same paper, a case of general alopecia apparently cured by the same treatment. It is an almost universally conceded fact that many other remote troubles may be brought about by reflex urethral irritation; and as there exists a particularly intimate relation between the functions of the genital organs and the sebaceous glands, it seems more than probable, though I have had no experience in the same myself, that the procedure is a justifiable one, and in certain cases of acne and other sebaceous disorders, when the prostatic or other portions of the urethra are over-sensitive, will be found productive of beneficial results.

In this connection I may mention a line of treatment which I have found preferable to any other in certain forms of acne, and which was published about a year ago.⁴ The principle of the treatment so far as I am aware, has not been referred to by other writers. Though applicable to all forms of acne it is more particularly useful in those forms where the lesions become deep and nodular, with little tendency

¹ Read at the Thirty-Sixth Annual Meeting of the Illinois State Medical Society.

⁴ Medical Record, Nov. 7, 1885.

⁵ Western Med. Rep., vol. vii, p. 20.

to pustulation on the surface, and described by various authors as *acne indurata*, *acne cachecticorum*, etc. In this condition the lesions, though apparently papular, are situated deep in or underneath the skin, and will invariably be found to contain, in their centre, pus; which, instead of coming rapidly to an inflammatory surface, remains the same almost indefinitely, with a tendency, rather, to burrow deeper. I am in the habit of lancing these lesions deeply with a Graefe's cataract knife, and invariably find pus. Now if these lesions were left, after being lanced and evacuated of the pus, they would immediately heal over on the surface and leave the pyogenic nidus to continue its work as before. I therefore, after lancing, pass a probe dipped in carbolic acid to the bottom of the incision, and then fill the whole from the bottom to the top with a piece of absorbent cotton, and allow it to heal from the bottom. In this way no lesion will fail to entirely disappear, leaving only an almost invisible scar. New lesions will of course now and then appear, which may be treated in the same way. Other measures will be kept up as deemed necessary in the meantime.

CURE OF LEPROSY.

Fox, of New York,⁴ suggests the possible if not probable cure of leprosy when the proper *moral effect* can be brought to bear upon those patients; and reports in support of the same, the apparent cure of a case, wherein he attributes it largely to this therapeutic measure. He aptly says: "I need not dwell upon the well-known influence of the mind upon the condition of the body; no one doubts it, though few appreciate it." True it is that the moral effect upon patients suffering from this malady is greater in its depressing tendency, perhaps, than in any other disease, banished as they are from society and imprisoned for life, as it were, with the hope only of a most miserable existence and a lingering death.

PIGMENTARY SYPHILIDE.

Dr. R. W. Taylor, of New York, reports a case with illustration,⁵ in support of the claim originally made by Hardy, that we may have, though rare, a pigmentary discoloration of the skin due to syphilis, which differs, and is to be diagnosed, from *chloasma*, *tinea versicolor*, ordinary *vitiligo* or *leucoderma*, and all pigmentations found as relics of other eruptions. He concludes, as the result of his observation, that the unequal distribution of pigment which syphilis may cause may be either in the form of hyperpigmented spots, deficiently pigmented or leucodermatous spots, or the two combined. I may add to the above the report of a most typical case of the same that recently came under my own observation. The patient was a white female in the Cook County Hospital, Chicago, to whom my attention was called by my colleague, Prof. S. A. McWilliams, the attending physician. There was an unmistakable history of syphilis. Large patches almost as dark as the negro were to be found on various parts of the body, which gradually faded away to a surface almost if not quite destitute of pigment.

CARBUNCLE.

At the annual meeting of the American Medical Association held at New Orleans, 1885, Dr. Bulkley read a paper on "The Treatment of Carbuncle Without Incision," in which he substituted for the old plan of crucial incision and hot poultices an ointment containing ergot and oxide of zinc locally, and sulphide of calcium and saline laxative with iron internally. By this method he claimed a shorter duration, less pain, and less scarring. For the same malady Dr. James F. Hibberd, of Richmond, Indiana, in a paper read at the Indiana State Medical Society, 1885,⁶ advocated the local use of oleate of morphia applied with gentle friction every three hours. By this treatment Dr. Hibberd's cases, if not aborted, did not last over about a week and were attended with only a minimum of pain and soreness.

URTICARIA.

Lassar⁷ cuts short the duration, and reduces the frequency, of violent attacks of urticaria by 24-grain doses of salicylate of sodium, repeated every two hours until three doses are taken. It is certainly well worthy of a trial, as the trouble is undoubtedly at times a very stubborn, not to say serious one.

RINGWORM OF THE SCALP.

Alder Smith⁸ recommends, as a parasiticide in ringworm of the scalp, chrysarobin dissolved in chloroform—7 grains to the ounce. The chloroform, in addition to serving as a vehicle, dissolves the fatty matters out of the follicles and thereby facilitates the penetration of the chrysarobin.

A. J. Harrison⁹ applies first a mixture of $\frac{1}{2}$ drachm iodide of potassium to 1 ounce of liq. potassæ. When this has penetrated he applies a solution composed of 1 ounce of sweet spts. of nitre and 3 grains of bichloride of mercury. His theory is that the liquor potassæ softens the hair-bulbs and hairs and thereby allows the iodide of potassium to be conveyed to the bottom of the follicles. Then, when the mixture of nitre and bichloride of mercury is applied (the nitre being used merely because it forms a thin mobile menstruum) the mercury comes in contact with the iodide of potassium in the bottom of the follicle and the important chemical change which is there set up—the formation of the biniodide of mercury—he regards as very important and beneficial.

CHRYSAROBIN INTERNALLY.

The internal administration of chrysarobin for various diseases of the skin was suggested by Stocquart about two years ago.¹⁰ Since that time his success has not been so great with the remedy, but he still speaks highly of its use in eczema and impetigo of children, stating that it decreases the blood supply to the part, thereby reducing the redness and secretion.¹¹ In regard to the curative properties of this remedy, administered internally, it may be stated

⁷ Jour. Amer. Med. Assoc., vol. iv, p. 542.

that it is a generally conceded fact that remedies which have any action upon the alimentary canal, usually diminish the supply of blood to other parts. This I have found to be particularly true in regard to cutaneous hyperæmia. It is my usual custom, therefore, when this condition exists, as is usually the case in eczema, to act upon the alimentary canal, giving usually a saline laxative. For the purpose of demonstration I have frequently in dispensary practice cured cases of eczema by this method alone, restricting of course, at the same time, the patient from scratching the parts. I may add, therefore, that from both theoretical and practical reasons I do not regard the drug as having any special merits as an internal remedy; nor perhaps the laxative above referred to over many other laxative or purgative remedies having an irritant effect upon the alimentary canal.

COCAINE.

Brief mention of the comparatively new and much talked of drug, cocaine, may perhaps be tolerated. As common sense should teach any intelligent person, this drug, if useful as a local anæsthetic in one location, must necessarily be so in any other where it can be properly applied and sufficiently absorbed. It, however, is not well absorbed by the skin, and therefore not as useful as in certain other localities. To control the itching in eczema, if there be sufficient abrasion to favor its absorption, it will be found useful in a strong solution; also in pruritus ani. I have not found it to be of much service in relieving the pain due to the removal from the face of superfluous hairs by electrolysis.

LITERATURE.

Of the new publications that have appeared during the past year, may be mentioned the "Photographic Illustrations of Skin Diseases—Syphilitic and Non-Syphilitic," by Geo. H. Fox; also, by the same author, "The Use of Electricity in the Removal of Superfluous Hair and in the Treatment of Various Facial Blemishes;" "A Manual of Dermatology," by A. R. Robinson, of New York; "Acne and Its Treatment," by Bulkley; "Practical Notes on the Treatment of Skin Diseases," of which the first two numbers, on "Diseases of the Perspiratory and Sebaceous Glands," and "Eczema," respectively, have appeared, by Geo. H. Rohé, of Baltimore; also a valuable Handbook of Diseases of the Skin," by Ziemssen.

INTRA-VENOUS INJECTION OF SALINE SOLUTION IN COLLAPSE FOLLOWING HÆMORRHAGE.¹

BY CHARLES WESLEY ROOK, M.D.,

PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, QUINCY COLLEGE OF MEDICINE, QUINCY, ILL.

In order that our profession may know of the benefit to be derived from the intra-venous injection of

salt solution and its preference to either the transfusion of blood or the intra-venous injection of milk in the collapse of hæmorrhage, the following case is related;

On November 30, 1885, the writer, assisted by Drs. Bassett and Irwin, of Quincy, and King, of Payson, Ill., removed from the mouth of Mr. Thomas Seals, age 50 years, what was diagnosticated as a malignant epulis, springing from the left lower maxillary bone and filling the oral cavity. After the operation the growth was examined microscopically by Dr. Gilmer, of Quincy, who pronounced it a round-celled sarcoma. The shock of the operation was very slight.

Within two weeks the growth was seen to be recurring, but as Mr. S. was rapidly regaining strength it was thought safer to delay for a few days the second operation. December 19, 1885, just twenty-one days from date of operation, I was summoned to the house of Mr. S. In company with my brother, Mr. J. H. Rook, I answered the call, and found bright arterial blood streaming from the mouth of my patient. Rupture of the facial or lingual artery was suspected, but examination revealed no ruptured vessel, only a rapid oozing from the sarcomatous tissue. A cloth saturated with Monsel's solution of iron was thoroughly applied to the bleeding surface, which arrested the hæmorrhage. At the moment the hæmorrhage was checked Mr. S. fainted. He was laid upon the floor and assistance was sent for. Looking at my patient, who was in the unconscious and pulseless condition of extreme collapse, I determined to attempt his resuscitation by the intra-venous injection of a dilute saline solution. Asking for a bowl of warm water and some table salt, I proceeded to ligate the left arm. After waiting a few moments, the veins not distending sufficiently to show their location, the right arm was ligated, patient turned to his right side, where in a few moments the median basilic vein was seen. At this moment Dr. Lee, of Quincy, came in, and readily seconded my efforts. The skin was incised, a grooved director passed under the vein, into which was introduced a small trochar and about which was passed a catgut ligature to prevent regurgitation. I then took from my case a Mattson's rubber syringe, removed the nozzle with metal piece attached, filled the syringe with the warm water made slightly saline to taste, slipped the end of the rubber tube on the canula, and slowly injected the warm saline solution until a good radial pulse was produced and the patient returned to consciousness. The canula was then removed, the vein occluded by tightening the ligature, and the patient lifted from the floor to his bed, where in a few moments he was attacked with a severe chill. He was quickly surrounded with bottles of hot water, and in twenty minutes was resting comfortably. He experienced great thirst for some hours, during which he drank freely of cold water and milk, which were occasionally rejected by the stomach. No alcoholics were administered.

Notwithstanding the great loss of blood, our patient was able to undergo, four days later, his second operation, which was performed by Dr. Byrd, assisted by Drs. Lee, Irwin and myself. Since the date of

¹ Read in the Section on Surgery, at the Thirty-Seventh Annual Meeting of the American Medical Association.

the second, seven subsequent operations have been performed, the last being on April 27, 1886. Mr. S., though much enfeebled by the continued recurrence of the disease, is yet able to take much outdoor exercise. The quantity of blood lost at the time of the hæmorrhage was found by measurement to be one hundred and ninety ounces, while the quantity of salt solution injected was only eighty ounces.

Having seen and treated only the case narrated, does not perhaps entitle me to the privilege of formulating rules for the guidance of others, yet a little argument in favor of the method may not be without interest. It is a known fact that the blood corpuscles multiply very rapidly, and all that is needed in a case requiring transfusion is the injection of a suitable fluid in which the corpuscles can multiply. Such a fluid is the dilute saline solution, which will also prevent the remaining blood from coagulating. The dangers and difficulties attending the execution of other methods, for which the salt solution may be substituted, are apparent to all. In the process of immediate transfusion advised by Aveling we are met by the difficulty of finding a willing and suitable donor, the necessity of having a special transfusion instrument, and the danger of carrying coagulated fibrine into the circulation of the recipient. If the method of injecting defibrinated blood be employed, a suitable donor must be found, after which valuable time is consumed in extracting the blood and removing its fibrine. When employing milk for intravenous injection we are rightly advised to use only the warm freshly-drawn milk, a condition of that fluid not easily obtained in our cities.

In conclusion, I ask a trial of the salt solution, for I am convinced that it is as efficient, more practical, and safer than the transfusion of blood or injection of milk.

VENOUS BLOOD TUMORS OF THE CRANIUM

in Communication with the Intra-Cranial Venous Circulation, Especially the Sinuses of the Dura Mater.

BY WM. M. MASTIN, M.D.,
OF MOBILE, ALA.

(Concluded from page 344.)

PATHOLOGICAL ANATOMY.

Fortunately the collected cases represent a goodly number of authentic post-mortem sections, together with valuable surgical examinations; and consequently, these furnish pathological data of a character sufficiently definite to enable, it is believed, the formulation of rational and decisive conclusions—conclusions which are also added to and strengthened by marked symptoms and conditions, as manifested by numerous clearly analyzed cases without post-mortem demonstration.

A rapid rehearsal of the anatomical facts collectively, before entering into the examination and consideration of individual pathological points, seems advisable.

Moreau's Case.—There was a venous varix formed

of congeries of veins, terminating in enlarged and dilated vessels which passed, by means of three perforations in the frontal bone, into the longitudinal sinus. For a large extent around these osseous openings the dura mater was inflamed and covered with pus,—a phlebitis and meningitis the result of the previous operative treatment. This is an example of venous varicose tumor.

Michaud's Case.—Two erectile growths, one over brow and eye-lid, the other located on the head. They were composed of a cavernous tissue, under the seat of which the bone was perforated by a multitude of little apertures giving passage to the veins coming from these structures in their course to the superior longitudinal sinus.

Foucteau's Case.—Occupying the site of the posterior fontanelle was a blood tumor which communicated directly with the superior longitudinal sinus through a single opening in the fontanelle the size of the little finger, by means of a tubular pedicle of which the cyst appeared to be an expansion. The tumor was composed of two principal cysts with a small accessory pouch, which were lined by a vascular serous membrane. This serous membrane was of the same character as, and continuous with, that of the cerebral sinus through the above-mentioned pedicle. Thus it would appear that this was a blood-cyst formed by a hernia of the sinus through the unclosed posterior fontanelle, in which only the serous coat of the sinus was recognizable by the eye alone.

Demme's Case.—Located on the top of the head (in the middle of the sagittal suture) was a tumor composed of a pouch the interior walls of which were covered by fibrinous laminations, of different color and consistence, according to their respective ages, as in a true aneurismal sac. In the coagulum in contact with the bottom of this pouch was a funnel-shaped depression which proved to be the entrance to an opening leading to the cranium. The superior longitudinal sinus was distended and filled with a coagulum, and was considerably dilated at a point corresponding to the external tumor with which free communication was demonstrable. The external wall of the cyst consisted of the normal scalp, but the other layers were composed, very evidently, of the sinus walls protruding through the osseous opening. Traction upon the tumor showed that the opening in its base consisted of a tubular pedicle connecting its cavity with the sinus. The pericranium did not enter into the formation of the cyst coverings, but was intimately attached to the circumference of the skull opening and the pedicle, showing that it had either ruptured or been absorbed. The cranial tissue was thinned throughout the space occupied by the tumor, rather transparent, and in a state of rarefaction. The walls of the sinus were thickened, especially the fibrous elements, but otherwise little altered. The microscope was employed in the examination. This presents a case of true ectasia of the superior longitudinal sinus through the anterior fontanelle, probably the anterior angle.

Acland's Case.—The growth was a venous capsule communicating through a foramen in the protuberantia occipitalis, by means of a fibrous tube, with the

Torcular Herophili, thus putting the cyst in communication with the intra-cranial venous circulation. Brain greatly enlarged, and anterior horn of one lateral ventricle distended with serum (hydrocephalus). Here is shown a circumscribed venous varix of an emissary vein (emissarium occipitale) passing to the Torcular.

Bruns' Case.—Located over posterior fontanelle, with a thick pediculated base. Surgical examination after strangulation and removal of the growth demonstrated the structure of the formation to be a mass of areolar tissue containing a bunch of greatly thickened veins, in which were several spherical enlargements or dilatations. Beneath the cicatrizing ulcer left after removal of the tumor the underlying fontanelle was plainly felt. This is another instance of varicose emissary vein or veins passing to the sinus through the posterior fontanelle or below it.

Busch's Case.—A large fluctuating tumor, occupying the superior occipital region, including the small fontanelle. Contained a quantity of dark, viscous blood. The fluid situated between bones of skull and pericranium, and was in communication with the sinus. Several vessels extending from the tumor to superior longitudinal sinus were divided by the post-mortem incision. Character of tumor not definite, but possibly a venous varix.

Flint's Case.—A tumor in occiput. Contained venous blood, and communicated with superior longitudinal sinus. Probably an example of ectasia of the sinus.

Jacobi's Case (Morbid Specimen).—A large cyst filled with coagulum located on occiput. Perforating the os occipitis was a large and long opening or canal through which the sinus protruded as a hernia under the scalp. The question arises, Was this not a varicose occipital emissary vein traversing its normal but enlarged foramen? However, it is received by several authors as a true hernia of the sinus, and, with the unsatisfactory data at hand, I must now also accept it as such.

Melchiori's Case.—Located on left parietal bone. Tumor composed of a net-work of empty veins ranging in size from a thread to a pigeon-quill, freely intercommunicating, and finally terminating in a common trunk about the thickness of a goose-quill. This trunk passed through the galea aponeurotica capitis, and piercing the skull at the lower and posterior edge of the parietal bone, emptied into the transverse sinus where this canal lies on inner surface of temporal bone. There was meningitis, and all the sinuses were filled with partially suppurating clots, although without disease of their walls. This was a case of varix of the external cranial veins communicating with the sinus.

Andrews' Case.—On removal of the scalp a number of enlarged and distended veins were seen about middle of the occipital bone. Just below the external protuberance was found a depression in the bone of one-third inch in diameter and one-fourth inch in depth, and covering which was a membrane that appeared to be formed of thickened walls of a distended vein, and upon puncturing this venous blood escaped. The depression was then found to be a

complete perforation, about the size of a crow-quill, which led into the sinus. There were tubercular deposits in brain, and serous effusion into both membrane and ventricular cavities. This was a case of circumscribed varix of the emissarium occipitale.

Pott's Case.—A blood collection on top of head. Operation disclosed depressed fracture with a sharp fragment piercing superior longitudinal sinus.

Hutin's Case.—Blood pouch on right frontal region, communicating, through an old traumatic bone perforation, with the superior longitudinal sinus. Osseous atrophy also evidenced.

Hutin's Case.—Fluctuating blood pouch on right side of summit of head, between osseous vault and pericranium. Perforation of under and right side of longitudinal sinus by a thick bone splinter, thus placing the blood sac in communication with the sinus. Another blood collection internally between dura and skull, which also communicated with both sinus and external tumor.

The individual points which call for consideration are these: I. The general character of the tumor; II. The anatomical relations of the tumor, including the nature of the tissues composing and limiting it; III. The contents; IV. The method of communication with the intra-cranial circulation.

I. *The General Character of the Tumor.*—This tumor may be defined as, an indolent swelling external to the skull, in the form either of (i) a cyst—single or compound—or of (ii) a varicose or an erectile growth, containing venous blood, and communicating, directly or indirectly, by one or many skull perforations—normal or pathological—with the intra-cranial venous circulation.

The indolent nature of the growth is too fully and prominently shown in the detailed history of the cases to necessitate further notice,—the only inconveniences complained of in the large majority of instances being subjective, or due to the annoyances of its particular location.

(i). The pouch—or cyst—variety is, as its name implies, composed of a pouch or sac variously formed, and the character of this formation being dependent upon the cause in operation. It can be asserted, therefore, from an etiological standpoint, and largely sustained by necropsic evidences that this form is encountered in circumscribed dilatation of an emissary vein (fusiform); in ectasia or hernia of the sinus and in dilatation of a diploic vessel (sacciform); in cranial perforation the result of a rarefying osteitis, and in the greater number of cases produced by direct injury, including both skull fracture and rupture of an emissary vessel (false). These features mark this variety as being closely allied to aneurismal formations in general, and whereas these characters are met with in the majority of cases, at the same time they cannot be considered so characteristic of this division, as was formerly my opinion.

Several post-mortem dissections, with every physical indication in many other cases without the conclusive proof of autopsic examinations, furnish sufficient demonstration for these conclusions.

(ii). In the other form—the varicose variety—the tumor is composed of tortuous and varicose veins

(chiefly the emissaria Santorini) with numerous dilatations, or, occasionally, of a structure resembling true erectile or cavernous tissue (Michaud's case). These varicose formations may be in both fine and gross bundles held together by a meshwork of areolar tissue, and consisting of simple tortuous veins alone or combined with dilatations. Many cases in all three of the classes, the congenital, spontaneous and traumatic groups, illustrate this variety.

II. *The Anatomical Relations of the Tumor.*—Taking the coverings of the cranium in their order from without inwards, I find the anatomical location of these formations may be, (a) between the integument and the cranial aponeurosis; (b) between the fibro-muscular layer (aponeurosis) and the pericranium; (c) between the pericranium and the bone; and (d) occasionally extending internally between the skull and the dura mater.

These conclusions, which were reached in my previous paper, were then based upon the recognition chiefly of one principal variety of this formation, namely, the *diffused*, where the effused blood escapes beneath the scalp tissues; and even with a more extended knowledge of the etiology and pathology, including the wider and more comprehensive classification now given to the lesion, these relational divisions are, in the main, still appropriate.

(a) The situation of the growth between the skin and the epicranial aponeurosis, although not determined by the positive evidence of actual dissection, can be considered as, at least, probable, especially in certain injuries where all the soft tissues, together with the bone, are torn through or divided except the skin, leaving that covering intact; or, again, in those cases where absorptive action is particularly prominent; and, also, in long-standing cases with a disposition to rapid tissue change, hastened, perhaps, by increased blood-pressure. But clinical observations alone are not adequate to fix this exact seat, for, it must be noted that the sensation and appearance of the swelling are very deceiving in the impressions they convey of the composition of its walls. Thus in many instances both the skin and aponeurosis may be so extremely thinned or attenuated as to impart to the touch the sensation of only integumentary thickness, and accompanied, at the same time, by a violet hue as if the contained blood was immediately beneath the cutaneous covering. Furthermore, the probability of this position is re-enforced somewhat, if the first proposition of Demme be looked upon as tenable, that is, rupture of an external cranial vein from injury, producing an *epicranial* or *aponeurotic* blood-collection which results in a cyst, and finally in communication, by various ways, with the sinus through absorptive changes in the underlying tissues. Under such circumstances it can be readily appreciated how a venous blood-tumor of this description may be located between the integument and the fibro-muscular layer of the scalp.

Again, in thickening and dilatation of the cranial veins, the diseased action may originate in and be confined to that portion of the vein lying between the skin and the aponeurosis, and thus the tumor be so situated, as is shown in the case of Melchiori, and some others.

(b.) I am inclined to consider the location of this formation between the aponeurosis and the pericranium as its most frequent seat,—an opinion, it should be remarked, that applies particularly to those cases arising from within outward or from the interior of the cranium. This position was demonstrated by post-mortem examination in a number of instances; and theoretically it may be looked for in the majority of these tumors due to spontaneous perforation of the skull, cranial fracture with sinus wound, ectasia of the sinus, and disease of the diploë veins, in which, especially the two first named, the periosteum is, in all probability, lacerated, and the blood extravasated in the cellular tissue beneath the more movable aponeurosis. Opposed to this view, however, is the opinion of Stromeyer, who expresses the conviction (*Maximen der Kreisheilkunst*, S. 362, 1861) that the cyst is always beneath the pericranium. He declares that the case of Dufour's in which the necropsy exhibited the bone covered by a thin periosteum is not opposed to his views, since all bone reproduces its periosteum when deprived thereof. But as evidence that the assertion cannot be applied unconditionally to all cases, it is only necessary to refer to the simple example of Demme's case, where, with the aid of the microscope, in a hernia of the sinus through the anterior fontanelle, it was seen that the pericranium did not enter into the cyst coverings, but was perforated and intimately attached to the circumference of the skull-opening and to the pedicle of the tumor as it passed into the cranium.

(c) Notwithstanding the assertion of Stromeyer and others, that the cyst (pouch-variety) is always seated between the pericranium and the bone, I am forced to regard this location as rare; or, at any rate, it is not the rule. This opinion is held not only from the fact that I have succeeded in finding but two examples of such a location, but also from the anatomy of the periosteum and the associated tissue involved. Such, however, may sometimes occur, of which the testimony of Stromeyer with the illustrative cases of Busch and Hutin present sufficient proof.

(d) The location between the pericranium and the bone and extending internally between the skull and the dura (vide Hutin's case) is accidental, and consequently exceptional, and does not demand further consideration. It can occur, obviously, only in serious injury to the cranium with both internal and external hæmatoma, and is not particularly connected with this class or character of tumor.

From the foregoing remarks it is very apparent that the coverings or walls of these venous formations of the head communicating with the intra-cranial circulation, are absolutely dependent upon the etiology and special form of the lesion. For example, the tunics of such a growth arising in diseased action of the coats of the sinus with protrusion through the bone, cannot be compared with simple blood effusion from skull and sinus perforation, under the scalp, and, therefore, its location and the composition of its walls must necessarily vary with the form and mode of origin of the tumor.

Again, each and all of the tumor coverings may be normal in texture and relationship to each other, or

considerably modified or changed by diseased or natural processes, and, indeed, even differing according to the age of the individual affected.

III. *The Contents.*—Besides normal fluid venous blood, which is of course always present, this tumor may contain occasionally solid elements; but, as would be naturally anticipated, such substances seem to be confined to the cyst or pouch-variety, and, perhaps, in certain examples of the varicose form where gross dilatations with thickened walls exist.

These solid elements may be of the character of condensations from the cellular tissue, or blood concretions (phleboliths) as indicated in one of Middel-dorff's patients, and also the case of Jules Dubois, where, after complete emptying of the sac, a "core-like" substance about the size of a lentil was felt; or, again, the cyst may be lined by laminated fibrinous deposits identical in formation and composition with aneurismal coagula, and of which the case of Demme furnishes an excellent illustration.

In the instance mentioned by Foucteau three cysts were present,—the third or accessory cyst being filled with serum. But this was, undoubtedly, of accidental formation due to recognizable causes (witness the occasional formation of similar cysts in encephalocele and meningocele), and hence, although noteworthy, is without any associative significance.

IV. *The Method of Communication with the intra-Cranial Circulation.*—The manner of communication (direct or indirect), and the nature of the passage connecting the tumor with the dural circulation (normal or abnormal skull-openings), are as different and various as the causes which originate the lesion, and, indeed, it may be considered as bearing a very intimate, if not constant, relation to the etiology.

When the union takes place through normal or preëxisting cranial apertures, as the emissary foramina and the fontanelles, the perforation partakes of the usual qualities and appearance of the natural and healthy tissues forming the opening, although in some cases they may be changed, in both size and contour, and, perhaps, with alteration in the quality of the bone. This method of connection is exemplified in hernia of the sinus through the fontanelles and in varicose dilatations and enlargements of the emissaria Santorini.

When the communication is effected by means of abnormal perforations then the distinctive qualities and features of the communicating opening and passage must be largely influenced by the causative agent in operation, that is, whether it be produced spontaneously or by appreciable traumatic forces, together with the probable changes caused by the duration of the tumor.

In the instance of the former where the glandular Pacchioni appear to be the exciting or active causes of the resorptive changes in the bone—a rarefying osteitis—an aperture may be looked for of moderate capacity, and presenting an irregular and uneven outline; whereas a rarefying osteitis the result of, possibly, extensive contusion, especially if located on the frontal region with involvement of the diploe, may be attended by a very extensive loss of substance, forming an opening with jagged edges, according to

the extent of the osseous tissue subjected to the exciting cause.

In the latter or traumatic cases, the orifice is directly dependent upon the character and severity of the injuring force, that is, it may vary from a delicate crack or minute puncture with displaced spiculæ to an extensive loss of the cranial wall; or, again, it may assume the features of a wide fissure, as in suture separation with displaced bone.

The number of the apertures, also, is dependent upon the special features of the tumor, varying from one to a large number, but where they are numerous, or, at least, several in number, the tumor is probably composed of an aggregation or bundle of fine varicose vessels, which penetrate the skull by exceedingly small foramina.

Again, the communication may be either direct or indirect—a condition which also stands in a certain ratio to the cause. Examples of the direct connection, where the tumor-cavity opens immediately into the sinus, are shown in spontaneous perforation through the fovea glandulares, ectasia of the sinus, and in some traumatism.

The indirect, where the bone perforation is sinuous, or, in other words, there is a medium, in addition to the perforated bone, through which the tumor is connected with the sinus, is illustrated in all dilatations and varicosities and ruptures of the external veins, or where the communication is through the intermediary of the diploic canals.

Therefore, if any generalizations can be based on the revelations already made by clinical and post-mortem investigations, it can be safely affirmed that, First, in the *simple* or *diffused* class the cranial perforation is usually of abnormal production or formation, single, of moderate size, irregular contour, and direct; and, Secondly, in the *venous* or *vascular* class the communication takes place more frequently through a normal skull opening, is variable in size and number, of a definite shape, and indirect in its course—but exceptions to this may exist, as seen in certain cases of rarefying osteitis with diploic involvement.

SYMPTOMS.

In the majority of cases the presence of the growth produces so little discomfort or uneasiness, and in some instances not the slightest inconvenience, other than that of location, is experienced by the patient, that it is scarcely possible to name any general symptoms which may be regarded as characteristic of the lesion.

Among such indefinite or variable symptoms encountered, however, *vertigo* or *dizziness* is the most prominent and most constantly present. In many of the cases this symptom was complained of, especially when the tumor was at its maximum volume, but not always appearing spontaneously, and more often the result of posture with the head dependent or flexed; or produced by compression of the growth, particularly such as to cause the rapid forcing out of its contained blood, although, on the other hand, once or twice it was noted that slight pressure or supporting the tumor by the hand lessened or relieved the

vertigo. But it may be stated that, as a rule, when dizziness is complained of it is the result of those causes which produce increased blood-pressure, or determination of blood to the head, such as compression of the jugular veins, position, muscular exertion, mental emotions and so forth.

Again, it is possible for pressure upon, or forcible reduction of, the tumor to cause serious cerebral disturbance, amounting almost to compression, as is vaguely referred to in one or two records; but such is rare, and must be regarded as a very infrequent attendant.

Accompanying vertigo, although much less frequent, *pain* is sometimes met with, and finds expression chiefly in the form of headache. It rarely arises spontaneously, and when present is usually associated with increased tension of the tumor, or, in other words, increased blood-pressure; and in some instances it was only produced by direct pressure exerted upon the swelling. Pain localized in, or confined to the vicinity of, the tumor is mentioned in one or two cases.

The local symptoms are much more characteristic and reliable than the general or systemic ones above mentioned.

The most conspicuous point in the examination of the tumor is its *seat* or location, which, in a general way, is nearly always in the tract of the superior longitudinal or some other sinus, or adjacent thereto; and, consequently, the proximity of a blood swelling to the course of any of the cranial sinuses, especially if presenting obscure symptoms, should be suggestive of this variety of sanguineous formation. But, as naturally anticipated, its actual or anatomical situation is positively dependent upon the form or variety of the lesion. Thus it may be briefly stated that the *diffused* form the result of a rarefying osteitis, especially erosion or resorption of the skull by the Pachionian bodies, is found in or near the median line on the upper and posterior part of the cranial vault, that is, on either side and along the course of the sagittal suture (in which position the glandulæ Pachionian are in greatest numbers), at its junction with the lambdoidal, and even extending a short distance on each side along the latter suture.

In the second or *venous* variety the situation is again influenced by the special structures involved. First, if the growth be formed at the expense of an emissary vessel it will be located on that portion of the cranium where these exist, and particularly over the site of the parietal and occipital veins, which are the larger and most often implicated; Secondly, if a true varix sinus exist involving the coats of the longitudinal sinus, then the pouch is more frequently located over one of the fontanelles; whereas, thirdly, in involvement of the diploic system of vessels it is apt to be confined to the os frontis and ridges of the occipital bone, but particularly the forehead, in which localities the diploic structure reaches its most complete and highest development. In traumatic cases the location is governed, of course, by the portion of the skull receiving the injury, but usually such forces are applied to the frontal and anterior-summit regions of the head.

The moderate *size* of the tumor together with the direct influence exerted over its volume by certain conditions, are noticeable features. Even when distended to its fullest capacity it is usually of medium dimensions, although several cases are mentioned where it attained the volume of a large apple; whereas when quiescent, that is when the swelling is relaxed or at its minimum enlargement, the growth is quite small and sometimes scarcely perceptible if not completely indiscernible.

These changes or alterations in the size of the growth are very characteristic, and can be seen and felt to take place under those conditions affecting its distension and relaxation: the tumor slowly rising and swelling up in the dorsal decubitus or any position with the head lowered; by interference with the proper return of venous blood from the interior of the cranium, as in compression of the jugular veins, forced expiration, crying, coughing, sneezing, and the like; occasionally by a full stomach, muscular exertion, or mental emotions; and, rarely, during the normal respiratory effort; however, in converse influences or those conditions lessening or reducing expansion or dilatation, the tumor recedes gradually to a lower level, and often entirely disappears.

The *color* of the swelling in most instances is normal and does not differ from that of the healthy skin, but this may be materially influenced by the consistency or thickness of the tegumentary coverings, and may also vary with the degree of distension of the tumor. Thus, when the walls are very thin it may assume constantly a purple or violaceous hue, or again the discoloration of the walls may be recognized only during distension, and fade away to a natural color with the relaxation of the tumor. Furthermore, changes in its color may be the result of coexistent disease of the skin of the tumor itself, namely, of a nævoid character, as was noted in several cases; but such a complication is infrequent, and when it does occur may be looked for, everything being equal, in congenital in preference to the other classes.

The influence of *head posture* on the volume and resistance of the tumor is so apparent to both the touch and eye that, manifesting itself as it does always, perhaps, in this affection, the symptom of *dilatation* and *reduction* produced thereby may be reasonably regarded as a pathognomonic character. Without an exception, I believe, this effect of position was decided and marked,—the tumor being felt to attain its maximum volume when any position with the head lowered was assumed, and even simply bending the head forward producing very evident increase of size and tension; whilst the reverse attitude, with the head fixed and erected, being attended by a diminution in both resistance and bulk.

Similar results are produced by *compression of the jugular veins*. This was employed in a number of instances, producing unequivocal impression upon the growth, and its influence may be taken as a rational symptom, and one of special value when associated with additional evidence; for, it is needless to remark, its range of applicability is much too wide and extended to be alone of diagnostic import in this type of sanguineous tumor of the skull.

Probably next in importance to postural influence (in the pouch-variety) may be regarded the symptoms of *compressibility* and *fluctuation*, which taken together furnish positive evidence of a fluid-containing pouch or cavity with an intra-cranial outlet. In all the cases of the pouch—or sac—form these symptoms were observed, and were among the chief distinctions—the swelling readily, and nearly always completely, but slowly subsiding under continuous lightly applied pressure with the hand or fingers, and tardily redilating upon the removal of the compressing force,—and distinctly conveying to the touch the sensation of a sac filled with fluid, which was being emptied.

The rapidity and ease with which pressure accomplishes evacuation of the pouch is dependent, necessarily, upon the freedom and directness of the communication with the cranial cavity, but, as a rule, the reduction is rather slow and gradual.

Another symptom of considerable weight is the ability in many instances to recognize by the finger, after reduction of the growth, some *osseous alteration*, or even depression or indentation in the skull, corresponding to one or more openings leading to its interior, and which may be of considerable dimensions.

Furthermore, *puncture* by means of a trocar and canula with direct exploration of the bone, may disclose the existence of the aperture where it had eluded careful digital search. However, even such unsuccessful efforts to discover the communicating entrance should not be considered as conclusive evidence of its non-existence, for failure to detect the osseous perforation by this method occurred in several cases in which a subsequent incision or post-mortem examination demonstrated its presence.

The *sensation* or feel of the tumor-walls, as conveyed through manipulation, is to be taken into account in a description of the symptoms. In uncomplicated cases of the pouch-variety, especially the simple diffused form, after being emptied, the sensation is that of a loose, lax, movable covering of healthy skin tissue, of different degrees of thickness according to its constituents; whereas if partaking of aneurismal qualities, that is, with fibrinous depositions on its interior surface, these are recognized as usually irregular but firm or solid masses occupying the substance of the walls, or, perhaps, the cavity of the growth. In the varicose-type there is readily discernible after evacuation or reduction of the swelling, a spongy mass or substance, varying according to the character of the varicosity, but which nearly always remains as an irreducible structure between the fingers.

Pulsation and *bruit* require notice only because they are mentioned as occurring in several cases. They are to be regarded in the light of extremely rare accompaniments, and practically must be entirely eliminated from the list of symptoms. When met with they are explicable on the ground of contiguity to the cerebrum and a dural sinus or artery.

Finally, a symptom of no indifferent significance is that attending the employment of *circular compression*. This constriction may be applied either to the

head, by means of a band or cord tightly drawn around the cranium with compresses in the temporal fossæ, or to the tumor itself, as by a ring or similar apparatus closely encircling the base of the growth. By this means the external or superficial venous blood current is largely separated from the internal or intra-cranial venous circulation, and the subsequent manipulation of the growth now enables one to decide from which system of veins the blood supply is derived.

The method was employed quite a number of times, and in each instance fully demonstrated its utility and importance as a diagnostic measure.

DIAGNOSIS.

In uncomplicated cases, the history of the lesion, its location, want of marked elevation, and slow progress; the usual normal color and texture of the integument of both the tumor and adjacent surface; the positive influences of the posture coupled with those resulting from pressure of the jugular veins; compressibility of the growth—its easy and usually complete but slow evacuation; frequent fluctuation; the recognition by the finger or exploring needle of bone alteration; and very often of perforations in the cranium; the absence of bruit and pulsation; the effect of the application of a circular compression; vertigo produced by certain positions and movements; and lastly, the demonstration by puncture of the presence of venous blood filling the tumor, constitute a symptom-group scarcely to be misinterpreted. Hence, as a rule, the diagnosis should not offer specially confusing or obscure features.

There are, however, a number of lesions presenting symptoms in common with this formation, which might claim consideration in a nice or accurate differential diagnosis, and, therefore, the principal of these affections call for a brief reference:

Thus a certain degree of resemblance is borne to (1) meningocele and (2) encephalocele, or (3) superficial *nævus* coexistent with these; (4) cephal-hæmatoma; (5) simple subcutaneous venous erectile or vascular tumor (including, possibly, the capillary variety); (6) lymphatic vascular tumor; (7) certain cystic tumors; (8) venous aneurism; (9) rarely aneurism of the middle meningeal artery associated with bone erosion; (10) fungus of the dura mater; (11) pneumatocele; (12) traumatic cephalhydrocele; and, under rare circumstances, (13) circumscribed abscess, especially where skull perforation has taken place.

In those instances, however, where an individual case offers specially confusing difficulties, or, at least, where questionable points prevent a definite conclusion, the demonstration of a tumor containing fluid, completely or partially reducible under lightly applied pressure without producing cerebral disturbance, directly influenced by posture and circular compression, and of which puncture or aspiration shows the fluid to consist of living venous blood, would be quite sufficient, against otherwise doubtful symptoms, to confirm the diagnosis.

PROGNOSIS—PROGRESS.

Analysis of the cases collated shows that, this class

of sanguineous tumors if left to nature and not disturbed by treatment, does not incline to a fatal termination; and, therefore, the prognosis may be looked upon as favorable in all the types of the lesion as far as life is endangered or even serious impairment of health is concerned, and, indeed, spontaneous cure is said to have resulted in one recorded instance.

Where, however, surgical interference is resorted to with the view of a radical cure or permanent resolution of the growth, then the prognosis becomes of very different import—assuming an important, if not serious, phase—and being materially influenced by the special type or variety of the tumor involved, with also the particular operative method adopted.

In the large majority of those instances where no active surgical treatment was employed, and which were kept under observation for a longer or shorter period, there was not only no marked change in the attending symptoms, but the progress was noticeably slow—there being but little tendency evinced to extension or any decided change whatever. Thus, in illustration of the general stationary tendency of these tumors after a certain size is attained, it may be mentioned that of twelve cases, embracing all the classes and the several types, which were followed up, eight were noted as remaining unchanged after five, twelve, fourteen, twenty, forty, forty-three, forty and seventeen years, respectively; and in the latter instance the growth disappearing spontaneously after a long examination, including repeated palpations. But in two other instances moderately rapid growth was reported,—in one of which the progress being slow for twelve years, and then in the succeeding four years rapid increase took place, with the development at the same time of a second tumor or sac communicating with the first.

Whereas, on the other hand, among seven patients upon whom operative measures were practiced, comprising free incision, strangulation by ligature of the base, the actual cautery, and electro-puncture, there were four deaths, two each from immediate hæmorrhage and suppurative phlebitis with meningitis. The three successes which resulted were respectively from strangulation by ligature, incision, and electro-puncture. It must be referred to, also, that the two cases of M. Azam were unaffected, apparently, in their symptoms and progress by the repeated punctures of the pouch which were practiced for diagnostic purposes.

TREATMENT.

Notwithstanding the fact that *palliative* or protective measures have received the strong endorsement and recommendation of the larger number of writers upon this subject, and by some is regarded as the only treatment to be adopted (v. Gross, Dupont, and others), and although almost universally employed, with but few exceptions, in the collected cases, the histories of these prove that such methods exercise hardly any, if, indeed, not being wholly without appreciable effect over the progress or course of the affection, and hence must be declared not only fruitless, but, in some instances, positively harmful.

This can scarcely serve as a matter of comment

when the anatomical and pathological characters of the lesion are considered, and, therefore, beyond the mere statement of the results of palliative treatment, this portion of the subject does not demand further consideration.

Measures having a radical or *curative* object in view, were of two forms, namely, direct compression of the growth, and certain operative procedures.

The former, or the application of *direct compression* to the tumor, occupies a very similar position to that of palliation, as far as exerting any retarding or inhibitory influence over the course of the disease; and, at the same time, on account of the effect produced in several trials of the method, it should be regarded also in the light of a dangerous or hazardous operation when indiscriminately employed, and especially so in certain varieties of the lesion. Thus, in a case of probable varicose emissary veins, M. Azam punctured the tumor and practiced steady and continuous pressure for twenty days, but not the slightest benefit whatever was obtained, and the patient was dismissed in an unchanged condition.

Hecker applied compression for a considerable time without effect, in a case of frontal diploic tumor with loss of osseous tissue; continued and carefully regulated pressure proved equally useless in the patient of Nèlaton and Richard; and the efforts of Hutin to cure by compression, with leaden and silver plates, a blood-pouch resulting from cranial fracture and accompanying sinus-wound, were likewise ineffectual. Again, Dubois, in a case of frontal tumor, probably of the diffused variety, first attempted compression by bandages, but without benefit or change; then later forceps-pressure was employed for forty-eight hours, but such excessive pain associated with cerebral symptoms of an ominous character, and decided reactive or inflammatory changes both within and without the sac, were provoked, that the attempt was necessarily abandoned. This was also devoid of beneficial result.

In Verneuil's patient spontaneous subsidence of the growth took place after repeated and prolonged handling and palpation of the tumor. Such manipulation should be reckoned as a form of compression, but in this instance the observation loses its value because of the inaccuracy of the history, failure to follow up the case for a sufficient length of time, and the consequent doubts expressed by the reporter himself.

The nature and extent of the *operative* interference employed, are represented by the following methods, viz.: free incision, and incision combined with cauterization; constriction or strangulation of the base; the actual cautery; and electro-puncture.

The operation of laying open the tumor by *free incision* was resorted to in four instances.

Pott, mistaking a diffused form of the lesion following direct wound of the sinus from fracture in the person of a lad, employed incision and trephining with a favorable result.

In the case of an adult suffering from a growth composed of varicose venæ emissaria, Moreau divided the tumor directly across, and, in order to staunch the alarming hæmorrhage which ensued, he

made frequent cauterization of the wound with antimony. Death took place on the fourth day from suppurative phlebitis and meningitis.

Flint's patient was an infant with a probable ectasia of the sinus through the fontanelle, in whom immediate dissolution from hæmorrhage was the consequence of an extensive incision.

The last instance is the patient of Hutin, who had an old blood-tumor of the cranial vault produced by injury. During a subsequent attack of erysipelas, in which he became unconscious, this swelling was taken for a pus collection and freely incised. Venous blood flowed abundantly, but pressure easily controlled it. Pleuro-pneumonia caused a fatal termination.

In two other cases of probable varicose emissaries, small punctures were made to aid diagnosis, but without observable effect.

There are two examples of constriction or *strangulation*. Merseman's patient was an infant at the breast, with a venous tumor of the varicose type. Complete strangulation effected a cure. Foucteau encircled the base of a large tumor on the head of a child, which proved to be a sinus ectasia, with a stout ligature and then punctured the growth. A large quantity of blood was withdrawn, and the child succumbed on the following day, from hæmorrhage, he believes.

The *actual cautery* was employed by Michaud in a varicose formation. Erysipelas and meningitis followed the application, and death took place therefrom on the seventeenth day.

But one case, also, represents the use of electro-puncture. This was in an adult upon whom Bardleben successfully punctured the tumor, which was probably a varicose formation, communicating with the longitudinal sinus.

Summing up the evidence furnished by these several cases of operation, it is seen that incision gives one cure in four, and that one being of the traumatic diffused form; strangulation gives one cure in two, the successful issue being of the varicose type; the only instance in which the actual cautery was employed—a case of varicose emissary veins—ended fatally; and the single use of electro-puncture in a similar form of the lesion was attended by gratifying results.

The causes of death in these cases brings up the question of the dangers to be apprehended from surgical or operative measure, and which may be embraced by phlebitis, attended by thrombosis and embolism, meningitis, septicæmia, hæmorrhage, air-embolism, and serious cerebral disturbances.

Phlebitis, meningitis and septicæmia are so closely connected in the present relation that they may be properly discussed under the same heading. From this cause two deaths took place out of seven operations, and therefore on this account and for apparent anatomical reasons such a danger assumes an important and just significance. This is furthermore borne out by well-known clinical examples, and also by the experiments of Schellmann (v. Bergmann, l. c.) who found that the chief danger resulting from sinus-wound was the formation and subsequent disintegra-

tion of the thrombus—leading to septicæmic infection. However, the aseptic management of wounds which characterizes modern surgical practice, associated with our increasing enlightenment concerning the tolerance of the venous system in general, and especially, in the present instance, the veins of the brain and its enveloping tunics, to operation wounds and accidental injuries, not only marks a great scientific advance in surgery, but has reduced in a wonderful degree the risks and dangers to be apprehended therefrom; and consequently revolutionized our ideas of the once dreaded inflammatory and septicæmic processes.

Although two fatal results are reported in our collection from immediate hæmorrhage, I cannot regard this danger from sinus-wound in the same light as it is evidently looked upon by many authorities. Wounds of the dural sinuses if extensive are, undoubtedly, attended by profuse and even alarming loss of blood, but the methods at our disposal for controlling such hæmorrhage are both trustworthy and easy of application.

Thus the efficiency of simple pressure in arresting hæmorrhage is exemplified not only in the special lesion under consideration by the cases of Pott and Hutin, with those cases which were simply punctured, in which pressure sufficed to permanently staunch all bleeding, but also in different injuries and wounds of the sinuses, as illustrated by the patients of Reid (*Edinburgh Med. Jour.*, April, 1864), Sands (*Annals of Anat. and Surg.*, vol. viii, p. 100, 1883), Hopkins (*Annals of Surgery*, July, 1885, p. 67), and other easily cited instances, and more recently by the experiments of Senn, contained in an admirable article on the subject of Air-Embolism, read before the American Surgical Association, April, 1885 (*v. Society Transactions*, 1885, also *Annals of Surgery*, June, July, August and September, 1885).

Numerous other authorities might be adduced in confirmation of the efficiency of pressure, but, beyond the additional mention of the paper of Hector Cameron (*Lancet*, May 24, 1884), in which is shown that in many, or the majority of, instances only the gentlest pressure is required to stop blood-flow from a wounded sinus, further citations would be superfluous.

If I have spoken in commendatory terms of pressure as a hæmostatic measure in sinus injuries, I believe that I am warranted in speaking in an equal, if not more positive, manner of the ligature and suture, especially applied laterally. It is true that Senn (*l. c.*), and he is not alone in this opinion, considers suturing the sinus (including, evidently, lateral ligature) as unreliable and in most instances anatomically impossible, but the successful instances where such measures were adopted are sufficiently numerous to justify my expressions of confidence in the proceeding; and, as furnishing clinical and physiological support to the practice, the experiments of Schellmann, already referred to, demonstrated the important fact that wounds of the sinuses heal without causing obliteration of the sinus,—the wounded wall becoming thickened in the reparative process but the lumen of the vessel remaining unobstructed.

Such successful employment of the lateral suture and ligature in the cases of Brinton (*Philadelphia Med. Times*, vol. xii, p. 577, 1881) and Parkes (*Annals of Anat. and Surg.*, vol. viii, p. 118, 1883), are by themselves adequate testimony of its practical application and reliability.

Proximal and complete double ligature of the sinus has been shown to be largely devoid of serious results, and calls for adoption when other less severe methods have failed or proved incompetent to meet the indications required.

Besides other important facts shown by Schellmann, he has indicated also, by both experiment and collated cases, that contraction in the calibre or even complete obliteration of the lumen of the large dorsal sinuses need occasion no constant disturbance in the brain, but, on the contrary, that such obstructions may and do exist for an indefinite time without the manifestation of any grave cerebral symptoms. Additional evidence of the immunity with which these venous channels may be reduced or lessened in their calibre, is seen in the case of Parkes (*l. c.*), where the sinus longitudinalis was diminished at least one-third by lateral suture, and also that of Kuester (*Berliner Klin. Wochenschrift*, Nov. 14, p. 673, 1881), who, in the extirpation of a sarcomatous growth from the dura mater of the frontal region, successfully practised prophylactic double ligation of the exposed longitudinal sinus.

This subject of deligation of the sinus has been particularly studied by Senn, and, as a result thereof, he considers it a safe measure for the arrest of hæmorrhage, and believes that preliminary ligation will become an accepted procedure in the removal of dural and other tumors involving this structure. Certainly the subject is an important and interesting one, and with me fully maintains the feasibility of ligation of the sinus in specially severe cases of ectasia or hernial protrusion of the sinus-wall, and also of the diffused variety, demanding surgical action.

The aseptic tampon (Senn), cold (Abel), position, and styptic substances as means of arresting bleeding from this locality need not be discussed.

Air-embolus or aspiration of air into the sinuses is a danger which, although having but one known recorded instance of a fatal occurrence to demonstrate its possibility, namely, Volkmann's case (reported by Geuzmer (*Verhandlungen der Deutschen Gesellschaft für Chirurgie*, vol. vi, p. 32), must be recognized and borne in mind in all operations implicating these venous reservoirs; and, indeed, the assertion of Franck (*Sur la transmission de l'aspiration thoracique jusqu'aux canaux Veineux des os du Crâne, etc.*; *Gazette Méd.*, No. 25, 1881) that he has witnessed more than once after trephining the entrance of air into the diploic veins, should admonish us that the so-called danger zone is not limited to the cervical region, and to exercise due precaution in dealing with all operations and injuries implicating the cranial tissue.

It is unnecessary to examine any farther this danger of air-aspiration in these localities, and for more accurate information of the subject generally I cannot do better than direct you to the literature of the

entrance of air into veins, and in particular the valuable and elaborate paper of Senn, which has been already several times referred to and quoted from.

The occurrence of serious brain perturbations and disturbances attending operative measures upon the sinuses, rests almost entirely in an interference with the delicate equipoise of the cerebral circulation. This question has been clearly answered in the negative by the observations of Schellmann, and the cases I have referred to, to which may be now added the patient of Schüppel (*Ziemssen's Handbuch, Galle and Pfortader*, p. 324, mentioned by Browning, *l. c.*) in whom the superior longitudinal and both transverse sinuses were found obliterated by an organized thrombus, and with compensatory anastomosis.

In conclusion, after this brief sketch of the treatment of this class of sanguineous formations, I must express myself as favorably inclined towards curative operative measures—especially by the suture and ligature, electro-puncture, and strangulation of the base—in certain extreme instances, the particular method chosen to be governed by the type and form of the individual case involved.

RECAPITULATION.

As a result of the foregoing study the following summarized conclusions are reached:

1. Cranial venous blood tumors communicating with the dural circulation are to be classified into three divisions, namely: the congenital, spontaneous, and traumatic.

2. These classes are divided, upon both anatomical and pathological grounds, into two species or varieties: *a*, the diffused, produced by a perforation of the cranial plates and the wall of the subjacent sinus, resulting in a limited extravasation of blood beneath the scalp and thus forming a blood-cyst in direct or immediate communication with the affected sinus; and *b*, the venous or vascular, in which the tumor is directly formed at the expense of the venous coats, and includes in its scope the sinuses, the *venæ emissariae*, and the diploic vessels.

3. The venous type is the commonest in point of occurrence, and of this type, varicose involvement of an emissary vein is the most frequent form; whilst the diffused is the rarest of all the varieties.

4. The diffused variety is especially characteristic of the spontaneous and traumatic groups. The venous or vascular type occurs most frequently in the congenital class, but at the same time is often met with in the spontaneous division.

5. The medium of communication with the intracranial circulation is, in the very large majority of instances, represented by the superior longitudinal sinus, particularly its central and posterior portions. The emissaria Santorini most often implicated are, probably, the superior or posterior parietal emissories, which pair, also, are the most constant and uniform in their existence. When the diploë is involved the frontal region is the usual seat—no instance of a similar occipital formation having been observed.

6. In a causal relation, some morbid action in the venous walls is notably prominent in the congenital class; in the spontaneous group, atrophic or rarefying

osteitis ranks first as a cause, and venous disease secondly; and in the traumatic division, direct injury, which nearly always means fracture, is the only etiological factor.

7. Palliative measures for retarding or arresting the progress of the growth, and certain forms of compression intended to act as a curative agent, are useless applications—the latter, in addition, being capable of producing alarming head symptoms, and hence may be harmful.

8. General surgical interference is not called for, because the history, nature, and progress of the lesion is opposed to indiscriminate operation; being of that character to render such treatment unnecessary. When, however, operation is deemed expedient or is demanded, the following methods seem to be open for adoption:

First, if the growth be either of the diffused type, or that form consisting of a varix-sinus, exposure and ligation of the pedicle (if such exist), or, if necessary, deligation of the sinus in its course, the trephine being boldly employed to furnish requisite space for the necessary attending manipulation. The lateral ligature and suture, when applicable, are preferred to complete ligation.

Second, if the tumor be composed of varicose emissary vessels, or, perhaps, of diploic dilatations, either electro-puncture or strangulation of the base are justifiable procedures, but preference is given to electro-puncture.

MEDICAL PROGRESS.

CAFFEINE AS A DIURETIC.—Our knowledge of the physiological action of caffeine is insufficient to fully explain the powerful diuretic result that so frequently attends its therapeutic use. The modification of the pulse-rate and the increased blood-tension that ensue upon its use owing to excitation of the vaso-motor centre, do not explain the phenomenon. For this reason, W. VON SCHROEDER, of Strassburg, followed the question up experimentally. He has arrived at the conclusion that caffeine exercises a powerful and energetic influence upon the renal secretion through a direct stimulation of the specific secretory elements.

Caffeine may so influence the vaso-motor centre that urine-secretion becomes diminished. In order to eliminate any influence on the part of the vaso-motor centre upon the secretory apparatus, Schroeder produces paralysis of the named centre in animals by means of chloral hydrate.

Thus a marked reduction of blood-tension results. A rabbit of $4\frac{1}{2}$ pounds was profoundly chloralized, and canulæ were inserted into the ureters. Thereupon, within a space of seventy minutes time, one-half gram, seven and one-half grains, of caffeine were injected in three portions into the jugular vein. The amount of urine excreted during the seventy minutes was about eleven times the ordinary normal amount. In the absence of any specific secretory nerves of the kidneys, and from the circumstance that the circulation after chloralization takes place in strongly collapsed vessels, the reporter arrives at the opinion that caffeine must exert a direct influence upon the renal epithelia.

In order to demonstrate this conclusion more clearly, the experimenter proceeded by tearing all the nerve-filaments entering the one kidney of an animal, and left the nerve supply of the other gland intact. Thus all vaso motor influence upon the one kidney is eliminated. In order to preserve this influence in full force as regards the intact kidney, the

animal was placed, before experimentation, under the hydrochlorate of morphine. In a rabbit, the above described experiment showed an enormous increase of secretion from the kidney whose nerves had been severed, over the amount eliminated during the same time from the intact kidney, after caffeine had been introduced into the circulation. Therefore, it follows that caffeine stimulates diuresis by direct action upon the specific secretory epithelia.

The strong diuretic action of caffeine has, until recently, escaped general attention on account of the double influence exerted by the alkaloid, *i. e.*, the excitatory influence upon the central nervous system, similar to that of strychnia, and the stimulating influence upon the secretory elements of the kidney. The latter physiological action may be inhibited and even completely masked by the former. The method of pharmacological analysis adopted by Schroeder, threw out the vaso-motor element of action and brought the special influence upon the renal gland apparatus into prominence.

Schroeder compares this dual quality of caffeine to that of pilocarpine. Small quantities of these alkaloids are sufficient to promote specific secretion. This peculiar action of caffeine demonstrates, according to Schroeder, the glandular nature of the kidney in a more pointed manner than any hitherto adduced argument, and shows that the kidney is not a simple filter.—*Weekly Med. Review*, July 24, 1886.

CONTROLLING BLEEDING DURING EXCISION OF THE TONGUE.—MR. JORDAN LLOYD describes a method controlling bleeding from the tongue during partial or complete excision. The patient is placed under ether, a gag adjusted, the left index finger is carried well to the bottom of the glosso-epiglottidean pouch, defining clearly the hyoid bone with its cornua, the front of the epiglottis, and the back of the root of the tongue. A stout, long, well-curved, mounted needle, threaded with medium sized whipcord, is entered from the front of the neck, in the middle line, immediately above the hyoid bone; one feels for the point of the needle with the left finger, as the instrument is pushed through the root of the tongue. In this way, the epiglottis is protected from injury, and nothing more than the lingual tissues are transfixed; then hook up the loop of thread with the left finger, and pull it well through and out of the mouth. Withdraw the needle, liberate the thread from it, and cut through the loop. Now enter the empty needle at the same point of puncture, through the skin only, and pass it subcutaneously to the right, until its point is opposite the upper border of the root of the great cornu. Care must be taken to keep just under the skin, and so avoid the lingual artery. Now turn the point inwards above the great cornu, so as to enter the bottom of the side of the pouch, and feel for the point of the needle with the finger. Thread one of the ends of the cord, which is in the mouth, through the needle, and withdraw. This casts a loop around the right half of the tongue. The left half may be dealt with in a similar manner.—*London Medical Record*, May 15, 1886. *Boston Medical and Surgical Journal*, August 26, 1886.

TOXIC URINE AND SURGICAL OPERATIONS.

In a recent article, in the *Liverpool Medico-Chirurgical Journal*, of July, 1886, "On Toxic Urine in Relation to certain Surgical Operations on the Urinary Organs," MR. REGINALD HARRISON says that it is impossible to study a series of cases of internal urethrotomy without recognizing that, apart from their surgical interest, they may be regarded as extremely valuable physiological experiments in relation to some unworked-out problems connected with animal chemistry. All surgeons have noticed the frequency with which urethrotomy by the method of introducing a concealed knife within the urethra is followed, within three or four hours, by a rigor, and a subsequent development of more or less pyrexia; that these attacks may be repeated at varying intervals; and that they differ widely in degree, some being very mild, while others are fatal within a few hours. We cannot explain these attacks by referring them to something like reflex action upon a pathological kidney, for the post-mortem examinations have shown that they may occur in patients with perfectly sound kidneys. Nor can the attacks be explained by a supposed traumatic action: "If a man's brain or cord is damaged by a blow or a shock, he shows signs of concussion or nerve traumatism immediately upon the receipt of the injury, and not three or four hours afterwards."

Again, if it be a nerve lesion of the urethra which is the cause of the attack we should see urethral fever occur after the far more extensive nerve injuries produced by lithotomy and other severe operations on the urinary tract. "The improbability of urethral fever after internal urethrotomy, catheterism, and such

like, being due directly to nerve shock, is indicated by other collateral considerations which may be noticed. In the first place, we should expect such symptoms to follow Holt's operation for stricture just as frequently and severely as after section of the stricture from within. On the contrary, rigors and fever are far less commonly met with after dilatation with rupture than after internal urethrotomy—tearing or stretching is considerably less productive of urinary pyrexia than incision. In the next place the position of the wound in internal urethrotomy, relatively to the circumference of any given part of the urethra, should hardly be expected to exercise a sort of determining influence in the production of rigors and fevers, if the causation of these effects was a nerve lesion. Yet we find such symptoms more frequently follow when the section is made on the floor of the urethra in preference to the roof. A dependent position of the urethral wound is more likely to be associated with fever than one not so situated. Lastly, we should hardly expect the manifestation of these symptoms to be influenced by mechanical after-treatment if damage done to the local nerves was the cause of the symptoms that followed." But when we analyze a number of cases in which a catheter is worn for a time immediately after internal urethrotomy, and bladder drainage carried out in a thorough manner, we find that a very considerable proportion of these cases escape attacks of urethral fever.

If these effects, asks Mr. Harrison, are the result of nerve lesions, how is it we do not see them following lithotomy and properly performed perineal section for urethral stricture? In regard to perineal section, "the earlier experience of Syme only shows how easy it is to construct a perineal section which proves to be just as ready a cause for rigors and fevers as any internal urethrotomy. In looking over the notes of my earlier cases of internal urethrotomy, it struck me, as being worthy of remark, that neither rigors nor fever showed themselves until after mic-turition had been naturally practised, or there was evidence that urine had found its way into the wounded urethra and was lodging there." This again is opposed to the idea that nerve lesion is concerned in the production of the attacks, since the symptoms did not appear until urine had come in contact with the wound. These considerations led Mr. Harrison to think that the rigors and fever were symptomatic of poisoning rather than shock; and he determined to test the matter in practice. He resolved to perform a series of operations in suitable cases, in which, though internal urethrotomy was done, no urine would be allowed to remain in contact with the freshly

made wound. This involved an external perineal urethrotomy being done immediately after the stricture had been divided from within. After doing this a number of times he saw that it was possible to produce rigors and fever at will. "So long as the bladder drainage through the external perineal wound was free and uninterrupted, there was invariably a complete absence of rigors and fevers."

It is now proper to ask as to the different conditions under which the surgeon has to deal with wounds which are exposed to the action or influence of urine. "Running healthy urine may be regarded as absolutely innocuous. When it can make its way over a fresh cut surface, or out of a cavity, just as fast and uninterruptedly as it flows over or in, it need cause no apprehension; on the other hand, when it is pent up, as in a wound or space, it is apt to be speedily converted into a most destructive, and, I believe, poisonous agent." The conditions, for the production of urine fever, attending the operation for internal urethrotomy are very favorable. The incision which divides the contraction necessarily paralyses the urethra to a greater or less extent; and hence the process of repair must go on with the wound soaked in urine left behind to stagnate and decompose after each act of micturition—and this is a different matter from the incontinent flow of urine over the glazed and granulating open wound of a lithotomy or a perineal section. "In one case it is merely contact of urine with open spaces, in the other retention, and probably chemical rearrangement, within a space bounded by a freshly made wound. My direction and kind of work led me to believe some time ago that the urine could provide septic material of a kind which seemed to me to have been previously unappreciated in connection with the causation of urinary fever."

Valuable, as bearing on this question, are the experiments and work of Bouchard in regard to the toxicity of urine. Four years ago he showed that alkaloidal substances are constantly present in the urine in some infective disorders; and he showed that these alkaloids are of an intestinal nature—that is to say, they are produced in the intestinal canal by the growth of the vegetable organisms contained therein—and that they are analogous to ptomaines. These alkaloids were subsequently found in normal urine. Bouchard drew, among others, the conclusion that the alkaloids of normal urine represent a fractional part of the intestinal alkaloids, absorbed by the intestinal mucous membrane, and excreted by the kidneys. Two years after his first paper, he determined (in 1884) the effects of normal urine on rab-

bits, and found that the same doses produced different effects according as the animal furnishing the urine was or was not in health; that the toxicity varied in different individuals; that the symptoms depended on several different substances; that the alkaloids soluble in alcohol differ in their effects from those insoluble in alcohol; that although five or six substances may be present, they may be arranged in two groups, a *convulsive* and *narcotic*; and he concluded that the symptoms in different cases of uræmia may be explained by these groups being present in varying proportions. The symptoms of urinary toxæmia from the introduction of urine into the veins of rabbits are, in the order of their occurrence: 1. Contraction of the pupil. 2. Acceleration and diminished amplitude of the respiratory movements. 3. Increase of urine. 4. Fall of temperature. 5. Diminution and finally abolition of reflexes. 6. Convulsions usually with coma, and 7. Death; the action of the heart and the electro-contractility of the muscles persisting for a time after death. The fall in the temperature is due not to increase in the loss of heat but to a diminution in heat production. Bouchard calculates that a man excretes enough poisonous matter by the urine to kill himself. "During eight hours, if asleep, only from one-quarter to one-half as much poison is excreted as during the same period when awake. If the whole day be divided into three periods of eight hours each, the proportional quantities of poison excreted are—sleep, 3; early waking period, 7; late waking period, 5. The urine of the sleeping and waking hours also differs qualitatively as well as quantitatively. The alkaloid of the urine of sleep is *convulsive*, that of the waking urine *narcotic*. The urinary poisons of the sleeping and waking hours are not only different, they are physiologically antagonistic. Fasting increases the toxicity of the urine, probably because then the individual lives on his own tissues, and these are relatively more difficult of oxidation than the ordinary food, and are less completely oxidised. Labor greatly diminishes the toxicity of the urine, as does also the breathing of compressed air." Why are these symptoms not produced when urine, after ammoniacal, is subcutaneously forced among the tissues, sometimes in large quantities, as in cases of stricture and sudden urinary extravasation? "The conditions attending subcutaneous urine extravasation are essentially different from those associated with the continuing contact of urine with a wound in the urethra, as in internal urethrotomy. A mixture of blood and urine seems to be capable of producing very different compounds from those that extravasated urine

alone is likely to yield. Nor are we entirely to lay aside the consideration, that whatever *materies morbi* may be found at the seat of the wound by the conjoined decomposition of stagnant blood and urine, its entrance into the circulation must be favored by the contractile power of the bladder from behind. Again, when urine is extravasated amongst the tissues, its action is that of a virulent local poison, under the influence of which the contiguous tissues are killed outright, probably before they can exercise any power of absorption. Such a conclusion seems likely from some of Mensel's experiments, where putrid and normal urines were subcutaneously injected into various parts of the body." But why is it that the same symptoms have been produced in sufficient intensity to cause death within a few hours, when there is no evidence to show that the urethral walls have been lacerated by the catheter or bougie? There may be no external evidence of laceration, but it is extremely likely that some lesion has been produced. Mr. Harrison has frequently drawn attention to this point, and has shown how readily false conclusions in reference to it may be drawn.

THE ORGANIZATION AND PRACTICAL WORKING OF THE SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION.

In giving a brief account of the recent meeting of the British Medical Association at Brighton, in *THE JOURNAL* of September 25, we stated that there were some things in the practical working of the Sections that might be profitably imitated, or even improved upon, in the Sections of the American Association.

Among these were, more care in the early and complete preparation of papers and their announcement in the columns of the *British Medical Journal* a considerable time prior to the annual meeting, thereby making it possible for the officers of each Section to arrange for a more profitable discussion of all the more important topics to be presented. To accomplish these results requires no change in the by-laws or organization of the Sections of our Association, but simply a better appreciation of the duties devolving both upon the officers of the Sections and those who prepare papers. It has been too much the custom for the officers of each Section to rely entirely upon the voluntary or unsolicited contributions of members, and to give no notice of such contributions as are offered until they are announced in the programme prepared by the Committee of Arrangements and furnished to members at the registration table. Instead of this it should be regarded as one of the most important duties of the President and Secretary

of each Section, as early as possible after their appointment, to select at least three topics (one for each day's session) of importance and practical interest belonging to the Section, and to secure specially qualified members to present these subjects at the next meeting, and one or more equally qualified members to lead in the discussion of such topics. This would in no wise interfere with the acceptance of voluntary papers from any other parties who might offer them in due time, but it would be quite certain to secure something of special interest for each session of the Sections. And if the principal topics thus selected should be announced in the *Journal* of the Association one, two, or even three months before the time of the annual meeting, it would attract the attention of many, excite more investigation, and result in a much more constant attendance in the sessions of each Section. We respectfully invite the attention of the officers of the several Sections to this subject, with a view of promoting the interest and importance of the meeting of the Association in Chicago next Spring.

"DEADLY SANITARY PLUMBING."

Under this somewhat paradoxical head the *Chicago Tribune*, of September 12, steps from the world of science and fact and revels in the unlimited fields of ignorance and imagination. Without stopping to show how plumbing or anything else that is deadly can be *sanitary*, the writer of that editorial stumbles through a mass of misleading, weak and easily disproved assertions, to finally reach the conclusion (the only statement in the whole editorial which cannot be easily disproved) that "in those portions of Chicago where there is the least plumbing there is the least sickness arising from its effects;"—which is equivalent to saying that in those countries in which there are no railways there is no danger of being killed by a locomotive. But why limit the statement to Chicago? It is equally true of Hong-Kong.

"As at present constructed," says this remarkable editorial writer, "plumbing is simply an easy arrangement for the conveyance of the gas from bath-rooms, and water-closets, and sleeping-rooms, not to speak of the basins themselves, which assist in the deadly work (of carrying off the gas?). Where there is no plumbing to connect them (the water-closets and basins?) with the street sewerage there is no trouble from the gas." The greatest and most important discoveries are sometimes stumbled upon by accident, and sanitarians and plumbers have worked and waited for many years, only to have the real use of plumbing discovered by a "deadly sanitary" writer.

There has long been a popular superstition that plumbing was for the purpose of conveying waste water, slops and sewage from bath-rooms, water-closets and sleeping-rooms to the street sewers; but the *Tribune* has exploded this fallacious idea. The *Tribune* seems to think that "the gas" is generated in the wash-basins and bed-rooms, and yet complains of the plumbing for being "an easy arrangement" for conveying it away; the wash-basins themselves being accessories in the "deadly work of conveying the gas away." Here again is another new scientific fact: "Where there is no plumbing to connect them (bath-rooms, water-closets, sleeping-rooms and wash-basins) with the street sewerage there is no trouble from the gas." The fact is, it is just under this circumstance, or when the plumbing is defective, that there is trouble from the gas. If the plumbing and drainage of the *Tribune* office be in accordance with the unsanitary ideas of the editor it should be inspected by the Health Department.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Sept. 6, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. J. S. JEWELL gave a partial verbal abstract of his paper on

OVERFILLING AND DILATATION OF THE COLON.

He said that for the last ten years this subject had attracted more or less of his attention. During the last eight or ten years he had accumulated a list of over five hundred carefully studied cases, in which the condition named existed and concerning which he gave his observations. His mode of investigating the cases in which the overfilling existed has been as follows: The patient is stripped so that the abdomen is bare, the abdominal walls being relaxed. Then he takes a plate of soft rubber at least two inches in length by an inch and a half in breadth and one quarter inch in thickness, and a heavy steel hammer, quite as heavy as the ordinary surgical bone hammer. With this the abdomen is carefully percussed over the track of the colon, from its origin tracing it up under the liver, across and down to the sigmoid flexure. Thus percussing over the track of the colon and carefully locating every mass of feces, (even in persons with fleshy abdominal walls) he has been able to get at its course and contents. Out of these five hundred cases, perhaps a hundred have said that they were as "regular as clockwork" in having movements from the bowels. But upon examination, in most such cases the colon was found to have variable quantities of fecal material lying in it. The part of the colon

most subject to dilatation is the sigmoid flexure and the descending colon. At the flexure of the colon, deep in the left hypochondriac region, almost as frequent as in any other part of the course of the colon, he had found it dilated and filled with fecal matter. The next most common situation is the transverse colon, last of all the cæcum. In one case where the colon was very largely dilated, during the thirty or forty hours that were devoted to emptying the same (not continuously but at different times) two gallons or more of material were removed. The common way is to find masses of feces lying in lumps here and there, not filling the entire intestine.

In one case a mass was removed from the right extremity of the colon by massage, and flooding the colon its entire length with water. The fact that this mass had remained in the colon for more than nine months was ascertained in this way: The patient had taken a dish of dewberries such as appear in the fall after the ordinary blackberry has passed its season. He was in ill health, and growing worse during his visit returned home. This was in September. Dr. Jewell saw him early in June following. When the mass was removed it was found to be more or less filled with the seeds of the dewberry, and according to his own account he had not taken berries of any kind since the September previous, certainly no dewberries. This mass was about the consistence of soft putty and the size of a large Irish potato.

In most cases investigated the colon was dilated apparently, in some part or other, all the way from two to three times its proper caliber. This class of patients are all liable to become "bilious" and are habitually taking cathartic pills, mineral waters, etc. In every or nearly all instances, Dr. Jewell could trace their "biliousness" to gradual filling up of the colon, and the disturbance produced from this cause in the digestive apparatus higher up. The change in the secretions of the mouth, the bad breath, the unhealthy odor of the skin produced by absorption of foetid substances from the rotting masses in the intestine together with the coloring matter in the same, gives the skin of the patient a peculiar dirty sallow color. One of the first things to occur in addition to the dilatation, and weakening of the muscular coat of the colon by accumulation of material in it, is irritation of portions of the mucous membranes were the fecal masses lie, producing local catarrhs. This occurs with a frequency and to an extent that no one would suspect, unless they set the patient or nurse to carefully watching the stool. The next important factor in these cases is irritation of the peripheral ends of the sensory nerves of the intestinal mucous membrane, irritated by contact with the fecal masses. The nerves that return from the colon probably enter the spinal cord, at a level not lower than that of the tenth or eleventh dorsal vertebræ. Above the level named they probably enter the cord at various points higher up in the lower two-thirds of the dorsal cord, not to mention direct medulla connections, etc. Along these nerves are propagated the irritative impressions from the colon into the spinal cord or medulla, and thereby "switch" connections outgoing or reflex impulses are sent to other portions of the body,

producing thus various forms of disorder to be referred to later. He believes that he has not found one case out of twenty of ordinary melancholia that has not had its origin partly or in some cases apparently entirely in overfilling of the colon. Headache and a great many transient disorders referred to the head more frequently owe their origin to this source than he had ever supposed. Next is the influence upon the circulation in general, especially upon the heart's action, lowering its tension, and thus giving a feeble pulse.

Dilatation of the colon often causes a sluggish capillary circulation, and this accounts for the frequency with which patients complain of cold extremities. Dr. Jewell has found patients who could not remember having had naturally warm feet for years, when upon removal of the masses in the colon the feet would become warm. In insomnia he has found the condition of the colon described to be a frequent cause, the colon being the seat of the original disorder. There is lowering of the vascular tension nearly always in these cases, hence the feeble nutrition and feeble circulation in the brain, not to mention other parts. The next most important result of dilatation and overfilling of the colon is the fact that these masses of retained fecal substance in various ways poison the individual, by absorption of septic material. He has had three cases of epilepsy that he traced exclusively, as far as could be told by the results of treatment afterwards, to disease in the left extremity of the colon caused by fecal accumulations, and when the disorder was removed by proper means he was able to relieve the epilepsy. For the removal of these masses, as a rule, he does not use purgatives, but injections are given after the following plan: A large bag fountain syringe, holding half a gallon is adjusted at a convenient height from the floor, the patient lying down in the knee-chest position. The fluid should flow with considerable force until it makes its way past the upper sphincter which is at the lower part of the sigmoid flexure; pass one quart to one-half gallon of water, according to the size of the colon, so as to fill the entire organ to the cæcum. In some instances he has been able to introduce as much as a gallon of water into the colon, the patient feeling no serious inconvenience from it, and a half gallon is a common amount to introduce. The patient is then directed to lie down on the left side, and by proper massage over the ascending colon the liquid is moved and with it the contents of the bowel, toward the rectum. This should be done once or twice in the twenty-four hours until the colon is clear, and by this means it should be kept so. After this has been accomplished give the patient something that will act as a stimulant to the nervo-muscular coat of the colon. A good prescription for this purpose he has found should contain in pill or capsule form extract of cascara, a little belladonna, strychnia, hydrastis canadensis and aloes. By care the colon can be kept clear, and the disorders of the stomach usually disappear, the secretions of the mouth are improved, the skin becomes of a healthier color and loses the distinctly fecal odor that it frequently has.

He has met with a number of cases of so-called typho-malarial fever in their earlier stage with a temperature as high at times as 103-4-5, in which, by removing a great mass of material undergoing rapid fermentative decomposition at the high heat of the body, leading to rapid distension of the colon with gas, the signs of disease abated in a few hours and rapid recovery occurred. Where there is considerable inflammation in the bowel itself he introduces water pretty well charged with listerine or some other antiseptic, and a little glycerine or other medicinal agents, and in this way the intestine is purified and cleansed and the individual immediately improved. It seems now astonishing that it never occurred to him earlier, that to have a mass of feces undergoing fermentation and decomposition in the interior of the body, and in contact with an absorbent surface like the colon mucous membrane is or may be often the real cause of serious diseases.

DR. H. A. JOHNSON in opening the discussion said: This is a subject to which I have given no special attention, but perhaps if I propose one or two questions it may elicit some information. First, the inquiry suggests itself to me as to why this state of things exists, what is the cause of it? Perhaps as the author has suggested our rapid mode of eating, and our neglect of the natural demands of the functions of digestion have something to do with it, but this does not seem to me to cover it all. Secondly, the question arises in my mind as to how far such a state of things as he describes does actually exist in the colon, viz., putrefaction of the contents. So far as my observation goes the contents of the cavities of the body, including the alimentary canal and bladder, are kept from undergoing these putrefactive changes while they are inclosed. It is true that the fecal matters are full of bacteria in various forms, but I am not sure that the ordinary processes that take place out of the body, go on here. Thirdly, as to the function of the colon; it is both an excretory and secretory organ, and nutritive matter that are carried into it are undoubtedly taken up in their passage through it. There should be a delay, a normal arrestation of the progress of the fecal mass from the time it enters the colon at the cæcum till its discharge. In the normal condition the fecal mass is made up of the debris, of the waste matters of food, and the material removed from the blood; there ought to be, physiologically a retardation—time for the accomplishment of these two functions. What is that time?

DR. WM. E. CLARK said: The subject before us is one of great importance, and one to which I have given much thought. My first call in consultation, after my return to the city some twenty years ago, was to a female patient who had been an invalid for a number of years. A tumor could be felt through the abdominal walls, supposed by the attending physician to be a tubercular enlargement of the mesenteric glands, but which proved to be a mass of fecal matter in the colon. It had probably been accumulating for a long time, as after removal it was found largely to consist of bran from Graham bread—her principal diet for several years previous. Under ap-

propriate treatment, with particular attention to the condition of her bowels, the patient apparently recovered her health, though she died some years after with disease of the kidneys—the latter perhaps having some relation to the previous condition of the bowels.

Again, to-day I made an examination of a supposed uterine tumor, and found a tumor but not connected with the uterus—but an accumulation of fecal matter in the colon, and consequently have made arrangements for its evacuation. For the removal of these masses of fecal matter, I first gave cathartic with large doses of olive oil and then use injections of water into the bowel as far up as possible through a stomach tube; sometimes resorting to the placental forceps for the removal of large fragments.

DR. G. C. PAOLI said: I have listened with a great deal of interest to my learned friend to-night. We know that expansion of the colon occurs in many different diseases and there is hardly a practitioner who has not seen it in his practice for years. We see it in typhoid fever, nephritis, hysteria and lead colic. Constipation is undoubtedly a great cause of expansion of the colon. A man gets constipated, neglects himself, his feces become very hard and in consequence pains occur in the colon. With due respect to the author's experience and observation, he must admit that although we meet with cases in our practice they are not so common that we see them in the hospital. In regard to the treatment, we ought to administer such remedies as will give tonicity to the muscular coat of the bowels, such as cascara sagrada in combination with small doses of aloes. But without physical exercise medicine has very little beneficial effect. I have seen a shower bath over the abdomen have a good effect in producing contraction and tonicity of the muscular coat of the bowels. In regard to the injection which the author advises, it is well to remark that the rectum should first have a digital examination, because often hard excrement is impacted in it and under such circumstances the injection would meet with an obstacle. Strychnia may be very good in chronic but not in acute cases.

DR. JEWELL, in closing the discussion, said: The members of the society will of course understand that I have spoken only of the sick people who have come to me, a special class that is not met with so frequently in general practice. I am speaking entirely within bounds when I say that the number of cases that I now have on my record in which overfilling of the colon was one of the principal features of disorder, must be 700 or 800 during the last ten years, and 500 of these have been made the basis of my study. The question as to how long the matter may be left in the large intestine without harm is to me exceedingly interesting, and I have made that a study. The difference between the ordinary slow decomposition of fecal matter in the intestine and unhealthy decomposition, I have taken into account in my study, as well as the conditions or causes that bring about unhealthy decomposition. I am convinced that not enough stress is laid upon this subject. Many persons in the condition I have referred to have been all but ruined by taking by the week,

month and year, cathartics, which must be taken into the stomach first, dissolved and go the entire length of the small intestine before they reach the colon. The colon may be emptied in a much more satisfactory way by means of large injections, together with the use of medicinal agents, to stimulate naturally its weakened muscular apparatus.

DR. A. SCHIRMER reported a case of

ACTINOMYCOSIS HOMINIS,

with exhibition of patient and specimens of actinomycosis.

Frank P., a Pole, 25 years old, married, laborer in a lumberyard, has been five years in this country. No hereditary disease in his family. His occupation in the old country was farming during the summer months and during the winter months he attended to barnwork. He never was sick and never had the toothache. In his 18th year, while chopping wood he received an injury on the chin, which produced a bleeding wound. No medical attendance was necessary at the time. Shortly afterwards he noticed a swelling on both sides of the lower jaw. The swelling of the right side disappeared in a few days, but that of the left side remained three months after the injury. He was obliged, on account of pains, to consult a physician who injected at different times a clear fluid into the swelling. These injections were very painful. Shortly after the injections the skin turned white, and in the course of a few days it broke open and discharged a little pus. Later on the discharge of pus increased, the fistula remaining open. After that time the patient was not able to fully open his mouth. Three years ago, on account of a severe cough, he was unable to work for one week. From that time on he was able to work until last May, when on account of weakness, pains and stiffness in the neck, he was obliged again to quit working. At the end of July Dr. Schirmer saw him at his house. He complained of severe pains in the left side, and stiffness of the neck, being unable to move his head. He was feverish, pulse and temperature increased. He also had some cough; no appetite. Two days afterwards the opening of the fistula was enlarged and several small pieces of necrosed bones extracted. At the same time Dr. Schirmer opened an abscess situated between the jaw and the shoulder on the left side which discharged about one tablespoonful of a thin, serumlike pus, in which were sandlike granules of a greyish-yellow color. The opening was enlarged, and by digital examination and with the sound it was found that the crown of the abscess had no connection with the surrounding tissues. The abscess was superficial and did not extend into the deep layers. After this operation the patient could open his mouth better; ten days afterwards another abscess was opened on the right side of the neck. It discharged almost four tablespoonfuls of pus. The pus was thicker and the granules were considerably smaller than in the abscess of the left side. The skin was hard.

His cough and expectoration have become gradually worse. His appetite and sleep have also failed. For the last ten days he complained of severe pains in the right arm. A microscopic exami-

nation of the pus confirmed Dr. Schirmer's suspicions regarding the character of the disease, who found in the contents of the abscess actinomycoses. He also found actinomycoses in the sputum. Prof. Fenger, to whom he had given some of the contents of the abscess, also found actinomycoses.

DR. NEWKIRK asked if the patient knew of any disease among the cattle he attended.

DR. SCHIRMER: He said there was no disease among the cattle, and nobody else had such a disease.

DR. W. T. BELFIELD said: The case is hardly one for discussion, because Dr. Schirmer has not said anything about actinomycoses as such, but merely about the case. The finding of actinomycoses in the sputum is very interesting, it is undoubtedly a case of actinomycoses of the lungs and must prove fatal. There are only some thirty cases recorded in which this parasite has been found in men. I am not familiar with the literature on the subject for the last year, but up to that time there had been no well authenticated case of actinomycosis observed in man either in England or America.

DR. A. V. PARK read a paper on a case of
CARIES OF THE RIGHT PARIETAL BONE CAUSED BY
RAILWAY INJURY.

The patient was a stout German boy, aged 16, who was injured September 18, 1883, sustaining various lacerations and contusions on the body, besides a V-shaped wound over the left ear and a circular wound nearly over the centre of the right parietal bone. No fracture of cranium was discovered, although at the request of Dr. Park the case was examined by the family physician and the railway surgeon on different occasions. Patient exhibited signs of collapse and rallied slowly. Erysipelas ensued. After fourteen days the boy commenced to regain consciousness, but could not distinguish one person from another, nor remember events which occurred only a few hours before. It was over a week before he had complete control of his senses. Seventy days after the accident a piece of exfoliated bone, size of three cent piece and thickness of external layer of cranium, was removed from wound over right parietal bone. More dead bone was detected, and ninety-two days after the injury an area of two and one-half inches in width by three and one-half in length of diseased bone was removed, the bone being removed down to the diploë. Erysipelas again ensued and lasted about one week. One hundred and fifty-one days after the injury the patient was discharged, with partial deafness of the left ear and impaired vision of the left eye, as the only unfavorable results of the injury. Dr. Park gave as the result of his observations of railway injuries the following conclusions: 1. Sloughing is the rule in contusions and lacerations. 2. Hæmorrhage may be little, but is apt to be great in injuries to head, or extremities where large vessels are lacerated. 3. Examination of wounds should be thorough, and is best done during period of shock. 4. Shock may be excessive and death ensue rapidly, or reaction take place slowly with symptoms of collapse. 5. Amputations are attended with high rate of mortality, owing to liability of stump being at-

tacked by erysipelas, osteomyelitis, sloughing, or pyæmia ensuing. 6. Erysipelas may ensue rapidly and must be manfully combatted. 7. A large majority of persons injured on railways recover but partially. The sequelæ may be paralysis, insanity, loss of memory, impaired vision, deafness, etc. These results may follow immediately, or not appear until months or years after the injuries were inflicted.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, Friday, August 20, 1886.

THE VICE-PRESIDENT, HENRY T. BYFORD, M.D.,
IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

DR. W. W. JAGGARD exhibited

AN OVUM CORRESPONDING TO THE FOURTEENTH
WEEK OF PREGNANCY, SHOWING TWIN PREG-
NANCY, WITH ONE PLACENTA, ONE CHO-
RION, ONE AMNION, BOTH EMBRYOS
OF THE MALE SEX.

The interesting specimen was placed at his disposal through the courtesy of Dr. Daniel H. Williams, of Chicago. The egg corresponded to the fourteenth week of pregnancy. It was a case of twin pregnancy, with one placenta, one chorion and one amnion. The embryos were equally well developed and were of the male sex.

The case illustrated one of the modes of origin of multiple pregnancy. An ovum may have two nuclei, and an embryo may be produced from each nucleus. Under these conditions, the fecundated ovum has one placenta, (or there is anastomotic communication between two fused placenta), one chorion and two amnions. The amniotic septum may be broken down or absorbed, and the embryos may be contained in a single amniotic sac, as in the specimen exhibited.

In a case of single placenta, or fused placenta with anastomotic communication, and a single chorion, the twins are always of the same sex, (Hyrthl, Spaeth, Braun).

DR. JOHN BARTLETT read a paper, entitled

A PROPOSED MODIFICATION OF PORRO'S OPERATION.

After giving a concise history of the classical and Porro's operations, Dr. Bartlett said:

The substitute for Porro's operation which I have to propose is as follows: The operation proceeds as in Cæsarean section till the child is removed, the actual cautery being used in opening into the womb. Then, instead of dragging the womb out of the abdomen through the dominal incision, it is dragged out of that cavity through the vagina. The operator passes a Well's clamp, somewhat modified in its prehensile surfaces and properly curved in coincidence with the par-turient canal, to the fundus of the uterus and there secures a firm grasp into the uterine tissues. By traction upon these forceps, and pressure, and suitable manipulation from above, the fundus of the uterus is depressed into the body of the organ, dragged through the cervix into the vagina to produce complete in-

version. The clamping wire is immediately adjusted, and excision of the uterus and appendages effected at a suitable distance from the vaginal junction. The abdominal wound is closed, and attention is given to the stump in reference to hæmorrhage as in Porro's operation. In lieu of the clamping forceps, in some cases it would answer better, doubtless, to pass a loop of copper wire through the walls of the uterus to be caught upon a suitable instrument, as a rod possessing the flexibility of block tin or solder, passed *per vias naturales* to receive it. The advantages of this operation over Porro's method which suggest themselves are: *First*, that the abdominal cavity is thoroughly closed; the abdominal incision, not being embarrassed by the presence of the large pedicle is as perfectly and as quickly closed as in any other laparotomy. By the process of inversion the pedicle is placed outside of the abdominal cavity, while that may be termed the uterine inlet made into the peritoneal sac is closed by the clamping wire opposing serous surface to serous surface, thus offering the best prospect for speedy and certain agglutination and closure. *Second*, the relation of the parts in the suggested procedure are much more natural, and much less strained than in the *status* in which Porro's method leaves them. *Third*, in the event of drainage becoming necessary in the course of treatment, the effecting of an opening for a tube in the plan proposed can be accomplished very much more easily and safely than in Porro's plan and the tube being introduced, its situation and direction would be the best possible for thorough cleansing of the cavity to be washed.

Serious objections at first thought will occur to the mind of every gynecologist. These will be here stated and subsequently met, as well as may be, by considerations that may be urged in answer to them.

First.—Of all the accidents *post partum* none is generally accredited with so violent a shock to the patient as the very condition which is here made a main feature in a method proposed as conservative. In the old, and in Porro's operation it almost always happens that, either with or without the partial or complete separation of the placenta, the uterus contracts. With such a condition of the uterine walls inversion would prove difficult and sometimes probably impracticable. Hunter said a contracted uterus was as difficult to invert as a jack-boot. When to these difficulties incident to the first step of the operation are added the shock from clamping and incising the uterus, it would seem that the dangers incident to the method proposed might exceed those of the Porro operation.

Second.—In Porro's operation, as in the old Cæsean section, danger begins from hæmorrhage at the moment of incising the uterus, and in the method proposed this danger would be so much the greater as the time elapsing between the two events, incision and snaring of the pedicle, is longer. In the established operations in at least one-sixth of the cases the placenta has been encountered directly in the line of incision. In such instances the bleeding from the double wounds, uterine and placental, would, in an especial manner, embarrass the operator and endanger the patient.

Third.—It must be remembered that in the great majority of cases in which the operations under consideration are undertaken there exist contractions of the pelvis, which may seriously interfere with the main step of the operation, inversion of the uterus.

Fourth.—Apart from these more serious objections it may be urged against the plan by inversion that dilatation of the *os uteri*, a *sine qua non* of the method proposed, does not always exist at the time of operation, and that it may not always, or even often, be practicable safely to effect it.

These objections will now be considered seriatim. As to the first, regarding the shock to the system so often reported in association with inversions, it may be stated that associated with inversion also is very generally hæmorrhage, and to this all-powerful cause of depression may be ascribed much of the shock noticed in cases of inversion. While it must be admitted that in some instances inversion alone, entirely unassociated with bleeding, seems to have produced great shock, and even death, it may yet have happened that in some of these cases, other injuries, as laceration of the uterus, accompanying the inversion, may have been partly responsible for the profound impression observed, and one is the more justified in assuming that this objection may be over estimated, from the fact that in a number of cases carefully observed and reported, inversion has produced no shock whatever, and has in fact been accomplished without the knowledge of either the patient or obstetrician.

Blundell, Dailiez, Dugé, Crosse, Lee, were quoted to support the proposition that shock *per se* is not the cause of alarming symptoms or death, in inversion of the uterus.

By reference to veterinary surgery, cases may be adduced to show not only that uterine inversion among animals is not *per se* especially dangerous, but that inversion, complicated with accidents in themselves accounted most dangerous, is not necessarily fatal. In such cases reposition alone, unaccompanied with any care for existing uterine lacerations may be followed by perfect and speedy recovery. In support of this proposition, cases were cited from the writings of J. Rainard, Guillin, Gellé, Elevout.

As to the objection regarding the difficulty of inverting the uterus after contraction, it must be admitted that contraction of the uterus into a firm body would certainly render more difficult the inversion. The facility with which the flaccid uterus may fall into itself like tripe, or a wet bladder or the finger of a glove, certainly contrasts strongly with the difficulties encountered by experts in restoring the inverted uterus, even as early as four hours after labor. In the absence of any experience in the matter of purposely inverting the uterus, it will be necessary in support of the practicability of this feature of the proposed operation to draw upon experience derived from practice in midwifery. A variety of facts may be brought to bear to show the likelihood of success in efforts at inversion which may be in a measure classified thus: direct facts as to the ease with which it has been accomplished directly after labor; facts showing the readiness with which from trifling causes inversion may be induced within a few weeks after

labor; facts seeming to show that it may even occur in the virgin uterus, and apparently from minor causes. Replacement of the uterus after inversion, whether that organ be lax, moderately condensed, or in a state of complete involution, is an act so nearly akin to that of inversion that any facts tending to indicate the facility with which an inverted uterus may be restored to position have a bearing upon the question of the practicability of inverting the uterine tissue. Hence in the category of available facts for our present purpose belong those showing facility, or possibility of reduction of the inverted womb at any stage or condition of inversion. Referring to inversion, Barnes, Hunter, Byford, Gooch, Boivin, Dugé, Baudelocque, Radford, Cowan, J. T. Simpson were quoted to prove (1) the ease with which inversion has been accomplished directly after labor, (2) the readiness with which from trifling causes, inversion may be induced within a few weeks after labor, (3) that inversion of the uterus may even occur in the virgin uterus. Facts were adduced to prove the ease with which even the chronic inverted uterus was restored. Fraenkel's experiments with atropia, morphine, and chloroform in cases of spastic contraction of the uterus in the second or third stage of labor, were suggestive.

This combination recommended by Dr. Fraenkel, injected into the *cervix uteri* at the proper moment before the operation, might be relied upon to antagonize any excess of contraction of the uterus which experience might show to interfere with the efforts of the operator to invert the uterus.

In regard to the objections having reference to hæmorrhage from the uterine incision, it will be observed that in the plan proposed, the incision through the uterine walls is made with the cautery. While it is probable that the protecting power of this agent would guarantee the arrest of the bleeding from the uterine wound for a time under conditions of rest, it must be admitted that, in subjecting these seared edges to the changes of relation incident to the process of inversion, there would be danger of re-opening the vessels and loss of blood. In such a case the assistant managing the thermo-cautery would follow the edges of the wound with the purpose of retouching bleeding points when practicable. That the actual cautery will arrest the hæmorrhage from the uterine wound, even under circumstances of change in its size, etc., the following facts prove.

R. W. Felkin, Breitmann, Playfair, Baudelocque, Edmunds, James Whitehead, Robert P. Harris, Fancourt Barnes were cited in support of the proposition that hæmorrhage is rarely the cause of death.

In regard to the third objection having reference to the narrowing of the pelvis, and the difficulties in the way of the suggested procedure thereby presented, it may be stated that while narrowing of the pelvis would always prove more or less of a hindrance, yet it must be borne in mind that in the majority of cases of deformed pelvis, however much any given diameter may be shortened, there yet remains spaces to one or the other side of the narrowing line through which the womb might be made to pass by the *vires a fronte et a tergo*. Generally in the process of in-

version, as the uterus would be drawn through the superior strait, four thicknesses of the organ would be presented at the conjugate; and in cases of unusual narrowing, difficulty might be experienced in this manoeuvre. In extreme contraction of the pelvis, dexterity and ingenuity on the part of the operator might enable him to cause the organ to pass in the process of inversion a very narrow space, possibly no wider than twice the thickness of the uterine parietes. Thus by making the incision, where practicable, near the fundus the fold formed by one lip of the wound and its apposed surface of uterine wall might be made to pass; to be followed by a similar fold of the corresponding edge of the incision.

Stein and Wiegand recommend that after the operation of Cæsarean section if the uterus does not contract so as to sink into the pelvis, it shall be seized by the whole hand, as in taxis for hernia, and be pressed down into the pelvis. In a narrow brim, this procedure, they think, insures that the uterus once pressed into the pelvic cavity cannot rise out of it again. Spitzbarth makes a similar suggestion. These recommendations of practical men suggest the feasibility of inverting the uterus by adroit manipulation even in cases of marked contraction. It may as well be stated, however, that the plan of operation here proposed has its limits of practicability as compared to the Porro operation, cases of extreme pelvic obstruction as well as those involving such changes in the parenchyma of the uterus as would render inversion dangerous, if not impracticable would, of course, not fall in the category of those to which the method here suggested might be applicable.

In regard to the fourth objection as to the hindrance presented by a non-dilated *os uteri*; it may be said that according to the majority of authorities, the most favorable time for performing Cæsarean section is after labor has set in, and should interference be delayed till the *os uteri* were softened and ripe for dilation in the greater number of cases the delay would not prove injurious to the mother or child.

With the present means of dilating the cervix during labor, it is to be presumed that while an imperfectly dilated *os* would not unfrequently prove a hindrance it would not often be an obstacle in the way of the proposed operation.

Barnes, Thomas and Lusk were cited to prove the ease with which the *cervix uteri* might be dilated.

It may be inquired, what would be the relation of the ovaries to the proposed line of ligature in an inverted womb? Several writers refer to the ovaries as resting on the edge of the inverted uterus as if about to fall into the cavity. A specimen from which this statement has been deduced forms the original of one of the standard cuts representing that condition. It is a case of partial, not of complete, inversion. Some authors, as Boivin and Dugé, state that the ovaries are not within the cavity of the uterus. Other writers, as Levret, report cases in which the ovaria were found within the inverted cavity. Schultze states that they are there found, and the cut that accompanies his text so shows these organs. In a number of instances, recent and old, the amputated uterus has been found to contain one or both ovaries. In

many cases of chronic inversion the appendages have not been found within the cavity of inversion. A study of the relation of the ovaries after complete inversion of the uterus will lead to an indorsement of the statements of Winckel and Schroeder as correct. Winckel writes, "In puerperal inversion, as a rule, the tubes and ovaries fall into the cavity (of inversion.)"

Says Schroeder, "In recent puerperal inversion all of the appendages are in the uterine funnel."

In the records of medicine are not wanting quite a number of cases the history of which teaches that the plan of operation here proposed may not be fatal. Cases were cited from the works of Demmé on "Uterine Inversion" to prove the latter proposition.

In conclusion, Dr. Bartlett said: Mr. President: In the course of my researches in preparing this paper, I have looked expectingly for the presentation of the same proposition as I have here made from co-laborers in the field of obstetric surgery. I have been rather surprised to have met no allusion to the method. The germ of the plan here proposed may however be found in the writings of that brilliant obstetrician to whom more than any other, suggestions for improvement in the operation of Cæsarean section are to be credited, James Blundell. In his article on laceration of the uterus occur these words: "Would extirpation of the uterus, *with or without inversion*, be of service in these cases? This question may be answered next century."¹

DR. A. REEVES JACKSON said: I have never performed Porro's operation and am not sufficiently familiar with the literature of the subject to be a proper person to open, or even take part in the discussion. I confess I scarcely understand what advantages this operation proposed by the essayist offers over the improved operation by Sänger. I would like to know whether Dr. Bartlett has performed this operation either upon the living subject or the cadaver. It seems to me there are practical difficulties in the way. In a review by Harris, of Philadelphia, in the *American Journal of the Medical Sciences*, of the work of Mangiagalli "On the More Recent Modifications of the Cæsarean Section," it is stated that it had been proposed to invert the uterus; for the purpose, however, of lessening the danger from septic infection, and not to facilitate the amputation, as is designed by the suggestion of Dr. Bartlett.

DR. E. J. DOERING asked how often the Cæsarean operation had been performed in Chicago.

DR. W. W. JAGGARD thought Dr. Bartlett's paper a very ingenious essay, although not based upon sound surgical principles. In the first place, he thought the title of the essay a misnomer. The operative procedure proposed by Dr. Bartlett was

not in any sense of the term a modification of or a substitute for Porro's operation. It was a perfectly distinct operation. Dr. Bartlett's method offered no advantages over Porro's operation, as modified by Müller and others. The abdominal cavity is not more thoroughly closed. The presence of a large pedicle does not embarrass the closure of the abdominal incision. The relation of the parts in the suggested procedure are not more natural and much less strained than in the *status* in which Porro's method leaves them. Drainage is entirely unnecessary when Porro's operation has been skilfully performed.

On the other hand, the positive disadvantages are numerous: The dangers of shock and hæmorrhage in artificial inversion of the uterus has been very much underestimated by Dr. Bartlett. The cases, collected from the literature of the subject, when they were at all relevant, were questionable as to authenticity. Accidents occurring to the uterus among the lower animals could not be adduced in evidence as to what would be the probable effect upon human beings under similar conditions. The thermo-cautery was inadequate to the arrest of hæmorrhage from a large incision through the walls of the pregnant uterus.

The uterus could only be inverted with ease, when it was pathologically flaccid—an exceptional condition. Porro's operation was performed in cases of the simple, flat rachitic pelvis, when the antero-posterior diameter of the brim was 6 cm. or under. Above 6 cm. craniotomy or the forceps is indicated. It would be very difficult to invert the uterus through the conjugata, oblique or transverse diameter under such conditions. In the pelvis of Robert, or in the osteomalacic pelvis, in which the degree of contraction is usually higher, artificial inversion of the uterus would be wellnigh impossible.

Then amputation of the inverted uterus is a dangerous operation *per se*. Of the forty-eight cases collected by Dr. West,² twelve terminated fatally. Of fifty-eight cases of amputation of the inverted uterus, reported from a German source,³ eighteen terminated fatally. "In 106 cases of amputation by ligature and otherwise, over 31 per cent. of deaths occurred." But it is not necessary to multiply statistics. So great is the mortality of this operation, that A. Martin⁴ has proposed as a substitute the total extirpation of the uterus.

If, then, upon *à priori* grounds Dr. Bartlett's suggestion has no real advantages over the modified Porro operation, and, on the other hand, possesses actual disadvantages, it is scarcely probable that the expedient will receive serious consideration.

DR. J. SUYDAM KNOX said: Dr. Jaggard has about covered the objections I intended to make. My impression is that Dr. Bartlett in his paper has overestimated the relaxation of the uterus immediately after delivery, and the ease with which inversion can be accomplished. Atony of the uterus is the first cause of inversion; and when we consider how min-

¹ After writing this article the writer found in the essay of Dr. Harris on the Porro operation in continental Europe, published in the *American Journal of the Medical Sciences*, in 1880, the following sentences:

"Several other plans [of treating the cervix] have been proposed. * * * (2) to invert the uterus after its evacuation and constrict and remove it by the vagina. This plan tends to complicate the case and increase its dangers, etc."

Had the writer been aware that the suggestion which forms the basis of the foregoing paper had been previously published he would not have prepared it. Inasmuch, however, as the merits of the method proposed are in no wise affected by its having been previously suggested, he has decided not to withhold the article from publication.

² *Diseases of Women*, p. 240.

³ *American Journal of Obstetrics*, Aug., 1868.

⁴ Emmet: *Principles and Practice of Gynecology*, 1884, p. 436.

⁵ *Pathologie und Therapie der Frauenkrankheiten*, 1885, p. 144.

ute is the percentage of inversions in the vast number of labors, we can fairly assume that relaxation immediately after delivery seldom occurs. If this be so, inversion, even with the *vis a tergo*, would be extremely difficult. Again atony of the uterus is the cause of the most dangerous symptom or complication of inversion, namely hæmorrhage; therefore the cases most favorable for the operation of Dr. Bartlett would be the last ones in which so doubtful an experiment would be tried. The Doctor has made a valuable suggestion. Any method that successfully removes the uterine stump from the abdominal cavity, without attaching it to the abdominal incision, advances the operation of hysterectomy. In the ablation of the non-pregnant uterus, I think Dr. Bartlett's method finds its best opportunity.

DR. JAMES H. ETHERIDGE asked if the performance of inversion by forcible traction involved the full dilatation of the neck of the uterus. How does Dr. Bartlett propose to accomplish this, does he dilate it forcibly? With the uterus well up beyond the umbilicus, how do the broad ligaments come out of the pelvis, and with the uterus forced clear down out of the vulva, how much traction is there going to be on these broad ligaments? Is there room enough to permit the uterus to be drawn down?

Why, under the circumstances, could not forceps be immediately applied to the edge of the cut uterus, and arrest the hæmorrhage, and the work be then proceeded with at pleasure? I speak of hæmostatic forceps.

DR. E. W. SAWYER said: It seems a little presumptuous for one who has never had experience in this department to attempt to enlighten the Society. One of the most interesting questions to be decided is which operation to perform. I confess if I were confronted to-night with one of these cases I would be wholly incompetent to decide between Cæsarean operation and the operation of Porro. It may be interesting to read the words of Lawson Tait upon this very point, showing his preference for the new operation, so-called. In the fifth number of the *British Gynaecological Journal*, he says: "The whole of my experience in meddling with the pregnant uterus by abdominal section, consists of five cases, three of the ordinary Cæsarean section and the two I am about to describe in detail. Of the Cæsarean sections one was performed for malignant disease of the vagina about fourteen years ago, the other two for deformed pelvis respectively seven and five years ago and the mothers died, and only one of the children is now living. The results indeed are such as to determine me never to repeat this procedure, having before me the arguments of Dr. Godson and the fact that both my amputation cases have recovered." At the same meeting Dr. Routh said: "That he was much interested and instructed by Dr. Lawson Tait's paper. At the same time he could not help making some criticisms upon it. First, he believed that Mr. Tait had exaggerated the mortality of the Cæsarean section. It was not anything like 99.971 per cent. Churchill stated that out of eighty cases twenty-three mothers were saved, or 28.7 per cent., forty-four children being saved. Dr.

Radford out of seventy-six cases he collected, found 14.28 were saved, and forty-six children were also saved. Dr. West, out of 409 cases states the recoveries as 38.4 per cent. 237 children being saved. Now he (Dr. Routh) could not help feeling that if in these days of improved antiseptic abdominal surgery, the same skill and care were taken in cases of Cæsarean section, the safety of the mother would be much more common." It is interesting to see how gentlemen will differ in their opinions upon such an important thing as the selection of an operation in an emergency case. So I am still in doubt whether to adopt the modern method of Porro or to depend upon the Cæsarean section, which the remarks of Dr. Routh would indicate is quite as favorable.

At the request of Dr. Etheridge, Dr. Sawyer narrated the following case, showing the shock and hæmorrhage of acute inversion: I will state very briefly an experience which, no matter how long I may live, seems as if it would never become dim. I have never had any doubt that the determining cause of the acute inversion in this case was the enormous distension of the uterus due to the large quantity of *liquor amnii*. Before the woman was delivered, I was impressed with the fact that she probably had twins, but this was not the case. When the woman was delivered the bed was flooded, the *liquor amnii* flooding the room even. I put my hand upon the woman's belly, as is my custom, and at the first indication of contraction of the uterus, I substituted the husband's hand for mine that I might pay attention to the child. I am confident that the husband's fingers dimpled that uterus. I had no sooner detached the child than I gave the usual teaspoonful of ergot; I was in a hurry on account of the flabby condition of the uterus, and for fifteen minutes my time was occupied in paying attention to the child, getting it to breathe. The woman, who had recovered from a small quantity of ether which I gave her, threw up her hands and I saw she was pale. I put my hand under her husband's and felt the edge of the uterus like the edge of a saucer, I could define the margin of the crater, my finger in the vagina met the globe inverted and the truth flashed across me that I had an inverted uterus. Now fifteen minutes had not elapsed before that uterus was so firmly ergotized that it was impossible to replace it. I immediately resumed ether and the woman began to snore, but that made no difference, the womb was ergotized and the woman died from shock and hæmorrhage with the uterus unreduced.

Dr. Jaggard has called attention to the enormous hæmorrhage and this reminds me of a case in which I removed a foetus from the abdomen of a woman, in the little town of Boulder. The foetus had been in the uterus for three and a half years. It was an adventitious uterus the exact structure of which could not be ascertained, but the hæmorrhage from the false uterus was enormous and I think destroyed the woman. If the false uterus and adventitious sac could bleed to that degree and so early in pregnancy, the dangers of hæmorrhage must surely be greater in the uterus at term containing a living foetus and an active placenta.

This operation was done in 1874. The hæmorrhage was cavernous. We arrested the hæmorrhage by seizing the edges and puckering them up and tying an enormous ligature around the stump; for a moment that arrested it, but the woman subsequently died.

DR. H. T. BYFORD said: Like any other operation this one, supposing it to be an operation that has been performed, has its limitations. I think Dr. Jaggard's suggestion that a greatly contracted pelvis might afford sufficient difficulty to make the operation impracticable, is a good one, although I think that the uterus might be inverted through a pelvis too small or too much distorted for a safe craniotomy. Another limitation would be an undilated condition of the cervix. The irritation produced by rapid dilatation would certainly render the cervix unfit to be left as a stump, and make the Cæsarean or Porro operation preferable. If the os is already dilated, then Thomas' revised laparo-elytrorrhaphy must be given precedence, provided there be no counter-indications. The difficulty of inverting the uterus is not an imaginary one, and it seems to me that the best way to overcome it would be to invert the uterus, placenta and all, before the placenta is separated, and between pains. This would tend to still further limit the operation to cases without extreme contraction and would bring it into rivalry with craniotomy. Its chief advantage over the Porro operation lies in not fixing the cervix several inches beyond its normal position; and here lies the germ which the author seems to be trying to develop. Should there be a condition of the uterus which would not favor the Cæsarean operation as performed by Säger and Leopold, should the size of the cervix or vagina render fixation of the stump in the abdominal too difficult, were the uterine walls not sufficiently relaxed to be inverted, or the pelvis not roomy enough to allow inversion with the placenta attached, should the condition of the tissues about the vagina and bladder contra-indicate laparo-elytrorrhaphy, and should the os dilate naturally and easily, then this operation would find its rare opportunity. The process of coning out, or rather slicing around the cervix, and inverting the cervix, is easier to talk of than to perform. Any one who has seen the uterus amputated, even in cases of fibroid tumors, will agree that the loss of blood, including that taken off with the amputated pregnant uterus, and the vascularity of the stump would make the process of inverting the sliced cervix very hazardous. The stump, thus turned down, would undoubtedly shrink rapidly, and become a hard one to manage. As to opening the uterus with the cautery, I think this would not possess much advantage unless complete constriction of the uterus and broad ligaments could be made, so that bleeding would not interfere with the complete searing of the parts.

DR. BARTLETT in closing said: Some of the fellows taking part in the discussion, as they have stated, have not had an opportunity of hearing more of the paper than the bare proposition; not needlessly to occupy time, I shall pass over such objections (all of which I recognize as forcible), as have been fully considered in the paper now printed.

Dr. Jaggard refers to the authorities quoted by me as "questionable;" so far as my knowledge extends, not a case cited rests upon other than unquestionable authority. The Doctor thinks the actual cautery would prove useless as a means of arresting hæmorrhage from the uterine incision. Prior to the time of Ambrose Paré, the cautery was relied upon "to arrest all forms of hæmorrhage."

Dr. H. T. Byford has dwelt upon the difficulty of dilating the *os uteri* by artificial means, and in my opinion he has not exaggerated the difficulties often encountered in practice, where the parts are not prepared for dilation.

In regard to the embarrassment felt by the Secretary as to which operation to prefer, whether the old or the Porro method, I might say, that, in face of the several substitutes and modifications, he would be amply justified in preferring the old Cæsarean section.

DOMESTIC CORRESPONDENCE

BLACK CERUMEN.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Some time ago a lady told me that her little girl, about four years old, had, since birth, discharged black wax from her ears. Never having met with such an instance, except where inspissated, although I do a considerable ear practice, and not recollecting ever to have read of anything of the kind, I concluded it was either a mistake or an anomaly, and so asked an immediate examination to determine the facts.

The mother and child being at my house, I proceeded at once with the investigation. I found both external auditory canals bathed with soft, fresh looking cerumen, more abundant than usual, of about the consistency of thick treacle or thin tar, in fact, looked much like tar, being intensely black and so tenacious as to bear drawing out in long threads. Under the microscope it presented identical appearances with freshly secreted healthy cerumen. No vegetable cells, spores or filaments were found, as I had anticipated, nor were there any pigment granules. The coloring matter seemed to be of a soluble nature, and was thoroughly incorporated with the wax, giving it an amber tint under the cover glass where thickest.

The child's hearing is, and has always been, perfect; nor has she ever had any disease of her ears. She has auburn hair, a beautiful fair and clear skin, and dark brown eyes. All the other secretions and excretions of skin and other organs are normal. Her mother assures me that the wax from her ears has been black from her birth, and always unusually copious.

If any of the readers of THE JOURNAL can cite a similar case, or offer any scientific solution of this, I shall feel under many obligations.

Very truly,
T. E. MURRELL, M.D.

Little Rock, Ark.

POTASSIUM CHLORIDE.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—As regards the use of the chloride of potassium, as recommended by Dr. A. F. Pattee, of Boston, Mass., and published in your journal, I desire to say that I have used it in several cases of *anæmia*, and also in myalgia, and found it highly satisfactory. I can only wonder that its use in cases of this nature has never been recognized before. I have also found it a most excellent mouth wash.

Yours very sincerely,

H. C. FIELDING, M.D.

Toledo, Ohio, Sept. 24, 1886.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

ASSOCIATION OF THE SURGEONS OF THE PENNSYLVANIA COMPANY.—The eighth semi-annual meeting of this Association will be held at the Seventh Avenue Hotel, Pittsburgh, Pa., Tuesday, October 19, 1886, commencing at 9 A.M., Eastern time. A number of papers on appropriate subjects are promised.

FITE-STEVENSON.—Married, at Calvary church, Memphis, by the Rev. Father Klein, Sept. 18, 1886, at 9 A.M., Dr. C. C. Fite, recently of Nashville, now of the East Tennessee Hospital for the Insane, near Knoxville, and Miss Bessie M. Stevenson, of Dallas, Texas. No cards.

Long life and abundant happiness for both is the wish of the Editor.

IRREGULAR MEDICAL SCHOOLS.—The Iowa State Board of Health will not recognize diplomas from the following colleges: American Eclectic College, Cincinnati; American Health College, Cincinnati; American University of Pennsylvania (Buchanan), Philadelphia; Beach Medical Institute, Indianapolis; Bellevue Medical College of Massachusetts; College of Physicians and Surgeons, Buffalo, N. Y.; College of Physicians and Surgeons, Milwaukee; Eclectic Medical College of Philadelphia; Edinburgh University, Chicago and St. Louis; Excelsior Medical

College, Boston; Hygeo-Therapeutic College, Bergen Heights, N. J.; Hygeo-Therapeutic College, New York City; Joplin Medical College, Joplin, Missouri; Livingston University, Haddonfield, N. J.; Medical Department of the American University of Boston, Boston; New England University of Arts and Sciences, Boston; New England University of Arts and Sciences, Manchester, N. H.; Penn Medical University, Philadelphia; Philadelphia University of Medicine and Surgery, Philadelphia; Physio-Eclectic Medical College and Physio-Medical College, Cincinnati; St. Louis Eclectic Medical College, St. Louis; St. Louis Homœopathic Medical College, St. Louis; Curtis Physio-Medical Institute, Marion, Indiana; American Anthropological University of St. Louis; Medical Department of Drake University, Des Moines, Iowa; and King Eclectic Medical College, Des Moines, Iowa.

SCIENTIFIC EXPERTS AS WITNESSES.—*The Chemical News* says: Let us look at this question as it presents itself to men of science, alike to the chemist, the physicist, mechanician, the geologist, the physician, and the microscopist, though certainly not to the astronomer, who is in no danger of being called, as such, to give his testimony. The expert occupies a totally anomalous position in court. Technically he is a mere witness; practically he is something between a witness and an advocate, sharing the responsibilities of both, but without the privileges of the latter. He has to instruct counsel before the trial and to prompt him during its course. But in cross-examination he is the more open to insult because the court does not see clearly how he arrives at his conclusions, and suspects whatever it does not understand. The late Dr. R. Angus Smith complained of being "contemptuously compelled to herd with thieves and scoundrels in a witness-box." He adds: "I have seen barristers speaking to a scientific witness in such a way as to show that to them a witness was always an inferior person." Surely, every person who has been present at a technical trial, or has had to appear as an expert in a poisoning, a patent, or an adulteration case, will be able to confirm this from his own observation and experience.

Now it may, perhaps, be cynically hinted that men of science should be willing to bear all this annoyance for the public good. But is it for the public good? In the first place, not a few of the most eminent men in every department of science distinctly and peremptorily refuse to be mixed up in any affair which may expose them to cross-examination. "I will investigate the matter, if you wish it, and will give you a report for your guidance, but only on the distinct understanding that I am not to enter the witness-box." Such in substance is the decision of not a few men of the highest reputation and the most sterling integrity. Certainly it is not for the interests of justice to render it impossible for such men to give the court the benefit of their knowledge.

Further, the spectacle of two men standing contradicting or seeming to contradict each other in the interest of their respective clients is a grave scandal. Men of the world are tempted to say that "science

can lay but little claim to certainty, and is rather a mass of doubtful speculations than a body of demonstrable truth." To us, at least, there is nothing more saddening than to read the trial of a notorious poisoner, or the report of a great patent case, especially if taken along with the comments of the press and of society on these occasions.

Here, then, we see that our present mode of dealing with scientific evidence is found on all hands unsatisfactory. The outside public is scandalized; experts are indignant; the bench and the bar share this feeling, but unfortunately are disposed to blame the individual rather than condemn the system.

But we fear that this unanimity of dissatisfaction will vanish as soon as a remedy is seriously proposed. To that, however, we must come, unless we are willing to dispense with scientific evidence altogether.

As it seems to us, the expert should be the adviser of the court, no longer acting in the interest of either party. Above all things, he must be exempt from cross-examination. His evidence, or rather his conclusions, should be given in writing, and accepted just as are the decisions of the bench on points of law.

THE BACILLUS OF MALARIA.—In 1879 Professor Tommasi-Crudeli published in the *Atti della Reale Accademia dei Lincei* at Rome, a memoir on the distribution of the subsoil water of the Roman Campagna, and on its influence in the production of malaria. In this research, which proved the starting-point of new studies on the etiology of malaria, the author traced the natural history of this morbid ferment, discarding many errors and prejudices of old medicine, and maintaining that the causal agent of the disease could only be a living organism. Towards the close of the same year Tommasi-Crudeli and Klebs published in the same *Atti* a memoir embodying the results of inquiries on malaric airs and soils, and of experiments on rabbits, proving that the living organism is a schizomycete, named by them "bacillus malarie." As the result of researches on the individual affected with malaria, Marchiafava and Celli announced that within the red-blood globules are constantly found plasmatic bodies (*corpi plasmatici*) endowed with lively amoeboid movements, in which the hæmoglobine is transformed into melanine (melanemia); and in a further memoir which they have published this year, they suggest as a more probable hypothesis the opinion that those plasmatic bodies are the living organisms which produce malaria. Thus Marchiafava and Celli confirm in substance Tommasi-Crudeli's opinion, that a living organism is the cause of malaria, but they regard its form as differing from a schizomycete. These observations are embodied in a note with which Todaro prefaces a communication by Tommasi-Crudeli in the April number of the *Lincei*, on "a bacillus found in the malaric atmosphere around Pola (Istria)." This bacillus resembles the most typical forms of the bacillus malarie which Tommasi-Crudeli and Klebs found in the air and subsoil of the Roman Campagna, which is *par excellence* the home of malaria. Since identity

of form does not necessarily imply equality in infective power, Tommasi-Crudeli reserves his definite opinion on the bacilli discovered in the air of Pola, until they shall have been submitted to experimental research, a plan of which he has sketched.—*Lancet*, August 21, 1886.

AMERICAN RHINOLOGICAL ASSOCIATION.—This Association will hold its fourth annual meeting at St. Louis, Mo., October 5, 6 and 7.

NEW YORK STATE MEDICAL ASSOCIATION.—*Fifth District Branch.*—The second annual meeting of the Fifth District Branch will be held in Brooklyn on Tuesday, Oct. 12, 1886. There will be a morning and afternoon session. All Fellows are solicited to contribute to the meeting, either by reading papers, notes or communications, or by exhibiting specimens. The Secretary desires to be notified of the title of any paper to be offered. E. H. SQUIBB, M.D., *Sec'y*.
P. O. Box 94, Brooklyn.

PROF. LUDWIG BANDL, of Vienna, has been appointed to Prof. Breisky's Chair in Prague. Breisky goes to Vienna.

THE AMERICAN ACADEMY OF MEDICINE will meet in Pittsburgh on October 12th and 13th.

SMALLPOX AND VACCINATION IN NEW YORK.—We take the following from the "Fifth Annual Report of the State Board of Health of New York:" "The objections and occasional resistance to vaccination which are met with among immigrant passengers, indicate a considerable scepticism in European communities, more particularly among the English people, as to the protection afforded by it, or else a fear that constitutional disease will be introduced by that means. The groundless character of the fear that disease will be communicated by vaccination, when proper care is used in the selection of the vaccine virus, has been too often demonstrated to require any argument in this place. The result of the teachings and influence of the anti-vaccinationists is well illustrated by the fact, that in the hospitals of the city of New York not a single case of smallpox exists at this time, while in the city of London the reports have shown for months past an average of upwards of eleven hundred cases in hospital. In New York City, where a 'from house-to-house' inspection and search among the tenement population for the unvaccinated is practiced every year, smallpox is not met with, except as it was imported and developed by persons from other localities; in London, the weekly average of new cases, as indicated by bills of health and the number in hospital, has been from four to five hundred. The number of cases of smallpox on vessels that entered that port in 1883 and 1884, was twenty-five."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 18, 1886, TO SEPTEMBER 24, 1886.

First Lt. W. W. R. Fisher, Asst. Surg., granted leave of absence for one month, to take effect Sept. 10, with permission to apply for one month's extension. (F. O. 88, Dept. Arizona, Sept. 1, 1886.)

SURGICAL RELATIONS OF THE ILEO-CÆCAL REGION.¹

BY J. MCF. GASTON, M.D.,
OF ATLANTA, GEORGIA.

In considering the functions of the different portions of the alimentary tube, and their liability to derangements, none seems of more importance than the ileo-cæcal division of the small and the large intestines. Apart from the intimate connections of the duodenum with neighboring organs, there is no part of this highly vitalized conduit, from the stomach to the rectum, whose physiological operation is so essential to health and whose pathological conditions are so hurtful, as this valvular mechanism. A complete separation of the nutritious and excrementitious processes is effected by this somewhat complicated apparatus; and an entire transformation in the contents of the alimentary canal ensues after passing through this peculiar connection of the small and large intestines.

A brief outline of the relations of these organs, given by Weisse and by Ziegler, may prove satisfactory for a proper comprehension of the various affections, involving the ileo-cæcal connections, which require surgical treatment. The cæcum, lodged in the superior part of the right iliac fossa, and completely invested by peritoneum, is inferior to the ileo-colic opening—the latter at the junction of the cæcum and colon. From the cæcum is appended a blind tube, the appendix vermiformis, which curls inferiorly and is suspended by a special meso. The ascending colon for its first half is fixed to the interior of the right posterior wall of the flank by the ascending meso-colon (Weisse's Anatomy, p. 61). Upon the surface of the cæcum, its longitudinal muscular fibres are so collected as to form three bands, one anterior, one postero-external, and one postero-internal; it is these bands that determine its sacculated character. These longitudinal bands are presented in the course of the lower portion of the colon from the bundling of the longitudinal muscular fibres, with the peculiar sacculæ of this gut interposed; having the appendices epiploicæ at the clefts between them. The inner mucous membrane is raised into transverse prominences between the three longitudinal furrows.

The superior branch of the ileo-colic artery dis-

tributes to the commencement of the ascending colon, the inferior distributes to the cæcum, and the terminal portion of the ileum and anastomoses with the trunk of the superior mesenteric artery. The inferior portion of the ileum is covered by peritoneum, and at the line where the two layers meet upon its circumference its arteries and nerves enter and its veins and lymphatics leave it. The valvulæ conniventes furrowed by the reduplication of the mucous membrane in the other parts of the small intestine, are absent in that portion of the ileum adjoining the valvular connection with the large intestine. The ileo-colic valve is formed by two reduplications of the mucous membrane of the colon, which effects a button-hole slit of communication, that only admits of the passage of solids or fluids from the small into the large intestines. This may be demonstrated by filling the ileum with water, and allowing it to pass through the valve into the colon, when reversing the current it will be arrested effectually by the valvular folds. The canal of the vermiform appendix opens into the cæcum, passing through its wall obliquely, thereby forming a valvular opening. Its mucous lining membrane differs from that of the cæcum (Weisse's Anatomy).

Colitis is sometimes caused by the arrest of faecal matter in the ascending colon and the formation of hard masses; it is also due at times to septic infection, and again to a specific poison, as in dysentery. We learn from Ziegler's "Pathological Anatomy," that catarrh ending in atrophy is commonest in the large intestine, and especially in the cæcum. Nothnagel found that in 80 per cent. of the adults he examined there were traces of atrophy in the large intestine, at times confined entirely to the cæcum. The ascending colon came next as regards frequency, and then in diminishing order, the upper part of the ileum and the jejunum. The muscular coat is usually unaffected, but here and there it may be atrophied. It is not very liable to degeneration, but sometimes, as in phthisis, it is found to be fatty. Lastly, there is a congenital form of atrophy, a hyperplasia of the muscularis, which is not made up in after life. In chronic catarrh atrophy is occasionally associated with the development of hyperplastic growths. They take the form of hyperplastic indurations of the submucosa or polypous excrescences arising from the mucosa. When fully developed these last consist of fibrous tissue enclosing a few remains of glandular structures, which here and there are degenerated into closed cysts.¹

¹ Read in the Section on Surgery at the Thirtieth Annual Meeting of the American Medical Association,

¹ Ziegler, Text-book of Pathological Anatomy, p. 281.

Inflammation of the ileum is often marked by the swelling and prominence of the solitary and agminated follicles. The former appear as reddish or grayish protuberant nodules; the agminated follicles as flat elevations, grayish, red or pink in color, and pitted with numerous little depressions. When these follicles break down they leave behind them follicular ulcers.²

The vermiform appendage is peculiarly adapted to catch and retain substances passing through the cæcum. Matters which have been swallowed—such as grape seeds, apple-pips, cherry-stones, and the like—and feces, may accumulate in the appendage and set up inflammation. Sometimes these become encrusted with phosphates and carbonates, and so form fecal concretions or calculi. The inflammation thus set up may extend to all the coats of the appendages and then attack the contiguous structures; and in this way necrosis and gangrene, with perforation, may be caused. The issue differs in different cases. It is comparatively favorable if the inflammation continues to be circumscribed, while the exudation is moderate in amount; protective adhesions and false membranes may thus be formed about the affected spot. It is very unfavorable when perforation takes place before adequate adhesions are formed; fatal peritonitis is nearly always induced. When perforation takes place into a part of the peritoneum shut off by adhesions a burrowing fecal abscess is produced, which may burst internally or externally. Sometimes the appendage is entirely obliterated by adhesive inflammation; but if the inner or intestinal end becomes closed while the remainder continues to be patent, the natural mucous secretion may collect into the latter and distend it into a cyst.

Typhlitis and perityphlitis are sometimes due to the extension by continuity of inflammation already existing in more distant parts of the cæcum or colon. Tuberculous and typhoid ulceration localized in the vermiform appendages may give rise to dangerous lesions.³

As autopsic observations afford us an insight to the pathology of cases otherwise obscure, it may prove satisfactory to present an abstract of two cases from the report of Dr. W. T. Bull, in the *New York Medical Record*, touching suppurative peritonitis: A laborer, aged 25, with pulse 120, respiration 30, temperature 103°, with considerable general tympanitis and great pains, referred particularly to the right side and iliac fossa and radiating down the side, had a chill, followed by high fever and vomiting. He was constipated, but the bowels had moved once after an enema. The needle detected pus only in the lumbar region, where there was no tenderness. An incision was made down to the very wall of the colon, and but a drachm of offensive pus was found behind the colon. The symptoms of general peritonitis persisted, and he died in two days. The autopsy disclosed a general suppurative peritonitis, perforation of the appendix in two places near the cæcum, and feces in the connective tissue of the

iliac fossa, which was softened and necrotic as far up as the liver, but not yet broken down so as to form much pus, and *nowhere communicating with the peritoneal cavity*. In a like case of Dr. R. Wiener there was found general peritonitis and an abscess behind the cæcum and ascending colon, which contained a pint or two of fluid fecal matter.

A peculiarly instructive case of traumatic origin is reported in the *Medical Press*, of London, for March 31st, 1886, by Mr. W. A. Meredith, of a feeble woman aged 58 years, who was operated on at the Samaritan Free Hospital in April, 1885, for double ovarian cystoma, complicated by very extensive adhesions. At the end of a week, the bowels having acted and the pulse being normal, the stitches were removed and the abdominal incision was found well united. On the evening of the same day the patient suddenly complained of nausea and soon after vomited a quantity of dark-green fluid. The examination revealed some dulness over the region of the cæcum and the condition was diagnosed as commencing intestinal obstruction. On the following morning an operation was undertaken, and on opening the abdomen the peritoneum was found intensely red and congested, evidently in an early stage of acute inflammation. Attention was attracted to a coil of greatly distended small intestine, which was badly kinked and obstructed in consequence of the traction exerted upon it by a portion of the ligated omentum, which was closely adherent to its surface. This having been released with some difficulty, owing to the inflamed and softened state of the bowel, another distended coil, similarly obstructed by a separate omental band, was also set free. No further obstruction being discoverable, the abdomen was then closed. The acute symptoms were at once relieved by the operation, and the temperature fell to normal again on the third day, but convalescence was tedious. The bowels were evacuated for the first time on the twenty-third day by enema, and thenceforth they acted daily. The patient left the hospital on May 16th, exactly six weeks from the date of her first operation, and when last heard from in the end of October she had quite recovered her health.

The favorable issue of this operation on the eighth day after a previous laparotomy, from which inflammation had ensued, presents a crucial test of the efficacy of operative interference in abdominal troubles complicated with peritonitis; and is corroborated by other successful laparotomies after inflammatory development. This confirms my remark⁴ when treating of Duodeno-cholecystostomy, as follows: It is an interesting fact that in some conditions of traumatic origin secondary operations are attended with less risk to life than those undertaken soon after the receipt of injury; and we are led to infer that the reaction or tolerance of the organization in its abnormal state may be favorable to the result of surgical procedures in the human system after the disorders connected with biliary obstruction have diminished the tendency to active or acute inflammation in the organism. A problem of serious import for the sur-

² Ibid., p. 282.

⁴ On page 240 of the "Reference Handbook of the Medical Sciences," Vol. ii.

geon is, however, sometimes presented as to the extent of impairment in the vital energies that is compatible with recovery from an operation; and we must not delay surgical relief until the capacities of the physical constitution are exhausted; yet, the tendency to destructive inflammation must be lessened by this adynamic element, so as to impart a tolerance of surgical interference.

A case reported by Dr. Charles A. Leale, in *Gaillard's Journal* for April, 1886, illustrates an interesting phase of injury to the intestines, from a gun-shot wound. In this instance at least two portions of the bowels were perforated, one below the cæcum, in the ascending colon, and the other in the small intestines, each of which subsequently was the seat of an artificial anus, through which all the discharges took place from March 25, 1865, the day the wound was received, until April 27, when, to relieve a desire to empty the rectum, an enema of soap and water was given *per anus* with the desired effect of reëstablishing the potency of the entire length of the intestinal canal. After using the opium and stimulant treatment for thirty-one days, several sloughs of tissue and omentum were removed. Diet of beef extract and light nutritious food brought about steady improvement, and the doses of opium were gradually diminished until the seventy-ninth day. At this time the openings were thoroughly irrigated with sol. sodæ chlor., dil., the surrounding tissue down to the intestinal canal was denuded so as to represent an incised circular wound; the walls were approximated and the parts were hermetically sealed externally. In ten days the dressings were removed, showing complete success in the closure of the anterior wound, but failure of the operation as to the posterior, from the presence of a cherry-seed in the aperture, which had been swallowed while eating the fruit surreptitiously. Two weeks subsequently another operation obliterated the posterior fæcal fistula, after which the fæcal matter passed alone by the anus.

On the 30th of July, 1885, over twenty years after operating in this case, a letter was received stating that the patient "enjoyed pretty good health," and it is inferred that it was a complete success.

The fact of passing over a month subsequent to the injury without a rectal evacuation, and having intestinal communication restored by such simple means, corroborates the evidence afforded by discharges from both apertures, that no arrest occurred at the intervening ileo-cæcal connections, and substantiates the recuperative powers of nature.

The ileo-cæcal connections become involved in disease of an acute or chronic form, and the pathological condition may be of a benign or malignant nature. That abnormal relation of the parts connected with invagination of the ileum, by its passage through the valvular opening into the cæcum or colon, is, at the outset, simply a mechanical displacement, but very soon induces modifications of the nerve elements and in the sanguineous circulation, accompanied by an inflammatory state of the tissues. There may exist a considerable constriction by spasm of the muscular components of the ileo-cæcal valve causing all the symptoms of obstruction, with the de-

velopment of inflammation only as a secondary modification, and we are warranted by the speedy fatal termination of some cases, with indications of collapse, in attributing the result to an operation through the nervous system simulating shock. I had an opportunity of making a post-mortem of a case which was diagnosticated as intussusception in my private infirmary during my residence in Brazil, that died on the third day; and there were really no indications of inflammation in the tissues. A very remarkable feature of this invagination of fourteen inches of the ileum within the colon was such a constriction remaining at the valve four hours after death, when the autopsy was made, that no traction short of a rupture of the gut was sufficient to withdraw it. But upon insinuating a probe-pointed bistoury and nicking the edge of the valvular fold, the bowel was readily drawn out, being in such a state of preservation that there could have been no liability to disorganization of its structure had laparotomy, with release of the constriction, been resorted to some hours before the collapse ensued. This case is unique in that a spasmodic constriction continued after death.

In another case of death on the third day, to which allusion is made in my article on "Obscure Impediments of the Intestinal Canal," in the December, 1887, number of *Gaillard's Journal*, all the symptoms warranted the diagnosis of intussusception, and yet under the influence of chloroform there was no tumor found, or other evidence of local inflammation in any part of the abdomen.

The case of invagination through the ileo-cæcal valve in which laparotomy was performed on the fourth day, by Dr. J. C. Irish, of Lowell, Mass., only exhibited some congestion of the ileum for a few inches above the obstruction, and the remainder of the intestinal canal was free from any inflammatory action.*

It is evident, therefore, that inflammation is not set up generally within the first twenty-four hours after the symptoms of invagination indicate the nature of the case, so that the course inculcated by Mr. Frederick Treves, in the *British Medical Journal*, of August 29, 1885, as to the performance of laparotomy within this period is based upon correct pathological principles.

The great surgical desideratum in regard to this class of cases is a proper basis for forming a correct diagnosis, and a question of paramount importance is the propriety of resorting to an exploratory incision for the purpose of verifying the presumptive evidence afforded by symptoms of invagination. Simple incision of the coats of the ileum near the valve on account of arrested biliary calculi, and of the walls of cæcum for fæcal concretions or other solid bodies lodged in this depository, are required at times, all of which necessitate the preliminary measures of laparotomy.

In cases of doubtful diagnosis, presenting reasonable grounds for the conviction that there exists a disorder calling for operative interference, exploratory laparotomy should be resorted to at an early stage after other modes of treatment have failed to

* Boston Medical and Surgical Journal, Sept. 3, 1885.

afford relief; and the consequences of thus opening the abdominal cavity where operations upon the contained organs are not undertaken, are not generally serious.

With a view to afford temporary relief for ileo-cæcal disorders, enterotomy is recognized as a legitimate recourse in surgery; and some eminent surgeons have even recommended this procedure for forming an artificial anus, where the nature of the trouble was not apparent after exploratory laparotomy, yet it should be avoided whenever other means of relief are available.

"Typhlitis, strictly speaking, is limited to affections of the cæcum and its appendix vermiformis; perityphlitis is mostly due to extension of the inflammation to their peritoneal envelope; while the term paratyphlitis," according to Whittaker, "signifies an involvement of the extra-peritoneal and post-cæcal connective tissues," and may perhaps appropriately include all the inflammatory developments in the ileo-cæcal region. But the inquiry proposed extends to disorders of this division of the intestinal canal and its surroundings, which may occur without inflammatory action in the tissues, and hence not included in the above classification. I have therefore adopted the comprehensive phraseology which heads this paper, as a general expression, embodying the various derangements of the ileo-cæcal connections that call for surgical interference.

The modifications of structure from acute and chronic disease of an idiopathic nature, as well as those changes which are induced by obstructions of various kinds from within or without the intestinal canal, on either side of the valve of Bauhin, with the disturbance of function from volvulus and intussusception in this region, are the objects of our present investigation.

The degeneration of the normal constituents may result in fibrinous indurations or in malignant tumors, involving the walls of the cæcum and the vermiform appendix, as well as the adjacent structures, so as to interfere materially with their functions, and ultimately obliterate the lumen of the intestinal canal. On the other hand, suppurative action may ensue, burrowing in various directions, until a discharge takes place by ulcerations through the bladder, the colon, or into the peritoneal cavity, inducing peritonæa, with all its grave consequences.

There are sometimes complications growing out of the implication of adjacent tissues which do not enter into the ileo-cæcal connections, from their temporary or partial engagement in the internal opening of the inguinal canal or in the aperture of the femoral tract. The strangulation, though relieved, may set up a train of disorders which extends itself to the neighboring organs by contact or by transmission of the inflammation through the common serous investment. Cellulitis may likewise ensue from septic influences, more especially in females, and involves the structures proper of the ileo-cæcal region. Thus it turns out that this special division of the intestinal canal is amenable to morbid impressions from various sources, independent of the immediate origin of trouble in its own tissues.

A portion of the ileo-cæcal connections being covered by peritoneum, while another portion is attached by connective tissue to the wall in the lumbar region outside of the duplicature of this serous lining of the abdomen, the pathological conditions of the different segments are correspondingly modified by the inflammatory processes affecting the venous components of this complex organization. The mucous and serous membranes, the fibrinous and muscular elements, the cellular and connective tissues, show diverse effects. We learn from a concise paper of Mr. J. Bland Sutton, in the London *Lancet*, that inflammation is "*the method by which an organism attempts to render inert noxious elements introduced from without or arising within it;*" and that "the most important feature in the inflammatory process is the vascular disturbance."

The facts and observations adduced present the whole process of inflammation in an entirely new aspect, and instead of being a purely pathological process, it will rank as one of normal physiology, which when in excess comes within the domain of pathology.

Inflammation may be of two kinds, according to the nature of the irritant. It may be simple or specific. Simple inflammation is the reaction which follows mechanical, thermal or chemical stimuli or irritations. A specific inflammation is one which results from the introduction into the organism of a particular poison or irritant. The mode by which a piece of noxious tissue is encapsulated or cast out of the body illustrates the process by which bacteria, etc., are in some cases rendered inert by the activity of cells. If the invasion is large and the vitality of the organism enfeebled, the leucocytes are insufficient to cope with them, and disastrous effects follow.

It is not my purpose to treat of derangements in the pelvic viscera disconnected with ileo-cæcal affections, yet the consequences of inflammatory action extending to other parts, and the effects of perforation inducing peritonitis, with the suppuration involving adjacent tissues, owing to structural changes in this portion of the intestinal canal, belong to our inquiry. The results of operative proceedings in general peritonitis under the new régime encourages a resort to laparotomy under circumstances which formerly would have been considered as contra-indicating such a measure of treatment, and this is the most striking outgrowth of antiseptic surgery which recent investigation has developed. That the very condition of the abdominal contents which previously proved a barrier to incising its walls, should now present a sufficient reason for laparotomy with a view to its proper treatment, is a grand revolution in abdominal surgery. Not only in peritonitis following perforation, but in that from general morbid impressions, laparotomy is warranted by the record of cases in which relief has been thus secured.

There are cases of recovery or death reported in which accurate diagnosis could not be made, and in which consequently no operation was undertaken or autopsy permitted. The statistics of obstruction being always doubtful without an exploratory incision, we cannot draw a satisfactory comparison between the supposed cases of invagination which are

relieved by general treatment and those which are verified by the performance of laparotomy. But the number of cases in which the diagnosis has been confirmed by a detachment of some portion of the alimentary canal and its presence in the evacuations, may be compared with those fatal results in which invagination is recognized by autopsies, and it is very desirable that we should have accurate statements of all such cases, for the purpose of forming a table representing the percentage of mortality without laparotomy. These two proceedings have their advocates in British surgery, under the leadership respectively of Mr. Jonathan Hutchinson and Mr. Frederick Trèves, the former holding to the treatment without operative interference and the latter supporting early resort to laparotomy.

An elaborate report of Prof. Heinrich Braun, of Jena, upon the operative treatment of invagination, presented to the German Medical Congress, April 8, 1885, gives a table of cases with results as follows: Since 1870 out of sixty-one cases there have been fifty-one operations, eighteen of these cases having occurred in Germany and the remaining forty-three in other countries; of the whole, thirty have occurred in children and twenty-one in adults. In those operated upon eleven have been relieved while forty have terminated fatally. In twenty-seven of the cases disinvagination was effected and in twenty-four it was not; of the former eighteen were children and nine were adults. Four children survived while fourteen died. Seven adults lived while two succumbed.

Resection of the invaginated intestine was practiced in twelve cases, of which only one lived and the other eleven died, six being children and five adults. Enterotomy was performed in nine cases with death in all, there being three children and six adults. Enterotomy without disinvagination terminated fatally in ten cases, seven being adults and three children.

In eight of the sixty-one cases tumors existed and some of these were of a malignant nature. Of the cases in which the invaginated portion of the intestine was removed by resection, 42 per cent. died from peritonitis, perforation, or subsequent stenosis.

The inference drawn by Dr. Braun from the unfavorable results of those cases in which operative measures were delayed from a few to many days after the development of symptoms, is, that surgical operations should be resorted to promptly when the invagination is not relieved by simple measures. When the disinvagination is accomplished while the bowel maintains its vitality nothing further is indicated, but when gangrene has commenced, resection should be resorted to, provided the general strength of the patient favors it. But in cases of marked prostration, accompanied with meteorism, it is advisable to form an artificial anus, as the most speedy means of relief.

In the discussion upon Dr. Braun's paper, it appears that in German practice the early stage of all abdominal disorders is relegated to the physician's management, and it is only when operative interference is demanded that the patient comes under the surgeon's care, so that the case is usually of a grave

order before surgical measures are adopted. Even washing out of the stomach and enemata of various components, with inversion of the body, massage, etc., and internal medication or subcutaneous injections, are resorted to by the physician sometimes for days in succession before turning over the patient to a surgeon. There is no greater mistake in regard to the province of surgery, than to consider this sphere of duty as limited to instrumental appliances, and it should be understood that the highest and noblest achievement of the surgeon is to cure when it may be practicable without the knife, or in cases requiring it, to prepare his patient properly for an operation. Thirty-two of the cases reported involved the ileo-cæcal connection, and of these only three survived, being less than 10 per cent. of cures by operative measures in this class of invaginations.

In a table of resections of the intestine for malignant growth, accompanying a paper of Dr. Robert F. Weiss, presented to the New York Surgical Society, January 26, 1886, seven out of the thirty-five cases given were located in the ileo-cæcal structures. Four of these cases survived the operation of resection, and in another the result is not stated, but probably recovered from the operation, thus affording 71½ per cent. that escaped death from resection of the ileo-cæcal connections involved in malignant disease. The fact of recurrence in most of the cases at a longer or shorter interval does not materially affect the consideration of the propriety of such a measure; and yet there is an important lesson to be learned from the greater tolerance of the operative procedure in this chronic disorder of the tissues than in that acute inflammation connected with invagination.

A recognition of this pathological modification is essential for a proper comprehension of the surgical relations of the ileo-cæcal region and for a due appreciation of the different stages in the inflammatory processes affecting the various structures entering into this complex organism, at which separate steps may be taken for their relief. We have to encounter with surgical appliances the incipient hyperæmia or engorgement of tissues, the progressive changes of the inflammatory process, the suppurative degeneration and structural disintegration of acute developments; while on the other hand we must be prepared to combat the slower progress of fibrinous depositions, indurations, and accretions of material due to chronic disease, involving the elements which enter into the different tissues composing these organs. Again, the surgeon has to deal with those adventitious growths connected with malignant disease, which is very prone to manifest itself in the ileo-cæcal region; and each calls for a distinct mode of surgical treatment.

The operative procedures indicated by ileo-cæcal disorders are extra- or intra-peritoneal; the former consisting in exploratory punctures through the tissues in the inguinal or lumbar regions, and subsequent incisions to evacuate purulent collections; and the latter in laying open the abdominal wall for the purpose of correcting the abnormal relation of parts in the ileo-cæcal region. At the earliest period that pus may be detected in the iliac tumors deep inci-

sions have been attended with satisfactory results for the relief of faecal abscesses. With the lights of experience as to the serious consequences of delay in obstruction of the intestinal canal from any cause on either side of the ileo-cæcal connection, it is warrantable to resort to laparotomy as soon as the symptoms indicate occlusion from other sources than faecal impaction, without waiting to make a differential diagnosis, or delaying to test the effect of temporizing measures of treatment. The division of constricting bands, the unfolding of twists in the intestinal canal, the release of the invagination of one portion of the tube in another, the excision of gangrene or diseased segments and reunion by sutures, are demanded in various cases.

FIGURE 1.—A shows the insertion of needles for first stitch in intestinal walls. B represents the placing of initial loop. C displays the thread ready for closing. D gives the progressive stitching of walls in the opposite margins. E indicates the completion and knotting of threads.

Stenosis from fibrous depositions or malignant growths in the vicinity of the ileo-cæcal connection would seem to warrant the removal of the entire structure involved. But a grave question is presented as to the practicability of such a resection of this portion of the intestinal canal, and restoration of its tract, without a fatal result in acute cases. My experiments upon dogs by entire removal of the ileo-cæcal connection, and uniting the ileum with the colon, has caused death promptly in each case, apparently from the effects of shock, and it is doubtful whether favorable results can attend this operation on the human subject—the successful case of Czerny being incomplete resection, cannot be accepted as recommending excision in acute cases. The practicability of relief in this class of cases by effecting a direct communication between the ileum and colon, so as to cut off the passage through the ileo cæcal valve, is worthy of consideration. This may be accomplished by uniting their walls with the Gely suture in an oval or circular form, so as to strangulate the enclosed segment, and thus cause an opening, while the outer surfaces become agglutinated, thus

effecting union with immediate passage of the intestinal contents. The diseased structures become atrophied or may be excised subsequently. If it should be desirable to effect an immediate passage from the ileum into the colon, with a view to accomplish the resection of the diseased structures on the same occasion, there could be no difficulty in proceeding upon the same principle as indicated by my punch process for the communication of the gall-bladder and duodenum (in the article on “Duodeno-Cholecystostomy,” which appeared recently in the second volume of the “Reference Handbook of the Medical Sciences”).

FIGURE 2.—F exhibits the attachment of the exterior surface of intestinal walls. G, needles entered for last stitch in the united coats of the large and small intestines. H is a view of the stitches in mucous membrane through the incision of colon. I is the opening seen by making an incision in the walls of the ileum after separation of segment of both coats. J represents the consolidation of exterior surfaces around the communication between the canals.

The application of this suture is made equally well in the continuity of the intestinal walls or after removal of a segment from each through a doubling of their coats, and effects from without the canal what is proposed by Bishop's suture from within. A single thread having a needle attached at each extremity is passed by the respective needles through the two several approximated walls of the large and small intestine, making a stitch of corresponding length through the whole of the tissues; and then by passing across so as to penetrate on opposite sides at the point of exit, other stitches are made, which draw the exterior serous coats in close apposition. Quite recently I have met with a strong confirmation of the indications for the process of mediate communication in the statement of Mr. T. B. Jessett, in his lectures at the Cancer Hospital in London, as follows: “When the obstruction is caused by the pro-

jection of a cancer into the gut the calibre of the tube may be restored by the breaking down and sloughing of the mass; or the disease extending, adhesive inflammation may take place between it and the adjacent portion of the intestine; ulceration taking place between the two portions, and an opening established, whereby the passage of fæces may occur from the portion of the intestine above the disease to another portion below it."

We may imitate nature in her effort to obviate the difficulty of constriction in the natural course of adhesions and a fistulous communication directly, by adopting the measure for uniting the coats of the intestinal canal above and below the point of stricture, and thus establishing a direct route for the passage of the contents of the alimentary canal by cutting off the obstructed coil of intestine.

The practicability of this procedure is shown in the operation of gastro-enterostomy, which consists in forming a fistulous opening between the stomach and jejunum, as originally suggested by Wölffler. It has been proposed by Billroth to remove the pylorus subsequently, and stitch up the cut ends, thus turning the food entirely through the artificial opening; and a similar operation of a secondary nature would be available for the removal of the ileo-cæcal connection involved in disease. So soon as the direct artificial communication between the ileum and colon is fully established through the opening made by separation of the tissues included in a circular or oval row of stitches, the cessation of the passage through the ileo-cæcal valve must lead to a gradual atrophy of the structures adjoining on either side, and in case of simple stenosis, obliteration of the canal will ensue, while if carcinoma exists, there will be such a diminution of vitality in the healthy attachments as to lessen materially their susceptibility to shock or inflammatory action, so as to admit of the requisite operation for removal of resection and suturing for closure of the divided ends.

A thorough investigation of the morbid conditions of the ileo-cæcal region leads to the following conclusions:

1. That certain modifications are corrected spontaneously, or by the process of resolution under treatment.
2. In the early stage of ileo-cæcal disorders, medicinal or mechanical measures are advantageous.
3. That extra-peritoneal punctures and incisions are beneficial in cæcal inflammation, with or without fæcal abscess.
4. Disorders involving the peritoneum, when not promptly relieved by general treatment, warrant exploratory opening of abdomen.
5. Impediments of the intestinal canal or morbid accumulations in the abdominal cavity, accompanied by meteorism, call for immediate surgical interference, with laparotomy.
6. In case of simple stenosis or malignant growths involving the ileo-cæcal connections, ileo-colostomy is indicated.
7. Gangrenous portions of the intestinal canal necessitate resection, and either direct restoration by suturing the ends or the formation temporarily of an artificial anus.

8. Operative measures in the ileo-cæcal derangements should not be delayed until the physical powers have become prostrated, but resorted to while there is capacity for reaction of the vital forces.

WHY DISEASES OF CHILDREN SHOULD BE MADE A SPECIAL STUDY.¹

BY MARY HARRIS THOMPSON, M.D.,

OF CHICAGO.

The reasons why diseases of, or in children should be made a special study by the profession, are:

1. Because of the undeveloped and growing patient, which, though ill, must yet be nourished.
2. Because of the difficulty in diagnosing those maladies, termed by Dr. Billings in his last report of vital statistics, as ill-defined forms of disease to which children under one year of age are subject.
3. Because, remedies considered essential to the relief of adults, are illy borne by the young child, and that those used must be considered in regard to the administration with the peculiar food of the child, the minute dose appropriate to the age, and the susceptibility of the nervous system in the infant to narcotics.
4. Because the special study will reflect itself upon the minds of the laity, impressing them with the importance of saving a child's life, and that, in so doing, a life in its entirety has been saved.

It is presupposed that, as we advance in civilization and enlightenment, health and enjoyment of living, if not wealth will result. Examination, however, proves that health is no more common among the people of to-day, than it was among the people of a hundred years ago. The very beginning of life is injured, first by vices of heredity, and second by the manner of parental living. The end of foetal life is the beginning of a new one, beset with new dangers.

With the aid of the medical profession and its statistics, knowledge of the great mortality among children in the earlier months and years of life, is just dawning upon the minds of the laity. Although the subject is receiving some attention, there is no attempt to quarantine the vices of the nursery, the orphan asylum, the baby farms, much of the fashionable clothing of the children, the soothing syrups with their seductive amount of opium, and lastly, the fifteen-year-old nurse-girl, with careless habits, mouldy nursing bottle, and as little practical knowledge of hygiene for the child as she has of navigation. With a cordon around these and the abolishment of the "quiet homes for women during confinement," the advertisements of which are allowed to fill the columns of the daily press; homes which prove too frequently so quiet for the child, for all time to come, we should have hope for a better and stronger race. Thus fortified, and with mothers willing to forego the pleasures of fashionable life and to devote themselves to infants of a healthy parentage, there will remain,

¹ Read in the Section on Diseases of Children, at the Thirty-Seventh Annual Meeting of the American Medical Association.

with the accidents incidental to child-life, enough for us to study.

Let us take a child at six months or six years of age and without syphilitic inheritance. If pulmonary, cardiac, or renal inflammation sets in, do we have the same symptoms by which to make a diagnosis as in adult life? Can we discern rheumatic inflammation for a certainty, in a child of either of these ages, before it has expressed itself in the swelling of some joint, or in the endocardium, and has made a lasting impression on the economy? The difficulties which present themselves in diagnosis are, that we have at six months a little individual susceptible of human disease, but with little more language than that of the lower animals; and with certain organs out of proportion to those of the adult.

At birth there is the large liver, which under the effect of the new physiological action of respiration by the lungs, so frequently produces infantile icterus. There is that condition of chest wall, air cell, and bronchia up to ten years of age which produces the "puerile respiration." Through the same period the bones are so cartilaginous that though allowing much rough usage without resulting injury, the long bones frequently bend without any fracture, or partially break causing the "green stick" fracture, or break at the epiphyseal junction. In childhood there may occur injury to the skull which will result in epilepsy or mania in adult life. The simultaneous growth of the brain and nervous system with the other tissues is of such delicate balance and the nerves are so susceptible to the touch of disease in any organ that they may give a storm of action upon trivial causes, thereby, in the convulsions of this age, simulating most grave diseases and rendering a correct diagnosis difficult.

Though diseases *in*, or *of* children have not been a special study with me, a goodly number of the little ones have been placed under my care for treatment, and times have come when necessity has compelled me to pass from works on "theory and practice" to monographs on this particular subject. In consultation with wiser and more experienced physicians, in times of doubt in diagnosis, I have been deeply impressed with the general perplexity in determining which of the wheels in the miniature human mechanism before us, was out of order. In somewhat varied ways, we arrive at a correct diagnosis of the same disease in the different periods of life.

It is a gratification to have men of high culture and great experience, such as Eustace Smith, Goodhart, Barthez and Rilet, our own Smiths, and others, tell us of the difficulties of diagnosis in children. Eustace Smith says: That on account of the indefinite character of the symptoms, hæmorrhage into the brain or its meninges is very difficult to detect, and farther on that a diagnosis between hæmorrhage into the meninges or that into the substance of the brain is probably impossible.

Goodhart says that in pneumonia the sounds of consolidation are transmitted from side to side, particularly about the root with great readiness, and it is quite common in the auscultation of the lungs of children suffering from pneumonia to have evidences

of consolidation at one visit which have gone at the next, or within a short time, and which must indicate a still more ready interchange of collapse and expansion than has probably hitherto been appreciated. In mentioning the difficulties of auscultation in children, he says that the ribs are soft and the muscles act more unevenly and the different parts of the thorax expand with comparative irregularity.

In the case of the child, the diagnosis having been made, the *treatment* must next be considered, and changed greatly from that of the adult: this, not only in the size of the dose, but in the manner of administration. The younger the child, the more rapid the effect of the disease. Let me introduce an illustrative case which will show how rapidly disease may appear, disappear, or come to a fatal issue in an infant: C. H. was born in the Chicago Hospital for Women and Children January 31st, 1886. He was a large, healthy, well-formed boy, and although bottle fed, was well until nine days of age. At that date, February 11th, thrush appeared in the mouth and pharynx and was accompanied by diarrhœa with very green, thin, watery stools. For the thrush, the mouth was cleansed immediately after each feeding, and washed with the following mixture:

R. Sodæ bicarb.	3ss.
Acid carbol.	miv.
Glycerine and aqua, aa	3ss.
	M.

For the diarrhœa, the food was peptonized, and the hydrargyrum cum cretâ in one grain doses was given at intervals of three hours, and was followed at night with ol. ricini. in a m. x dose. On the succeeding morning the child seemed quite well. February 12th in the morning, the resident physician reported that one arm appeared paralyzed and hung motionless; the child had cried as if in pain and was sleepless. Examination revealed the head of the humerus, dislocated forward. The dislocation was easily reduced and bound in place, for we feared the child had had rough usage from the mother, as she had never welcomed it, but had always appeared impatient. None of the nurses knew how the accident had occurred. The child now ceased crying, and in the afternoon when the arm was unbound, used it as well as ever. On the morning of the 13th, it was reported to have begun a little moan the night before, and as having been restless all night, taking only short naps. We found it with slightly increased respiration, and a temperature of 101.3-5° F., which continued the same throughout the day. Percussion of the chest elicited nothing unnatural. Auscultation gave fine, dry, crepitant râles in the middle lobe of the right lung. There was some mucous râles in the upper lobe of the left lung. A warm bath containing bicarbonate of soda was ordered. The nurses through a misunderstanding added alcohol. This bath was given morning and night. Poultices were applied across the upper part of the chest, and under the right arm. They were renewed every second hour. They were ordered to be made as warm, not *hot*, as the child could bear. Having in view the desirability of giving the medicine in very small doses, in simple form, and with the food, the following was

given: Ammonia muriatis gr. x., was dissolved in aqua m. xv. S. One drop in milk every second hour, when not asleep.

On the morning of the 14th, the patient was about the same as the previous evening. The chest was not percussed or examined as the room was cool on account of an accident to the steam heating apparatus, and we feared the lady had been brought on by exposure by the mother, and possibly by us in reducing the dislocation. The child died at one thirty o'clock on the morning of the 15th, just a little more than forty-eight hours after the lung trouble had been recognized, and two hours after taking a usual quantity of food, with natural relish, and appearing more than ordinarily bright, and then sleeping as in health.

Examination of the chest and abdominal cavities was made nine hours after the demise. The digestive organs were healthy as were their contents. The right pleural cavity was so completely full of a reddish straw-colored serum, that it welled out upon the first break of the pleural sac when opening the chest at the highest point, and was estimated to be several ounces. The costal pleura was of a dark pink color; the pulmonary pleura was of a more opaque white and very slightly mottled, with large spots of a darker tint, but with a more transparent appearance of the membrane. Otherwise, the lung seemed normal with the exception of an apparent cyst, partially embedded in the parenchyma, and now about to burst the greatly attenuated pleura. When it was opened, about one drachm of perfectly transparent, thin mucus flowed from it. This cavity was formed by the rupture and coalescence of the air cells, leaving a direct communication from one of the larger bronchiæ to the pulmonary pleura. There was no congestion around this cavity; no staining as if small capillaries had been lacerated, no fringed appearance to the naked eye. There was no cyst wall, no thickening of bronchial tubes.

Had the child died immediately after the feeding, it would appear as if the quantity of food in the stomach, might have added its pressure to that of the already existing, and rapidly effused fluid in the chest, and so have been one factor in causing the death, but the stomach was nearly empty.

Queries: Had the pleurisy existed only forty-eight hours, and with this result? Was the pleurisy the result of the pneumonia or *vice versa*? Or did they begin simultaneously? The lung was not greatly compressed as in adults in even acute cases of pleurisy. Shall we ever so understand diseases of children, that upon approaching a very sick infant, we shall not feel as if we are approaching a mystery forbidden us to know?

In child life, there is one grave effect of some maladies, that is greatly to be dreaded. It is that of deformity. In many instances, it leaves the child as a care, or burden to the whole family. It is true, that it may be in some cases a pleasurable one, and in some, there may be a moral compensation for the misery entailed upon the sufferer and friends, but it too frequently warps the mental, as well as the physical powers.

Some years since, it became my duty to treat a young woman of sixteen summers, who was said to have had spotted fever at six years of age. The head was developed to the age of sixteen; the chest was but partially so. There was a twisted condition of the spine, from a lateral and posterior curvature caused by a *development* of portions of the muscles, and a *paralysis* of others. The lower portion of the body had grown but little since her illness in early childhood. She lay upon her wheel chair, or couch. A fortune had been spent on jackets and corsets for the curvature, and electrical treatment to develop *muscular* action. One sister had given nearly her entire time for the comfort of this child, during the period of ten years; and the family had cared for the two sisters. This young woman, while a beautiful character, never seemed to *live* in the full sense of the word. She could neither laugh nor cry in a natural manner. She was taken ill with inflammation of the larger bronchi. With a natural condition of the chest wall, there would have been no danger; but when bronchorrhœa set in, in the second stage, she was unable to make more than feeble attempts to cough, because of paralysis of the intercostal and other muscles, and almost immovable chest-wall; hence her sudden demise from asphyxia from occlusion of the bronchi.

The maladies of either adult or child life cannot well be considered with a view to successful treatment, without first studying their origin. By so doing, we learn in what way, the laws of hygiene have been violated, and approach the millenium in the practice of medicine. However, we are, as yet, far from the goal of complete success. Though Koch, with the bacilli of cholera, and Pasteur with those of hydrophobia have made great strides, yet cholera still makes its periodical visits, and inoculated patients still die of hydrophobia. It has not been altogether determined whether septicæmia is produced by bacteria or ptomaines, the latter supposed to be the result of the former. There seems to be some doubt even as to the real origin of typhoid fever. It is a question with me whether some minor affections such as anæmia, leucocythæmia, and leukæmia may not be the result of micro-organisms in the blood. Cases of these classes have come under my observation in such ways as to prompt me to learn if some special manner of living had induced them. In two recent cases it proved to be dark, damp rooms, in which the patients not only slept, but lived during the day. These recovered with the use of iron and constant sunlight.

A rather curious, but interesting case was that of a little girl four years of age. Her parents lived in a desirable residence region; but she slept in a room on a damp court. The face became pale, and there was a loss of appetite. She suddenly became lame, or, as she expressed it, her arm would hurt her. Upon examination, the arm or leg would be found swollen from a certain point downward. The greatest point of swelling would be marked by a large ecchymosis of a dark purple color, as if the result of a bruise. There was an elevation of the ecchymosed spot above the general surface, as if produced by a large flat clot

in the subcutaneous tissue. In the course of a week or ten days, the color would change to a greenish red, then to reddish yellow, then gradually fade to the natural color, the oedema disappearing with the change in color. The heart beats were weaker than natural, but slightly increased in frequency. Within two months, these spots appeared and disappeared several times upon both upper and lower extremities. Though taking iron and quinine in large doses, she did not wholly recover until she lived in sunny rooms and slept in those sunned by day. Her food had been good. Was this malady produced by micro-organisms, allied to the malarial plant and generated in the dark, damp court of a high building? Her sisters showed no symptoms of the same disease, yet lived as she did.

Let us ask for more knowledge in regard to the *hygienic* treatment of children, which, if systematically followed, would be a *great power* in our hands. Should there be baths, or no baths? If baths, what kind? Should there be exercise, or no exercise? What kind of food should be taken and how?

It is all important that the character of food be changed for certain wasting diseases, as, in this condition of *growth*, if the child be deprived of food, by a lack of it, or by a diseased condition of the digestive apparatus, the result to the child is as disastrous as that of hemorrhage is to the adult. Many a child literally dies of starvation, when the cause of the death is said to be ileo-colitis, or gastritis, or perhaps some disease not touching the alimentary canal itself. Yet had the physician given special directions regarding the food, the child might have recovered. Probably all have had cases of pertussis where children would throw off the food with a violent fit of coughing, and fade and grow thin if the meals were not immediately repeated.

Paradoxical as it may sound, children are often starved by what is called "good living." A full diet is allowed at a time when it produces so much irritation, as to cause an extension of some existing inflammation, or start a new one. For instance, a child of three summers with severe dysentery, which had recurred just two weeks after a former attack, was allowed not only the full diet of vegetables, pastry and fruit of the parents, but also full goblets of ice water. It died on the fourth day.

Another child of five years, with acute gastritis, a parched tongue, great thirst, nausea and vomiting, had all food by mouth discontinued. Only a few drops of water, perhaps a fourth of a teaspoonful, were allowed every fifteen minutes, an amount which might be absorbed before it reached the stomach. Nutritious enemas were given during a whole week; the boy recovered. The eruptive fevers of childhood have not been referred to, as their effects are as deleterious in the adult as in the child, except if deformity occur in childhood it is to be the longer borne. In these cases, however, when the exanthemata appear in full blossom upon the mucous membrane of the alimentary canal the only direction in regard to feeding should be to give the food in liquid form.

I cannot drop the subject of diseases in children, without reference to two remedies which are probably

as old, if not older than any others in the pharmacopoeia. They are opium and alcohol in their great varieties of form. Reference to them is made in order to raise the question if they cannot in any way be replaced. Administered once or twice, or for several days, for the relief of pain, opium may be most acceptable; but it is too frequently given before pain, the kind monitor, has made us understand in *what* way the economy is suffering. Again, if we allow the pain to continue until its source is found, the cause may be removed without the deadening opiate. The opiate is given to *quiet*, the alcohol to *stimulate*. The opiate proves to be the stimulant to many constitutions unless given in dangerous doses. If it be necessary to give opium for *acute* pain, it is certainly necessary for that pain which exists a long time. Twenty years ago it was regarded as *the* remedy in puerperal diseases, especially septicæmia; but it seemed to me that many patients died of the remedy instead of the disease. To-day many children die of the remedy instead of disease. Others live to recuperate after a *long* time, from a shattered condition of the nervous system, and an unnatural condition of the circulation, both having been induced in a measure, by the opiate.

Alcohol first stimulates, then quiets, leaving the system under great depression, and with a desire for further stimulation. In time vitality is lost. I am hoping to find in the new remedies, something which will not lead the patient into a condition of servitude, as do opium, alcohol, cocaine and chloral. Heat, an old remedy, will in many instances take the place of opiates and alcoholic stimulants. When applied to a part it increases the circulation in the capillaries of that part. When first applied it relaxes the wall of the capillary, thereby increasing the size of its lumen, allowing the collecting blood cells to pass on, and so causing the pain to cease. Opium, taken into the stomach, "slows" the whole circulation. If to quiet a local pain, the whole circulation is decreased below the normal standard, the whole economy suffers therefrom. If the circulation is increased when stagnation is occurring and producing pain, the relief is secured in a more natural manner, the secretions are not checked, and the *materies morbi* pass out of the economy, doing but little harm. I have used heat, applied externally, for pain in the chest, abdomen and pelvis. Even in diphtheria, when the tissues around the neck were swollen to their utmost, heat has relieved the pain speedily.

If obliged to use alcohol, let us, in the treatment of children, intentionally make it unpleasant. But if we cast about, we can often find that which *will* take its place. Let us use ammonia, heat, or *any* remedy, that will not dwarf the growth, through the nervous system, as *opium* does; that does not form in the child an uncontrollable appetite as alcohol or opium does if continued for any length of time; an appetite which the full force of a *man* cannot break.

A NEW POISON CASE.

BY G. W. WEBSTER, M.D.,
OF CHICAGO.

Cases of poisoning, either accidental or otherwise, are, unfortunately, quite numerous and very many of them are fatal. The treatment, in order to be suc-

Messrs. Charles Truax & Co., 81 Randolph street, Chicago, manufactured and filled the case for me, and succeeded in making a very desirable case, one that is neat, compact and durable.
1920 Indiana Ave., Chicago.

cessful, must be precise, energetic and prompt. In many cases, especially in the country or small towns, it is often difficult and many times impossible to procure the proper antidotes or remedies in proper form for administration, or even to obtain them at all. Then, again, not every physician carries in his mind a precise knowledge of the symptoms of all or even the important poisons, together with the proper antidotes, remedies and treatments.

In order to overcome these difficulties at least in a measure, I have designed the following described case:

It contains a stomach tube, hypodermic syringe, and the following remedies and antidotes: Ether, ammonia carbonate, amyl nitrite, apomorphia, atropia sulphate, brandy, camphor, animal charcoal, chloral hydrate, chloroform, digitaline, iron sulphate, dialyzed iron, tr. of chloride iron, calcined magnesia, mucilage, morphia sulphate, potassium bromide, potassium iodide, liquor potassæ, strychnia acetate, sodium chloride, sulphuric acid, tannic acid, and zinc sulphate.

The case also has a small pamphlet, compiled by the author, which gives a summary of the general treatment of poisoning, together with a list of substances which are poisons, with the prominent symptoms and treatment of each.

Each bottle is labeled with the name of the drug, the dose, how administered, and in which cases it is most serviceable. I do not assume to offer anything new in either methods or remedies, but only to have the latter in a convenient form for immediate use.

INHALATIONS OF MURIATE OF COCAINE IN
WHOOPING-COUGH.

BY A. Y. P. GARNETT, M.D.,

OF WASHINGTON, D. C.

In the *Medical Record* of July 31st, we find a résumé of the most modern methods of treatment for this disease, embracing a brief notice of the remedies used by several German, Spanish, French and Brazilian practitioners of distinction, with reported results as late as the present year; each claiming for some particular agent, specific virtues in modifying or curing this intractable and distressing malady.

Whilst the remedial agents employed by these gentlemen differ materially in their therapeutic results and topical effect, their use has obviously been predicated upon the theory that the disease is purely a local one and amenable to local treatment only. Hence we find insufflation through the nostrils, sprayings and pencilings to the throat and pharyngeal surface, the principal methods adopted for the topical application of these remedies. In one instance only have we observed the practice of inhalation mentioned and that of Dr. P. Sertoli reported in the *Revista Clínica e Terapeutica*, of June, 1886.

This writer extols the effects of iodoform and spirits of turpentine in whooping cough and claims that by the use of these remedies through inhalation he was able to diminish both the frequency and severity of the attacks. In January last, I had under my care two cases of pertussis, one a child of five and one of two years of age. The children were seen,

one in the second and the other in the third week of the attack, both suffering with all the distressing phenomena incident to a full development of this disease. Many of the ordinary and some extraordinary remedies had been used without in any degree mitigating the severity of the paroxysms. Sympathizing with the unhappy mother, as well as the little sufferers, I resolved to employ, if possible, some hitherto untried agent that in my judgment might afford immediate relief. With this view I determined to try the use of hydrochlorate of cocaine by inhalation, and in order to procure it in a form sufficiently volatile to be readily vaporized selected chloroform as the solvent. A six per cent. solution of muriate of cocaine in chloroform was prepared and ten minims poured in a wine glass made warm by tepid water was placed under the patient's mouth, whilst the mother was directed to keep the nostrils closed. No difficulty was experienced after a few trials in getting the patient to breathe in the vapor, which seemed to produce rather an agreeable effect than otherwise. This practice was repeated every four hours and whenever it was possible to do so, immediately preceding or at the outset of a paroxysm of coughing, in the latter instances using double the dose of the solution. It was found that by this means many of the paroxysms were arrested entirely or materially cut short, and, although the treatment seemed to fail in curing the disease or shortening the usual period occupied by its three stages, it certainly altered and mitigated the severity and distress of the paroxysms.

The present epidemic of whooping-cough in Washington, which commenced in the month of June has afforded me ample opportunity of multiplying my experiments with the use of the chloroform solution of cocaine, the result of which has confirmed the conclusions, of its marked effect, arrived at with my first two cases in January. Some difficulty is usually encountered in administering the remedy by this method with very young children, in which event the ten or twelve drops may be poured upon a handkerchief, which can be substituted for an inhaler, the latter instrument being easily managed by elder children.

Whilst I am aware of the popular theory which attributes the origin of pertussis to the presence of specific micro-organisms or parasites, and recognize its power of self-propagation and contagious character, I am inclined to regard it as entirely a neurosis, tracing the initiatory morbid impression or manifestation to those nerves which are distributed to the laryngeal mucous surface, resulting at first in functional disturbance of the vaso-motor nerves, impaired innervation and local irritation; that this condition, although resembling in its pathological and physical features ordinary catarrhal affections of this organ, is essentially different and due to some specific cause, is shown by the fact that ordinary laryngitis and bronchitis are never attended with the pathognomonic spasm of whooping-cough. The additional evidence of its nervous origin and complications, especially with the pneumogastric, may also be found in the distressing vomiting which accompany the paroxysms of coughing. The hyperæsthesia, hyperæmia and turgescence of the mucous lining of the larynx and

trachea consecutive to and consequent upon the primary nervous disturbance, in the second stage, is followed by a metamorphosis of cell products, copious secretions and slight tissue changes. The bacteria, micrococci and other micro-organisms found in these secretions, are in my opinion the *post hoc* innocuous products and not the causative agents, of the disease. The "contagium vivum," or *materies morbi* has not yet in my judgment been clearly demonstrated. The fact that infants have been born with whooping-cough contracted during foetal life would seem to show that the cause producing this disease is not always extraneous. Taking into consideration the local manifestation of this disease with the morbid conditions which we find in the lining membrane of the upper air passages in connection with the known action of cocaine upon the terminal extremities of arteries and nervous filaments, we are forced to acknowledge that it possesses in an eminent degree the power to fulfil the indications presented in the treatment of whooping-cough.

Topically applied to the inner surface of the larynx and trachea, the sentient nerve filaments are temporarily benumbed or anæsthetized, the peripheral arteries are diminished in calibre and secretion greatly checked, whilst the lining membrane of the larynx is reduced in vascularity. No other remedy yet suggested possesses the capacity to exercise in so potential a degree these several therapeutic desiderata.

In assuming to doubt the correctness of the theory that this disease owes its origin to a specific germ or microbe, I am aware that I expose myself to the criticism of a large number of my professional brethren, since it has become the fashion to attribute every disease to some special or specific micro-organism whose all-pervading and omnipotent influence is not alone confined to the rôle of pathogenesis, but according to some of the more enthusiastic micro-maniacs, are essential components of the atmosphere we breathe, equal in life sustaining qualities to oxygen itself. Nothing can be more gratifying and satisfactory to the medical mind than such a theory. It explains everything and furnishes a plausible solution for many of the most difficult problems encountered by pathologists. I have no doubt that these investigations which are now being prosecuted with such ardor and zeal are destined to develop in the domain of microscopy both marvelous truths and phenomenal fallacies, either or both of which will be eagerly accepted by the profession at large, and he who may have the temerity to reject either, will in their estimation most assuredly "Write himself down an ass." I think I see in the near future established here in Washington, a National Health Department, with a Bureau of Prophylaxis attached, whence there will be issued daily bulletins warning us of the approach of zymotic or epidemic waves of deadly microbes of yellow fever, scarlet fever, diphtheria, with as much accuracy as the Signal Bureau now predicts the advent of those thermal frigid waves which alternately cremate or freeze the inhabitants of this section of country.

MEDICAL PROGRESS.

SUBLIMATE INJECTIONS IN GONORRHOEAL CYSTITIS.

—The history of an obstinate case of gleet and cystitis is given in *El Dictamen* by SEÑOR GARCIA ANDRADAS, which after being treated unsuccessfully by means of injections of nitrate of silver, yielded very quickly to injections of corrosive sublimate. The patient, who was a river fisherman, contracted gonorrhoea, which was treated for a month with balsams and astringent injections. The discharge then became serous, and exquisitely painful vesical tenesmus supervened, the calls to urinate being so frequent as to give the man no rest. An attempt to pass an instrument occasioned the greatest agony when it came in contact with the prostatic portion of the urethra. The diagnosis made was that of acute prostatic cystitis consequent on gonorrhoea, and so the local application of a sublimate solution appeared to be the most rational treatment, as it had in the author's hands proved very beneficial in cases of subacute cystitis due to the same cause; but it was thought well to try first Guyon's treatment. With great difficulty, owing to the extreme sensitiveness of the urethra, an elastic catheter was passed to the prostatic portion, and 10 grammes of a 1 per cent. solution of nitrate of silver injected. A few minutes afterwards urine was passed with great pain, so a warm bath and an opiate were ordered, which gave only temporary relief, the opium having to be repeated at night. The next day the patient's condition was the same as it had been before the injection. Three or four days afterwards a similar injection was given, with no better result. Four days later, as there was no improvement, the use of sublimate injections was commenced. The catheter was passed as far as the prostate, and 45 grammes of a 2 per mille solution of sublimate in warm water were injected. This the patient was compelled to retain for three minutes; the subsequent micturition was very painful, but at night he was able to rest and retain his urine for three hours. The next day the urine was less turbid, and it was voided less frequently. His condition continued to improve for three days, when a second sublimate injection was given of double the quantity of solution. This occasioned some pain, but it quickly passed off and the patient was able to rest. In four days' time he requested to be discharged, as his urine was clear and he had no pain on micturition. Thus, the author remarks, two injections sufficed to cure completely an affection usually most obnoxious to treatment of an ordinary kind. The superiority of sublimate injections has shown itself in several cases of a somewhat analogous character in which he has employed it. These he proposes to publish and discuss on some future occasion.—*Lancet*, August 21, 1886.

ANTIPYRIN AS AN ANALGESIC IN HEADACHE.—DR. JOHN BLAKE WHITE, Physician to Charity Hospital, New York, says:

During the past two years I have abundantly tested the therapeutic value of the drug known as antipyrin in various forms of headache. The prompt

relief obtained through its use compels me to accord to it a high rank among our medical resources. I have already called attention (*Medical News*, July 10, 1886) to the potent antipyretic power possessed by this remedy in the management of various forms of fever, and have observed that after its administration the urgent symptom of headache, so uniformly present in these cases, was soon controlled.

Antipyrin undoubtedly possesses bradycroto properties in a high degree, as the pulse is notably softened and moderated in frequency soon after a proper dose of it has been taken. It produces some somatic change favorable to a reduction of the pulse in cases of fever, and so exerts a calming influence upon the vaso-motor system. The capillaries, through its agency, doubtless dilate, and local congestions are dissipated, as the relieved patient usually sinks into a refreshing repose soon after its exhibition. In the course of large experience with antipyrin I have found that, when administered in masterful doses, it not only promptly relieves the symptom of headache whenever present, whether resulting from disordered digestion, disturbance of the menstrual functions, loss of sleep, undue mental effort, or even that associated with dreaded uræmia, but also possesses reliable prophylactic virtues against recurrent attacks of cranial neuralgia. So confident am I of the power of this remedy to disappoint neuralgic headache when imminent, that I have instructed many patients, who are liable to such visitations, to keep in readiness and take a dose of antipyrin as soon as they have premonition of its recurrence, and all so far testify in favor of its efficacy.

The value of this remedy in the above respect has not only been tested in my hospital and private practice, but I also record the fact that it has proved successful in the hands of professional friends, upon whom I had urged its employment for the relief of neuralgic affections of the head and face. I have been singularly impressed with the promptness of relief which often followed the administration of even a single dose of fifteen grains of the antipyrin. The grateful relief from headache usually ensues within half an hour after the drug is taken. A sense of drowsiness ordinarily supervenes, followed by a brief but sufficient slumber, and the patient awakens quite relieved of this distressing symptom. I have never yet seen the sleep-disposing properties of antipyrin alluded to by any other observer, although this effect seldom fails to ensue when a full dose such as I have named has been taken.—*Medical Record*, September 11, 1886.

A STUDY OF SOME NEW PURGATIVES.—DR. DENOS has been making a study of the physiological effects of the following four new purgatives: baptisine, sanguinarine, juglandine, and phytolaccine. He has given these purgatives to 48 different individuals in the following proportions: Baptisine to fourteen, sanguinarine to four, juglandine to thirteen, and phytolaccine to seventeen. They were given in pill form in doses of 10, 20 and 30 centigr. ($1\frac{1}{2}$, 3, and $4\frac{1}{2}$ grs.). The first dose was administered at 10 A.M. and the second dose at 10 P.M. The four drugs

had the common property of causing no disturbance whatever in the stomach. In some of the cases purgation occurred after the first dose, in the majority of cases not until some hours after the second dose, and in a few cases of obstinate constipation no effect followed until an enema had been given. Baptisine proved to be an efficient cholagogue, and excepting a few failures in patients who were in bed, it showed itself a faithful purgative. The dose employed ranged from 10 to 30 centigr. (gr. $1\frac{1}{2}$ – $4\frac{1}{2}$). Sanguinarine did not fulfill the expectations derived from experiment with that drug. The author has given it in as large a dose as 60 centigr. (gr. 9) with negative results only. Juglandine exhibited marked cholagogic properties in doses of 10 to 20 centigr. (gr. $1\frac{1}{2}$ –3). Phytolaccine is also an efficient cholagogue in the same doses as the preceding. The author prefers it to all the others. It produced easy and copious stools containing considerable bile. In large doses it provoked vomiting, followed by depression, and in a few cases even by convulsions. In conclusion, the author states that baptisine and juglandine are destined to render incontestable service as laxatives in spite of some inconveniences, and that phytolaccine, being most certain and attended with fewer inconveniences, will form a valuable acquisition to the therapeutics of constipation. Sanguinarine, on the other hand, does not deserve to come into favor.—*N. Y. Medical Journal*, Sept. 11, 1886.

COCAINE POISONING.—Dr. Lucas Champonnière's *Journal de Médecine et de Chirurgie* for last month devotes an article to cases of poisoning by cocaine, based on researches of M. CHATELLIER. The employment of the valuable remedy is not contraindicated by the occasional manifestation of toxic effects, nevertheless it is important to know them. In a case cited by Dr. Speer, a man was in the habit of self-injecting cocaine to combat the effects of drunkenness. The action closely resembled opium poisoning, but the patient recovered under appropriate treatment. A woman, aged 25, to combat hay fever, had a watery solution containing 15 centigrammes of hydrochlorate of cocaine injected into the nose. In about twenty minutes she became giddy, was oppressed by a sense of weakness, and could not see distinctly. A little later she was in a semi-comatose condition, pulse not countable, slight dyspnoea, pupils dilated. These symptoms disappeared in the course of three hours under the influence of internal stimulants and external friction. Dr. Ziem, of Dantzic, reports that he injected under the conjunctiva of a man, aged 40, 2 drops of a 40 per cent. solution. In the course of a few minutes the patient became pale, the forehead bedewed with sweat, and respiration embarrassed. He states that seventeen cases of cocaine poisoning have been reported by oculists. In three the agent was injected hypodermically; in fourteen merely into the conjunctival cul-de-sac. The usual symptoms are pallor and clamminess of the face, vertigo, and great prostration, sometimes lasting for days. Headache and vomiting are infrequent. In one case, after sub-conjunctival injection of 15 drops of a 2 per cent solution, the gait became uncertain,

articulation indistinct, and memory lost. In another case subconjunctival injection of 8 drops of a 3.5 per cent. solution produced loss of consciousness and convulsions. M. P. Tissier relates the case of a child, aged 4, affected with whooping-cough and coryza, whose nasal fossæ were pencilled with a 1 in 30 solution of hydrochlorate of cocaine. In the afternoon the eyes became distorted and the child convulsed, but these symptoms disappeared without treatment.—*Lancet*, August 21, 1886.

SALICYLATE OF LITHIUM.—PROFESSOR VULPIAN remarks that this salt is as efficient in acute rheumatism as salicylate of sodium, and, further, that it is also efficacious in acute gout. In a great number of cases of acute rheumatism salicylate of sodium relieves the acute pains, but the joints remain slightly painful and difficult of movement. In these cases salicylate of lithium substituted for the sodium salt will complete the cure. Again, in those cases of acute rheumatism in which the fibrous tissues seem most implicated the lithium salt will be found more beneficial than the sodium salt. In that form also in which the subcutaneous tissues seem involved, salicylate of lithium has proved more useful than any other drug. Even in chronic rheumatism in which the joints are deformed and partially ankylosed, salicylate of lithium has shown itself of some value.

For an adult the dose should be 4 grammes (3j) per diem, which may gradually be increased to $5\frac{1}{2}$ grammes (ʒiv, gr. iij). Larger doses are followed by symptoms of intolerance. Salicylate of lithium is soluble in water and has a pleasant taste. It contains more salicylic acid, proportionately, than salicylate of sodium. Like the latter salt, its administration is attended with unpleasant symptoms, which, however, do not attain to the same degree. These consist of a more or less severe headache, dizziness, and difficulty of hearing, without noises in the ears, as in the case of the sodium salt. Occasionally it produces colic and diarrhoea—symptoms never observed with salicylate of sodium. The latter symptoms must be attributed to the lithium and not to the salicylic acid.—*N. Y. Medical Journal*, Sept. 11, 1886.

TREATMENT FOR HYSTERO-MANIA.—DR. A. L. HODGDON, of Farmwell, Va., says: The following formula I have found useful as a calmative in hystero-mania (hysterical insanity):

R	Extr. cimicifig. fluid.	3 jss
	Extr. vibur. prunifol. fluid.	3 j
	Extr. conii fluid.	3 j
	Tinct. cannab. indic.	3 iss
	Syrup.	3 x M

Sig.—Two teaspoonfuls three times a day, and see that its components are thoroughly mixed before exhibiting.

Two of the ingredients of the formula before mentioned—the hemp and the hemlock—are of notoriously uncertain strength. Hence the proportion of each of these drugs to the rest of the prescription must always be governed by their respective strengths, and the mixture should never be administered excepting with extreme caution, carefully watching its effects.—*Maryland Med. Jour.*, Sept. 18, 1886.

¹ The tincture of hemp used in the formula was made from the English extract and alcohol, in proportion of 3i of the extract to 3ii of alcohol.

TUMORS OF THE BLADDER, AND THEIR
TREATMENT.

In Volkmann's *Sammlung klinischer Vorträge*, Nos. 268-269, is a most interesting article on this subject by PROFESSOR ERNST KÜESTER, of Berlin. Vesical tumors may be conveniently classified under the two heads: Neoplasms of the Prostate, and Neoplasms of the Bladder-wall; and of the latter we may distinguish three great divisions: First, those arising from the mucous or submucous connective tissue; second, those arising from the muscular layer of the bladder; and third, neoplasms of the epithelium and glandular structures of the bladder. We may also say that there are three subdivisions of the neoplasms arising from the mucous or submucous connective tissue of the bladder-wall: *First*, the papilloma of Krämer or the fibroma papillare of Virchow, which is certainly the most frequent of all the tumors of the bladder, and may appear singly or grouped. When single they are more frequent in the fundus vesicæ, then in the trigonum, and finally in the lateral walls, near the ureteral orifices. In very rare cases they have been found in other parts of the bladder, but then mostly as groups, several small ones being found around one large polypus. We need not here go into the microscopical details of the papillomata, which are given so elaborately by Küster.

In the *Annals of Surgery*, for September, 1886, Mr. C. J. Colles has written a most admirable review of this question of tumors of the bladder in connection with Küster's paper. It will be remembered that Sir Henry Thompson has described a transition form of vesical papilloma (to a malignant growth), which is characterized by rich vascularity and cell-infiltra-

tion in the tissues around its base, which is probably due to inflammatory irritation. The villi are so delicate that the stream of urine during micturition is sufficiently strong to tear them away and cause frequent hæmorrhages. "The delicate construction of the inadequately supported walls of the blood-vessels in these villi is often also the cause of hæmorrhages. Every contraction of the bladder-muscles must compress the blood-vessels at the base of the villi, producing, consequently, hyperæmia of these, and leading easily to rupture of blood-vessels. These formations, by becoming incrustated with urinal salts, may deceive one as to their real nature, as they are often taken for vesical calculi." Papilloma, as we know, is more frequent in males than in females; and this is probably due to the greater and more frequent irritation to which the bladder of the male is subject from the extension of inflammation from the urethra, any it may also be partly due to the greater difficulty in urination among men of middle and advanced age than among women of the same age; and this theory is supported by the fact that most cases occur between the ages of 30 and 60 years.

Fibrous polypi and myxomata are tongue-like or bulbous formations occurring in the region of the neck of the bladder and its base; not occurring in groups, as papillomata, but seem to be spread out over the mucous surface. They seldom cause hæmorrhages, as they are comparatively tough in structure. They occur most frequently in children. Sarcoma of the bladder is very rare, only five cases having been carefully observed and described. It usually occurs in females, as was the case with the five cases just alluded to.

Of the neoplasms arising from the muscular layer of the bladder Robert Knox first described, twenty-four years ago, and recorded a case of myoma. It was not until ten years ago, however, that a case of undoubted myoma of the bladder was thoroughly described, by Volkmann. The tumor was a considerable distance from the prostate, a fact which excludes any possible connection with this gland; and in the cases published previously there was some reason to suppose that the tumor was in some way connected with the prostate. In structure these tumors closely resemble myomata of the uterus. Five years ago Dr. W. T. Belfield found, by accident, myoma of the bladder in two dead subjects.

Under neoplasms of the epithelium and glandular structures of the bladder are included adenoma, carcinoma, and dermoid cysts; of these it is only necessary to speak of carcinoma. "Clinically carcinomata of the bladder are not distinguishable from those of

the prostate, so that the latter will have to be considered in this group. Careful study only of the microscopical structure will reveal the real starting-point of the tumor. This latter is of importance not only from a pathologico-anatomical standpoint, but also as regards the diagnosis and the therapeutic measures to be undertaken." It would be of vast importance, says Küster, if Kleb's assertion were true, according to which all carcinomata of the bladder originate in the prostate gland; by which a primary tumor of the fundus of the bladder in a female subject could not possibly be a carcinoma. The appearance of this form of tumor in the region of the neck of the bladder in male patients will naturally arouse suspicion as to its origin. There can be little or no doubt that many of the cases of so-called carcinoma of the bladder are but secondary growths from the prostatic carcinoma; but it must be admitted at the same time that primary carcinoma of the bladder does occur; and we may agree with Küster in thinking that it would be very remarkable if the mucous surface of the bladder, which is so much exposed to irritation, should be so very different from other mucous surfaces as not to be subject to carcinoma. Indeed, Bode has shown that primary carcinoma of the bladder in females is not so very rare, as there were 14 females among his 30 collected cases. "The form of carcinoma most frequently met with here is the papillary, although the medullary form is not seldom seen, cases of the latter having been recorded by Marchand and others. The cancrioid form has been often observed by Thiersch, Paget, Winckel, and Thompson, and the alveolar carcinoma, with its singular tendency to colloid degeneration is also occasionally found. All these forms of carcinoma, including also the glandular form occurring in the prostate, develop first as flat circular protuberances on the mucous surface or as more deeply lying lumps with a smooth surface, immovable over the tumor. Various changes in their appearance soon occur, in consequence of the irritation to which they are more or less exposed. Hæmorrhages soon follow, but in many cases precede the development of a cancer. The surface epithelium becomes necrotic and falls off, allowing the urine to come directly in contact with the badly nourished cancer-body which is prone to regressive metamorphosis. Putrid decomposition of the urine follows, producing rapid necrosis of larger or smaller portions of the tumor, keeping the former, in spite of frequent micturition, in a decomposed state. Catarrh of the bladder is the result, and the hyperæmic mucous membrane is consequently prone to hæmorrhages. The mucous layer of the bladder

is soon attacked, its hypertrophied condition, however, generally preventing rapid perforation. Through extension of the purulent inflammation upwards the kidneys become involved, and death soon intervenes."

In a very large number of cases tumors of the bladder develop without marked symptoms, and their existence may not be suspected until a patient, hitherto believed to be perfectly healthy, begins to pass bloody urine. We say *suspected*, for it is important to differentiate hæmorrhage from the bladder from that proceeding from other portions of the urinary tract. In cases of renal hæmorrhage the urine and blood are generally evenly mixed; but this may be the case when slight hæmorrhage of the bladder has taken place and the blood remained in the bladder long enough to be thoroughly mixed with the urine. In the early stage of tumors of the bladder the stream of urine is at first ordinarily clear, but gradually becomes bloody, and finally the stream is only pure blood. The passing of particles of the neoplasm with the urine is a very important symptom, and very large quantities may be passed in a short time. It seems scarcely necessary to say that a microscopical examination of these particles will determine the nature of the tumor. Other symptoms are disturbances in urination, slight or severe pain, frequently a heavy, bearing-down sensation in the perineal region, and a frequent desire to go to stool. Of course there is catarrh of the bladder after the disease has existed for some little time, accompanied by chills and fever. "The general form and consistency of a tumor of the bladder may be usually determined by palpation above the symphysis and through the rectum, in women through the vagina. The introduction of instruments should be undertaken with care, as catarrh often results from this procedure." The catheters should be thoroughly aseptized, and the glans and orifice of the urethra should be thoroughly cleansed in every case before introducing instruments. A good instrument is a catheter having a long opening near its extremity on the under side, which may be used as a scoop, pulling off portions of the tumor. Little, if any, bleeding will be caused by this instrument. As a means of further diagnosis endoscopy may be employed. Mr. Colles seems to attach but little importance to digital examination of the bladder in these cases, which, nevertheless, must be regarded as most important, as has been shown more recently by Dr. Belfield (see *THE JOURNAL*, Sept. 4, 1886.)

Even benignant tumors of the bladder threaten the life of the patient, and they should therefore be removed. A tumor with a thin pedicle may be twisted off, as has been done by Volkmann; or they

may be removed by means of a scoop passed into the bladder along the finger, as is done by Kocher. There is considerable danger of injury to the bladder and other parts attending the use of Thompson's denticulated forceps. Sometimes, especially in females, we may draw down the tumor far enough to see plainly its point of attachment on the vesical wall, in which case it may be cut off and the wound closed with sutures, so as to prevent hæmorrhage. If the tumor be favorably situated this may be done by dilating the urethra in the prostatic portion after a median incision. There are many cases, however, in which it will be necessary to open the bladder above the symphysis, or through the vagina. "Epicystotomy is without doubt the best of all methods of removal in both sexes, and gives the most complete survey of the interior of the bladder." As now performed, by filling the bladder with some aseptic fluid before the operation, or making the incision slowly and carefully, dividing the tissues layer by layer, there is no danger of wounding the peritoneum. Petersen injects from 400 to 600 grams of fluid into the bladder and then introduces a colporynteur containing about 400 grams of warm fluid into the rectum, which forces the bladder up over the edge of the symphysis, and thus almost precludes the possibility of injury to the peritoneum. To prevent infiltration of urine into the surrounding tissues careful drainage must be carried out; the urine must not be allowed to collect in the bladder and flow out through the wound. A good method of drainage "is to pass a rubber tube, having lateral apertures, through the wound and out through the urethra; at the same time plugging up the abdominal wound with pieces of iodoform mull."

Guyon's use of the thermo-cautery seems to have, thus far, but little to recommend it; the wound will be long in healing, and will prove a source of catarrh. Küster prefers an elliptical cut around the tumor, and then uniting the edges with catgut sutures. In dealing with deep-seated tumors we may employ Trendelenburg's method, which consists in suspending the patient, head downwards, by his legs over the back of an assistant, and turning towards the light so that it shines directly into the bladder when the edges of the wound are separated. The viscera sink, and the parts hid behind the symphysis come into view. Schede has shown that a catheter may be placed in each ureter, to carry away the urine and prevent its collection in the bladder—a very important point in the after-treatment of these cases. Thin, elastic bougies are probably better for this purpose than Simon's metal catheters.

PRACTICAL IMPROVEMENT IN THE ORGANIZATION OF THE AMERICAN MEDICAL ASSOCIATION.

Observations during the recent meeting of the British Medical Association demonstrated the decided superiority of having a smaller number of addresses read before the whole body in general session, and those prepared by parties appointed solely for that purpose, while the President of each Section read an address before his own Section. It was very evident that one well prepared address was listened to with greater attention and by a larger number than would have been two or three in succession at each general session. Again, if there be but one address on the programme for each general session, the certainty of its being listened to and perhaps criticised, stimulates the writer to greater care and wider research in its preparation.

The fact that the annual meetings of the American Medical Association continue, like those of the British Association, only four days, and but one general session each day of about three hours, shows that not more than one hour each day can be devoted to an address and leave any adequate time for the transaction of general business. And as the hour of the first day's general session is occupied by the address of the President of the Association, but three important addresses can be properly provided for in the three subsequent general sessions. And yet the by-laws of the American Association provide for eight Sections, and the Chairman of each is required to deliver an address in the general session on the topics embraced in the Section over which he presides. This makes three addresses for each of the general sessions of the second and third days, and two for the fourth, which is so obviously wrong that a change is demanded.

During the last two or three annual meetings no less than three of these addresses have been crowded into the general session of the last day, and none of them read much beyond their titles. Such results are unsatisfactory and unjust to all the parties concerned. On the contrary if the Chairman of each Section was required to prepare the same kind of an address as at present and deliver it in his own Section, not all at the same hour or necessarily on the first day that the Section meets, but as far as practicable at different hours and days specified on the programme, thereby giving opportunity for the largest number to attend the Sections at these times, it would contribute much to the interest of the work of each Section, and increase the number in attendance. Such appeared to be plainly the practical result of

the plan in the British Association at Brighton; and we commend the subject to the consideration of the committee on improvements in the plan of organization, appointed at the annual meeting in St. Louis, in May last.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Sept. 20, 1886.

J. F. TODD, M.D., SECOND VICE-PRESIDENT IN THE CHAIR.

DR. N. S. DAVIS gave his

IMPRESSIONS OF THE BRITISH MEDICAL ASSOCIATION.

An abstract of his remarks is as follows:

The British Medical Association held its recent meeting at Brighton, the most fashionable and desirable watering place in England, very favorably situated for such a meeting of the profession of that country, being accessible to London as the great central point and having accommodations that probably cannot be found in any other town or city of moderate size in Great Britain. The British Association impresses one as being a body of men more advanced in life with more solidity than our assembly, not more intellectual development but more of what you might call sturdy physical development. Indeed this impression of solidity is forced upon the mind about everything. We excel them very much in exterior ornamentation, variety of architecture and in a great many ways, but for an impression of solidity and steadiness without haste, as an ordinary rule they excel us.

The British Medical Association is not a representative body in any sense, but was composed originally much after the fashion of calling together an assembly, organizing a national body and selecting a certain number to constitute a council and submitting the business affairs to the council. Subsequently a rule was adopted by the original council qualifying the profession in any given locality to form a local society and adopt such rules as were not in opposition to the constitution and by-laws of the national society; these societies were recognized as Branches, and each member of a Branch became nominally a member of the general body with the right to attend the general meeting, but they are not entitled to take part in the general government. They may elect one, two or three members of the council, so that as Branch after Branch has been organized, and the membership increased, it has greatly enlarged the council, until, I gather from the proceedings of the Association the council of the British Medical Association numbers seventy-one. This council has the entire control of the organization; they determine the places of meeting, and all matters in reference to the workings of the organization come before them first. Certain matters are brought before the general body at their meeting for their sanction, but they

must originally go through the council. The council has at least four stated meetings in the year; they meet every quarter, and if business of importance is to come before them they may have other meetings. At the annual meeting of the Association the programme is so arranged, that when they open at half-past twelve (they do not hold sessions in the forenoon), the council holds an hour's session, that is the meeting of the council of the preceding year. New members of the council are elected by the Branches yearly, so that new members come in each year and others go out, and the council is not always made up of the same parties. Following this meeting, two o'clock is appointed as the time for the meeting of the general body, but that did not occur this year; it was crowded out. At a subsequent hour we had what they call the council of the present year. The first meeting was the council of 1885, the next, council of 1886. The Sections held no meetings the first day. I watched the proceedings carefully with special reference to learning what might be of use to our own National Association. One of the complaints made against us is that we lose too much time in eating and drinking, and social occasions, and too little advance is made in real science and professional knowledge. The meeting of the council was held with closed doors. This peculiarity runs through everything, the council not only prepares the reports on business matters, but when they are submitted to the general body the council designates the man to move its adoption and the man to second motion. I do not think that would be tolerated in America over one meeting, but it is a uniform, regular custom there and they seem to take it very easy.

The three Sections that had the largest attendance were Medicine, Surgery, and Public Medicine. They have the same trouble there as here, there is a certain class always coming and going. They come in and sit down, and if at a little distance they can't hear very well, they sit a little while and don't get enough of the run of the thing to interest them and they go to another Section, so they are always moving about. Of the Pathological and Laryngological Sections, one was held in the bedroom of old King George and the other in his china closet, a cupboard capable of seating not more than twenty or thirty people, and these seats were not full. While the attendance does not exceed our attendance there is about the same shifting and changing as at our general meetings. But the papers that were read had this characteristic to a greater degree than can be said of the papers as a whole with us, those who read papers had taken more pains to prepare them carefully and to make them cover the ground fully. They had spent more labor in their preparation. There was another feature—until the last three meetings there has not been any attempt with us to have parties informed of what particular papers are to be read in any of the Sections, so that they might be prepared to lead off in the discussion of the papers. In 1883 in the Medical Section there had been pains taken to do this; certain papers were to be read, and several parties in different parts of the country were informed that a paper would be read on a certain subject and they were as-

signed to lead in the discussion. The idea was to make the discussions of more value. This same course has been taken in a limited degree in our meetings since. It is a general practice in the British Association. The officers of the Sections when they learn what papers are to be presented judge as far as practicable who can impart interest, and have them informed of the general import of the paper and ask them to lead the discussion. Hence, they elicit genuine benefit from the papers that are read and from the discussions that follow. Many papers were prepared that were not read; undoubtedly they will find their way into print as they do with us; the title was read and referred without anybody's knowing of what they were made. Sometimes they are made of an abstract, the author thinks he will write it out, but fails to do so. I think in their work they are more deliberate, more complete, they exhaust a subject more nearly, and they endeavor to have the discussion so conducted as to elicit the most information from it. In studying their work as a whole it seemed to me that there are some things we might copy with advantage.

Some member may be here who remembers the proposition made in our own National organization years ago when the Sections met and chose their officers. A proposition was made to change the by-laws so that the officers of the Sections should consist of a president and secretary selected at each annual meeting for the next year, so that there would be officers already elected and the organization of the Section would be perpetuated. I remember that the late Dr. Gross made this motion, that instead of having reports from standing committees on medical education, medical literature, and so on, which we had had previously, these committees be dropped and in their stead the Association select at each meeting men supposed to be qualified for that especial work, in order to present an address to the general assembly, one on medicine, one on surgery, and one on obstetrics and diseases of women and children. That differed from the British programme only in substituting obstetrics and diseases of women and children for State medicine, but it was designed for the same purpose, to have one carefully prepared address read at each of the three last meetings, one on Wednesday, one on Thursday and one on Friday, while the president of the Association would have an address on Monday especially designed for the general body. I seconded Dr. Gross' motion, but instead of it being carried it was referred to a committee, as was also the proposition to have the officers of the Sections appointed each year for the next, and the next year the committee reported in favor of having the officers appointed for the next year, and at the same time they reported in favor of having the president of each Section present an address to the general body on the improvements in the Section over which he presided. That was a substitute for Dr. Gross' motion. He and I opposed it on the ground that the presidents of the Sections to be chosen each year ought to be selected from the older men, giving them an honorable position, but yet they would not be the men that

would be likely to be adapted to read such papers. However, the proposition of the committee carried. Now we have seven or eight Sections with seven or eight addresses before the general body, and what is the result? We find time the first day for the president's address, but the other days of the general meeting do not afford time enough for all the presidents to read their addresses, they are crowded off to the last day and one-third of the addresses prepared by the presidents of the Sections are announced by title and then go over. They crowd the entire time of the general meeting of the body, and I think it would be a great deal better if we were to change our by-laws and appoint the first day for the president's address, which should be of a high order, covering the general field of medicine, another to surgery and another to obstetrics and gynecology, or public medicine as you choose. Perhaps for the world at large it would be as well to sometimes change the order. Then let the president of each Section deliver his address as he pleases on any subject of interest to the Section. This would insure a larger attendance and promote the work of the Section, and yet would not crowd the entire time of the general meeting as it does when we try to get in seven or eight general addresses. That, I think, would be a real and substantial improvement in our body that we might copy from the British Association. And then we might go on perfecting still further the arrangement of the papers and interest parties to be ready for brief discussion.

There has been a good deal said of late years about the work of the nominating committee. The nominating committee is appointed in a hurry by little knots gathered together who want to get through. The committee is hurried to do its business and consequently the business is done very imperfectly. It has been claimed that we ought to have a more steady and conservative body, and the council of the British Association has been suggested as a pattern, but I do not think an organization like the British council would satisfy this country in any degree; I think we would not get along with it two years without rebellion all around. But it seems to me in studying the matter over that we might remove the real evils we suffer from and yet not incur the evils that would follow from attempting to make a permanent council. It has been suggested that it be so arranged that one man would hold his place nine years; instead of that I think all the evils from which we are suffering could be obviated by appointing a business committee to consist of two members from each State in the Union. Let each State Society that is represented in the organization be entitled to two members of that business committee and elect them the first year to hold office two years, and after they get started they would have one to elect each year, so that it would be permanent. By electing a new member each year it would be conservative and not totally changed. All the work that now devolves on the nominating committee would be done by this business committee, and if selected with proper care it would be a convenient committee to which might be referred various propositions that come up, and which require careful con-

sideration by members that represent the whole country.

There is an evil in the British council that is complained of now, they say this council has four meetings a year and they have to meet in London because London is the head centre of Great Britain. The practical working of that is that the profession within a radius of one hundred miles of London controls that council. It costs money to go from Edinburgh, Cork, Dublin or remote portions of England to London, and very few out of the whole number of seventy-one go. I learned that there were seven meetings held last year and thirteen of the members did not attend any of them. Not only that, but the remoter districts have found that their delegates so rarely attend, on account of the expense and loss of time, that half a dozen of them reported that they had not elected delegates. Now if we were to appoint a permanent body four-fifths of them would let their interest die out. Suppose you get up a council that is to meet and transact business three times or even twice a year, how many would be found to go from the Pacific Coast or from the north to a central point? It would not take ten years to gravitate so that your council would be in the hands of those within a hundred miles of the central point of meeting. If you made that Philadelphia or Washington or Chicago, the whole body would be ruled by a territory of two hundred miles, simply because parties would not pay out their money and spend their time to attend. They will not in Great Britain, and they are discussing the propriety of getting up some mode of compensating them to induce them to go. The plan I propose will, I think, after some degree of consideration, be found to obviate all the real evils we suffer from in hasty action and hasty nominating committees, and yet it would always secure us a satisfactory working body that would be reasonably representative of the several States to attend to such things as are required to be attended to, and it would be a standing body of intelligent men to whom we could refer such things as would require consideration. The features that I have mentioned are characteristics that struck me as belonging to the British Association, which differ from ours.

In regard to the International Congress: without solicitation the council of the British Association altered the programme of one of their days and announced that on Thursday at a certain hour the delegates from the American Association would be heard in regard to the International Congress. When the time came the hall was fuller than on any other occasion, the room was packed and through the hallways and along the corridors with people evidently having a decided interest in hearing what we had to say, and as the other Americans insisted on my taking the lead I went on the platform and occupied half or three-quarters of an hour in simple explanation. I made no allusion to anybody's differences except in general terms; we had had our troubles, and our frictions and our errors on all sides, but out of it all had come an organization truly National in its character, made up of delegates from all the States in the Union. This organization appointed an executive

committee to which had been transferred all further management of the Congress. This National committee had reported their work to the last meeting of the American Medical Association, and it was unanimously sanctioned, and so I felt justified in assuring them that this met the approval of the profession of the United States, and while we had no royal titles, the President of the United States, the Heads of Departments and the President of the Senate had lent their names as patrons. And I assured them that they would receive as cordial a reception at that Congress as the American profession knew how to give. I would guarantee that they would be met by the intelligent part of the profession of every State in this Union from the Atlantic to the Pacific, and I cordially invited them to come. They received my invitation with the greatest degree of enthusiasm, and after a few remarks from Dr. Pancoast and others, which simply endorsed what I had said, they voted us their thanks and accepted our invitation to meet us in Congress in 1887. Among some of the most prominent men in London and the Provinces there is a warm zeal for attending the Congress. Three or four Americans have been on the Continent for some time and report that in France there is a genuine enthusiasm for attending the Congress. In France they do not pay the slightest attention to any differences we have, and just as far as they imagine there is coldness in England or Germany, the Frenchman comes with the more enthusiasm to make it up.

PROFESSOR W. E. CASSELBERRY read a paper entitled

PHARYNGEAL AND NASAL SURGERY BY THE GALVANO-CAUTERY; WITH REPORT OF CASES AND EXHIBITION OF APPARATUS.

New methods of utilizing the galvano-cautery are constantly being devised and recent improvements in batteries and electrodes, and the introduction of the local anæsthetic, cocaine, have materially extended its field of usefulness. In nasal, pharyngeal and even in laryngeal surgery its utility is particularly manifest. Pathological conditions of the upper respiratory passages, which have long baffled the most skilful therapeutics, are now effectually remedied through the medium of this agent.

Case 1.—Folliculous pharyngitis with hypertrophy in the angles of the pharynx. Dr. — has suffered from fulness, soreness and pain in the pharyngeal region, culminating frequently in acute pharyngitis with extension of the inflammation to the middle ear. Examination disclosed two enormous hypertrophied follicular masses, occupying the latero-posterior angles of the pharynx, each about three-fourths of an inch in length, of the thickness of a lead-pencil, and jutting inward and forward from behind the corresponding posterior pillar. In the normal state a whole chain of muco-lymphoid follicles ranges along in this location, and it is the hypertrophy of this entire row of glands on each side which is the chief feature in the case.

Treatment.—For the purpose of destroying these growths by the galvano-cautery an electrode was extemporized by uncoiling the wire end of a Flem-

ing moxa-electrode, thus converting the coil into an elongated loop. This was so curved as to accurately approximate the mass. The loop heated instantly to a white heat by the action of the battery, produced its slough with but little pain and no hæmorrhage. After several operations, performed at proper intervals, the growths were entirely removed.

Case 2.—Folliculous naso-pharyngitis or adenoid vegetations at the vault of the pharynx. Operations by the galvano-cautery *écraseur*. The symptoms were those of post-nasal catarrh. Examination, in addition to morbid conditions of other parts, revealed numerous hypertrophied follicular masses—so-called adenoid vegetations covering and filling up the vault of the pharynx; some of these appeared in the rhinoscopic mirror as pendant pear-shaped bodies, others were sessile, and still others had the appearance of several cockscombs crowded together.

Treatment.—Removal of the hypertrophied masses is the only satisfactory means of relief. This he first sought to accomplish with a Löwenberg cutting forceps, but the effort resulted unsatisfactorily. The cold snare and other methods were tried and abandoned, until finally he found that the object could be attained most easily and with the least pain and inconvenience to the patient by means of a galvano-cautery *écraseur*. He constructed an *écraseur* for the case by bending a fine pair of straight tubes, threaded with a platinum loop, to the proper curve to pass behind the velum palati and touch the hypertrophied mass. The naso-pharynx was sprayed with cocaine solution. Guided by the rhinoscopic image he introduced the *écraseur* and caused it to encircle one of the growths, then connecting the battery, the loop heated instantly to redness, was as rapidly wound in on the windlass, and the vegetation thus severed at its base. There was no pain, no hæmorrhage, and but little subsequent irritation. The operations were repeated weekly until the growths were entirely removed.

Case 3.—Malformation of the anterior pillars of the fauces. The symptoms were a sense of constriction in the pharynx and snoring. The malformation discovered was of the anterior pillars, *i. e.*, of the palato-glossal folds. These originated properly in the velum, but increasing in breadth they covered a considerable portion of the inner surface of the tonsils, and then a part only of the fold continuing in the normal pathway forward to the side of the tongue, the larger portion swept *backwards* and incorporated itself with the posterior pillar, forming a thick band, which continued downward in the latero-posterior angle of the inferior-most portion of the pharynx.

Treatment.—The overgrowth of each tonsil, together with the portion of the anterior pillar which covered it, was excised by means of the galvano-cautery *écraseur*, and at the same time the abnormal attachments of the anterior pillars to the pharyngeal wall were severed.

Case 4.—Membranous occlusion of the posterior nares. Mr. E. suffered from complete obstruction of the left nasal chamber, most violent headaches, vertigo, left sided deafness and fetor of the breath. A tense membrane was found to cover the left choana

almost completely, and another to partially occlude the right choana. These membranes were incised by the galvano-cautery knife electrode, properly curved and introduced from behind. Complete relief to all symptoms. Certainly the galvano-cautery can be abused, and a word of caution is not unnecessary in this respect. Accurate diagnosis, precise indications for its use and a certain amount of skill on the part of the operator are essentials to its judicious employment. The Fleming battery has advantages over any other that he has seen, not the least of which is the arrangement by which the plates may be immersed and withdrawn from the fluid by means of a pedal easily manipulated by one foot.

DR. F. O. STOCKTON, in opening the discussion, said: I have listened with a great deal of pleasure this evening to the paper; the cases are all very interesting. It does not seem necessary to spoil an electrode in order to make one for a special case; it seems to me that the ordinary flat electrode, by simply bending it down, would answer the same purpose. The trouble is we must have new instruments for every case that comes up. Unfortunately all practicing physicians, many of them who understand the throat and nose, are not so situated that they can run into an instrument maker's establishment at any time and have an electrode made, and I think it is wise to keep down to the standard instruments which can be bought at any time and which are always at hand. Another point I would like to speak of is the idea that follicular pharyngitis and adenoid vegetations are one and the same thing. Some authors consider them the same and others do not. Bosworth, of New York, claims that follicular pharyngitis and adenoid vegetations are one and the same. The battery which Dr. Casselberry shows is the one I have used in my practice for three years. I have tried a number of others and found this one the most satisfactory. A short time ago I saw a modification of it which I think is a little better; it was devised by Dr. Sajous, of Philadelphia, but it is not on the market at present. Many of our prominent writers have rather discouraged people from using the galvano-cautery, as they say it requires a great deal of skill, and knowledge not only of the anatomy of the part we are working upon, but also of electricity and the management of instruments. Dr. Morell Mackenzie, of London, makes that objection to the galvano-cautery; in fact he says that all, or nearly all, the operations can be performed by simpler means. Dr. Cohen, in his last work, also refers to the difficulty of managing it, but I think if they had used the instruments of to-day they would not have found that difficulty.

DR. H. T. GRADLE said: The speaker's paper was so complete there is nothing left for comment except to deviate from the subject and take excursions into neighboring parts. It has been mentioned that galvano-cautery is not absolutely necessary. That may be true as far as the pharynx is concerned, but in the nose it is not. It would be almost impossible to do the same work as steadily by any other instrument, on account of the excessive hæmorrhage that would occur; these cases are unmanageable except with

the cautery, and in most instances we can obtain relief both of local symptoms and obstruction of the nose, as well as the nervous symptoms maintained by the excessive turgidity. The question was asked whether hypertrophy of the pharyngeal tonsil could be identified with follicular pharyngitis; I should say not. We may have one or the other, but the follicles in the disease called follicular pharyngitis are much below the level of the gland. I have often found the gland hypertrophied into a very solid mass of about the consistency of the tonsils. The hypertrophy may of course have any extent; it may be so slight as to leave room for doubt of its existence, while in other cases it is impossible to gain any view of the posterior choanal. In such cases nothing can be thought of but operation. I have used the cautery in the form of a white hot knife or hot snare for hypertrophy of the pharyngeal tonsil, but not satisfactorily. Where we have a distinctly pedunculated tumor it will do well enough to use the hot snare, but where the tonsil is hypertrophied into a solid mass not at all movable with the probe, I have found very little success with the battery, except that its removal is not so painful as by other means. I have at last settled down on the method suggested by Trautman, viz., a sharp curette, as sharp as the instrument-maker can make it, the shank of which is bent at an angle of 140° . The operation is a barbarous one as far as appearances go, because it requires force. There is pretty free hæmorrhage, but the pain is not very great. Unless the person is pretty tolerant it is not easy to remove the entire tonsil in one sitting, but in children I have not had any greater difficulty in coaxing them to the second sitting than I had at first. The results are extremely satisfactory, especially in cases of ear disease entirely due to this trouble. I have had considerable experience with different forms of battery; the kind which I should prefer and recommend is an accumulator, if a wire can be had from some electric light plant. I can speak well of the Mackintosh battery, but I prefer one in which the carbon plates are made of the electric light sticks. They are much harder than the ordinary carbon plates, and we can easily get a very large surface in the battery.

DR. R. TILLEY said: I have had some experience with the cautery and with batteries. I am now using the form of battery Dr. Gradle has referred to; I have the two cells attached so that I use them together, and have them so arranged that I can lift them up with a crank; they are thus very easily manipulated. I have used this battery for about eighteen months, and it has always given me satisfaction. I would like to speak of a slight modification in the fluid which I have recently used; it consists in the use of bichromate of soda instead of bichromate of potash; the advantage is that when the fluid has been used for a considerable length of time, in using the potash there is always formed a large number of crystals in the bottom of the cell, which are very hard and require quite a little time to remove, and which are so closely connected with the cell that there is more or less danger of breaking the glass. In using soda instead of potash this does

not occur; the compound thus formed is so soluble that no accumulation is formed at the bottom of the cell. I appreciate Dr. Stockton's remarks in regard to the increase in the number of instruments; I make all my own electrodes and use, practically, wire alone. I see no advantage in the knife over certain modifications of the wire. In operations in the post-nasal and pharyngeal regions, I almost always use the cautery to burn the tissues completely to the bone. The object that I have in view is to make a cicatricial tissue extending from the surface of the mucous membrane to the periosteum, so as to prevent that tumefaction which frequently occurs and fills up the nares. This tumefaction is quite remarkable sometimes and changes so readily that I have seen the anterior part of the turbinated bone swollen up, and a moment afterwards the swelling gone, so that there could not be any possible reason or justification for using the cautery from the appearance of the tissues at the moment. Yet when the patient lies down at night he finds the nose on the side on which he is lying so stuffed up that it is almost impossible to breathe. I have found that when the anterior part of the turbinated bone is burned well down to the bone that tumefaction rarely occurs afterwards. Then there is a necessity of looking after these burns, especially in the posterior regions. In the anterior aspect of the nose there is only a small amount of mucus coming over the part that is burned, and no difficulties follow cauterization; but when the burned area is situated far back the mucus flows over it and it not infrequently happens that unless the part is well attended to a certain amount of fungus growth develops in this region. I consider the after-treatment an important factor in cauterizations. I would like to say a word in regard to these adenoid growths in the posterior nares that Dr. Gradle has referred to. Dr. Trautman, of Berlin, removes all these vegetations with the sharp spoon, and claims remarkable success. I have not seen anything like relatively the same number of cases in my practice that it would seem are met in practice in Berlin. I think adenoid growths are more rare in Chicago. With reference to their removal with the galvano-écraseur, I should certainly be disposed to think that the ordinary wire-écraseur would be more efficient than the sharp curette, and I think it could be more easily manipulated and more of the growth taken off at the same sitting than with the galvano-cautery.

DR. W. E. CASSELBERRY, in closing the discussion, said: There are some points on which I would like to add a few words of explanation. In reference to spoiling an electrode in order to make a single loop to treat a special case, I spoiled the moxa-electrode because it was an easier way to get the loop than to send to Philadelphia and have one made. As to the merits of the loop over a knife electrode, I think that in cauterizing the soft tissue, by taking a small elongated loop and pressing it into the part you get a slough produced by each parallel wire, and it produces a larger slough with less pain than can be obtained by the knife electrode; the loop will sink further into the soft growth. If you use a plain knife

electrode the slough produced at once under the flat surface of the electrode prevents further effect from its caustic action. I have not only employed the small loop in this particular case, but have found it useful in cases of hypertrophy of the inferior turbinated body where it was unnecessary to cut off a large section by means of the knife or *écraseur*. By simply taking the elongated loop and pressing it against the body, a considerable slough is produced in the centre; after this has separated there remains an ulcer, and when the ulcer heals there is cicatricial tissue, which afterwards binds the body down. In regard to the multiplicity of instruments, of course the multiplying of useless instruments is to be deprecated, but I would call to mind the fact that a large portion of the advance of medical science during the last half century has been directly due to the invention of new and improved instruments and apparatus. If those who devised the microscope, the ophthalmoscope, the laryngoscope, etc., had been satisfied with the "standard instruments" already in the market, we would not now have those most important forms of apparatus. A new instrument should always receive attention, and if it is a real improvement the inventor should be given due credit. The glandular structures of the vault of the pharynx out of which adenoid vegetations are formed, and the follicles of the oro-pharynx, may not be histologically identical, but they are very similar in structure; they are both lymphoid tissues and both exhibit the same tendency to undergo the hypertrophic process and to form similar large masses which, if allowed to remain, produce morbid symptoms. I don't know that it is necessary to say anything more in regard to batteries; there are a great many in the market. I am favorably impressed with the one I use; it has never failed to work. Although it may not be detrimental to have the plates remain in the fluid, I have an uncomfortable feeling when I know that my plates are being spoiled and the fluid used up faster than they need be. The Sajous battery spoken of is an improvement on the Fleming in this respect, the pedal is not so high from the floor. When one is operating, if he raises his foot to the height of eight inches he is liable to throw himself out of balance and to lose his line of vision. The pedal of the Sajous battery is only about two or three inches from the floor and it is unnecessary to raise the heel off the floor to work it, thus maintaining the balance of the body. The Sajous plates also are corrugated, thus giving the most surface in the least bulk. But unfortunately, the Sajous battery is not in the market. The one which Dr. Sajous uses he had made to order, but I have no doubt that it will be put upon the market soon. The various methods of operating for adenoid vegetations have all the same end in view, that is, the removal of the vegetations. The sharp curette is a good method if the patient will stand the blood, increase of pain and the length of the operation. In the case of children it is, I think, a rather difficult method, and requires considerable skill and fortitude on the part of the patient. The case I have related in this connection was a girl about fourteen years old. I first tried the

forceps, but the pain in cutting off the adenoid vegetations was objected to very strenuously by the patient, and I was obliged to desist. Before I tried the hot snare I tried the cold snare, but I found that it took some time to draw up the steel wire and thus squeeze off the vegetation. After the adoption of the hot snare I had no difficulty. The mere introduction of the instrument caused no pain, and after getting it over the vegetation, in two seconds the growth was off, with but little pain and no hæmorrhage to frighten the patient. The treatment of hay-fever by the cauterizing method, I would like to discuss, but the lateness of the hour will not permit it.

AMERICAN GYNÆCOLOGICAL SOCIETY.

The Eleventh Annual Meeting held in the Hall of the Johns Hopkins University, Baltimore, Md.; September 21, 22, and 23, 1886.

TUESDAY, SEPTEMBER 21, FIRST DAY.

MORNING SESSION.

The Society was called to order at 10 A. M., by the PRESIDENT, DR. THADDEUS A. REAMY, of Cincinnati.

DR. H. P. C. WILSON, of Baltimore, delivered the *Address of Welcome*.

DR. H. P. C. WILSON, then read a paper on

THE DIVISION OF THE CERVIX BACKWARDS IN SOME FORMS OF ANTI-FLEXION OF THE UTERUS, WITH DYSMENORRHOEA AND STERILITY.

From want of a judicious selection of the cases, by being done by unskilled hands in proper cases, by being done in unsuitable cases and from want of appropriate after-treatment, this operation has been barren of good results in certain hands and followed by bad results in other hands. This operation has been substituted by the use of stems, sponge-tents and dilators, but I have found no measure so safe and efficient in the classes of cases to which I shall call attention, as the knife. The classes of cases in which I would recommend the operation are:

First, Those of anti-flexion of the uterus, with a hard indurated cervix, where the body is bent upon neck, or the neck upon the body, forming a more or less acute angle.

Second, Those cases of acute flexion where the cervix is hyperplastic and indurated and dense as cartilage.

Third, Those cases where there is a hard, unyielding internal os, through which the probe passes with difficulty and in its passage gives the sensation of passing over rough dense cartilage, while the finger in the sulcus between the body and the neck in front, gains the impression of a strong cord tied around the uterus. Nearly all these cases are sterile. In all of them the nabothian and utricular glands are hypertrophied and indurated.

The method of operation was then described. With the patient under an anæsthetic, the uterus is drawn downwards by a tenaculum in the anterior lip.

The posterior lip is then divided with scissors up to the vaginal junction. An uterotome is next passed and the internal os divided anteriorly and posteriorly to an extent sufficient to permit the introduction of a large sound. The parts are allowed to bleed freely. A pledget of cotton soaked in a mixture of Monsel's solution, iodine and glycerine is then introduced into the cervix and over this, pledgets treated with Monsel's solution and water and the vagina lightly tamponed. These are not removed until the third day. All the manipulation of the uterus is avoided for at least two weeks. A sound is then carefully passed and every second day the os is gently stretched with a steel dilator. The patient is allowed to fully recover from the operation which usually requires one month. Local treatment is then suspended for one month to allow the intra-uterine mucous membrane to improve. The patient then returns and applications of Churchill's tincture of iodine are made to the endometrium two or three times a week. The treatment after the lapse of a month is again suspended to be resumed in the course of one or two months. If this after-treatment is not carefully and properly carried out, the operation had better not be done. The speaker had performed the operation four hundred times and had never obtained as good results from any other method. In no case has he had a death which could be attributed directly to the operation. There are some cases of dysmenorrhœa and sterility where this operation is entirely unsuited. It was recommended only in the cases described in the beginning of the paper. Several illustrative cases showing the good effects of the operation in overcoming dysmenorrhœa and sterility were related.

DR. T. A. EMMET, of New York: Some years ago, I should have been willing to endorse all that has been said by the speaker, but since then I have had reason to change my views. Mechanical dysmenorrhœa I believe to be a myth. We must separate two conditions of flexion, one a flexure of the neck a congenital defect, and the other a flexure of the body of the uterus due to preceding inflammation outside of the uterus. Sterility resulting from this latter cause is not relieved by the operation, and its performance is attended with great risks to life. The congenital flexion is the only one in which I operate to relieve the sterility. In those cases where I have done the operation, I have not left a raw surface, but have drawn the vaginal mucous membrane to the bottom of the wound and secured it with stitches. This does away with the necessity for plugging and the fear of hæmorrhage. This operative procedure is not free from danger, I have known of at least twenty deaths from it. If all the effects of previous inflammation are removed, there is not the same danger, but I cannot see that the operation will do any good.

DR. JAMES R. CHADWICK, of Boston: I regard the flexion as always congenital, the result of the persistence of the infantile shape of the uterus. This I am convinced is not confined to the anatomy of the organ, but also involves its function. The defect probably extends to other portions of the genital

tract. The only cases in which I have had any results from operation, have been where there is flexion with a small external os. In a certain proportion of these cases impregnation has followed.

DR. W. H. BAKER, of Boston: Some ten years ago I saw a number of cases in which this operation was done, and while the immediate results were very gratifying, yet in many cases the patients did not retain these good results. Of late years I have limited the operation to the class of cases in which there is a congenital malformation and those in which there has been an inflammatory condition, the results of which have been removed. The good results which Dr. Wilson reports must be explained by the great care in the after treatment which he practices.

DR. FORDYCE BARKER, of New York: Some thirty years ago, I saw Simpson perform this operation a number of times. He performed it in his office and did not seem to apprehend any danger from hæmorrhage. I employed the operation in a few cases, but I soon gave it up. The only cases in which I employ it is where the narrowing is at the os externum.

DR. J. SCOTT, of California: I have practiced the operation, but while the immediate results, have been good, I have been disappointed in the ultimate results. After the operation, the patient should be confined to bed at perfect rest, and hot water injections be employed every two hours.

DR. W. T. HOWARD, of Baltimore: My experience has not shown me that any particular operation is the one for all cases. By the antero-posterior incision I have had some excellent results. With the precautions adopted in operating in other portions of the body, incision of this kind in the majority of cases should not be dangerous. In some cases I have employed the posterior incision, in others the bilateral incision, but in the majority of cases I dilate, using antiseptic precautions and never taking less than twenty to thirty minutes to complete the operation.

DR. R. STANSBURY SUTTON, of Pittsburgh, read a paper describing

ANOTHER MODIFICATION OF EMMET'S CERVIX OPERATION, WITH A CASE IN POINT.

A case of old standing neglected double laceration of the cervix was reported. The cervix was composed of dense, hard, hyperplastic tissue almost cartilaginous in character. An operation by the ordinary method was out of the question, for the sutures would not have held. In order to remove the greatest amount of cicatricial tissue and overcome the condition, the following procedure was resorted to: The lower lip of the laceration was denuded of its altered mucous membrane, leaving only a narrow strip corresponding to one-half of the strip usually left to serve for the future os. The upper lip was treated in the same way leaving the opposite half of the strip of mucous membrane. When the flaps were brought together, the strips of mucous membrane lay side by side. In this way, union in the position of the future canal was prevented. Good union followed the operation and at the end of three weeks a Simpson sound was passed without difficulty. This

operation may be of service in certain cases where the usual operation can not be performed.

DR. T. A. EMMET: The modification seems to be an ingenious one, but its value can only be determined by future trial. In such cases, however, where there has been such cystic degeneration it is often better surgery to amputate a portion of the cervix, so as to get into healthier tissue. In a certain number of cases, I have always performed amputation, I have always objected to amputation of the cervix in so-called elongated cervix.

DR. GEORGE J. ENGELMANN, of St. Louis: I have paid very little attention to the strip of mucous membrane. I have in such cases as has been described by Dr. Sutton, cut away nearly all the mucous membrane and insert a short piece of fine catgut. This keeps all the opening which is necessary.

DR. W. H. BAKER, of Boston: I think that if we can restore the healthy character of the strip of mucous membrane and retain it, that is the best surgery. In this class of cases I have been in the habit of removing a transverse wedge-shaped portion of each lip of the cervix and then bring the parts together. In this way the hyperplastic tissue preventing the apposition of the surfaces is removed.

DR. ELWOOD WILSON, of Philadelphia, presented a paper read by the Secretary:

NOTES ON THE TREATMENT OF RECENT LACERATION OF THE CERVIX UTERI.

Occasionally a tear of the cervix can be recognized immediately after labor, but sometimes this can not be done. The patient should always be examined ten or twelve days later. If laceration be found immediately after labor, injections of corrosive sublimate solution, one to five thousand with the insertion of an iodoform suppository should be resorted to. The vagina should be irrigated every other day and the suppository renewed. When the laceration is found within three weeks after delivery, the following treatment should be employed: After the surface has been carefully cleansed and dried, it should be painted with a solution of nitrate of silver one drachm to the ounce of distilled water. From three to five applications at intervals of five days are usually required. In every case in which the author had tried this measure (six in number) the result was entirely satisfactory.

DR. FORDYCE BARKER: It seems to me that the practice recommended in the paper is better worthy of trial. It is much preferable to the rule laid down within the past few years, that if there is a laceration it should be closed immediately after labor. If this method will effect union it should be tried.

DR. T. A. EMMET: I suppose that a certain amount of laceration occurs in every labor, but it is wonderful what nature will do to restore the cervix where septic poisoning is not present. It seems to me that in all cases, where under favorable circumstances, nature has failed to repair the damage, there have been symptoms indicating septic inflammation. In the cases reported I believe that the same results would have been obtained even if nitrate of silver had not been employed.

DR. J. SCOTT, of San Francisco: In only one case have I attempted to sew up the cervix shortly after labor. In this case there was an extensive tear of the cervix and of the peritoneum. There was considerable bleeding, and five hours after labor I thought it advisable to sew up the cervix. The tissues were so soft that it was with the greatest difficulty that I could get the sutures to hold. Union took place, however, both in the cervix and in the peritoneum.

(To be concluded.)

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

The Outbreak of Scarlatina at Marylebone—Restoration of the Color of Hair by Phosphorized Cod-liver Oil.

Some time ago attention was called to the circumstances which attended a remarkable outbreak of scarlet fever in the Marylebone district of London. The mystery surrounding the epidemic in question was of a profound nature. The ordinary sources of infection were proved to be inoperative. The presence of scarlet fever in the occupants of dairies from which the milk of the infected families was derived was shown to be a theory utterly unsupported by facts. There was in short no signs or trace of infection in so far as regarded the milk supply or its human environments. Yet, that the disease had spread from milk, and in particular from the milk drawn from one farm at Hendon, seemed to be a hypothesis suggested and supported by the facts of the case. Accordingly Mr. W. H. Power, of the Local Government Board, undertook the task of further investigation. As the result of a very full enquiry this gentleman was able to localize a disease which had appeared in certain cows imported into the dairy farm at Hendon, as the probable cause of the scarlet fever infection. By a process of elimination of all unlikely and unsupported evidences, the cows themselves were thus fixed upon as the defaulters in the matter of healthy conditions. It has long been suspected that milk under certain circumstances could give rise to scarlet fever in man. This was a theory of sanitarians, but it lacked proof and demonstration. Mr. Power's inquiry had traced the scarlet fever epidemic of Marylebone to certain affected cows at Hendon, but as formerly remarked, decisive proof was needed to prove that the disease of the animals could really produce scarlatina in man. That proof has now been supplied. It is therefore no longer a matter of speculation, but one of plain proof, that milk taken from cows affected with a particular disease is capable, when impregnated with the germs of the ailment in question, of giving rise to ordinary scarlet fever in human beings. This is a step gained in health science. It is true that this is by no means the first or only occasion on which an animal disease has been proved capable of originating a corresponding ailment in man.

The task of tracing out the exact nature of the disease in the Hendon cows was entrusted to Dr. Klein, whose labors as an investigator in this difficult branch of pathology are well-known and appreciated by the world of science at large. Two of the affected cows at Hendon were purchased by the Local Government Board, and were conveyed to the useful scientific depot, the Brown Institution. The disease Dr. Klein tells us in the Report which has been issued by the Board, made its appearance on the teats and udders of the cows. These sores were, however, only the localized manifestations of the constitutional trouble. The hair was also noted to be liable to come off in patches on the back and tail particularly. That the ailment did not appear to have affected the health of the animals in any severe or marked degree was proved by the facts that their feeding was not impaired in any way, while their temperature was normal. Post-mortem examination of the cows revealed prominent affections of the lungs and kidneys especially, while the liver tissue is described by Dr. Klein as being much softened. It was clear therefore that the disease, whatever its nature, had not left the system of the animals untouched. The crucial point of the inquiry, however, had reference to the nature of the local sores already mentioned as occurring on the teats and udders. It is from such manifestations that the true character of a disease can often be best determined. Dr. Klein inoculated four calves with matter taken from the ulcers of the cows. In each case a similar sore was produced, this fact proving the transmissibility of the disease, in one fashion at least, from cow to cow. Similar inoculations, made on guinea pigs and dogs resulted in the discovery that the former animals are insusceptible to the action of the poison or disease matter. In one of the three dogs inoculated a successful result was obtained.

The germs found in the matter from the ulcers, Dr. Klein describes as closely resembling the germs that are familiar as occurring in the well-known "foot and mouth disease" of cattle. Cultivating the germs in various solutions adapted to imitate the fluids of the cow's body in which they found apparently a natural habitat, Dr. Klein was able to study their development, and was also placed in a position to make experiments with the view of further testing if the germs in question were veritable sources of the disease. Using a cultivation of the germs he inoculated therewith two calves. In twenty-six days one of these calves was found dead. Examination of the animals body proved that it had perished from a very distinct form of disease. Dr. Klein tells us that this disease, artificially produced in the calf by inoculation with the germs derived from the cow "bears a close resemblance to human scarlatina." He specially quotes the appearances found in the kidney of the animal as indicative of scarlet fever attack. The symptoms produced in the calf, when compared with those found in man after scarlatina are, in Dr. Klein's ideas, absolutely identical. There is little need to enter at greater length into the history of these investigations, which have been satisfactorily brought to a point, leaving no doubt whatever that cow disease of a special kind is capable of giving scarlet fever to

human beings. It remains, however, to remark that the milk of the affected cows has been proved to be pure and harmless enough. It does not contain the germs of the disease. Hence, a question arises regarding the manner in which infection becomes possible. There can be no doubt that the milk becomes contaminated after it has passed from the udder of the cow. Dr. Klein says that the fingers of the milker must of necessity bring down into the milk disease particles from the ulcerations on the teats of the animal. In the milk these germs find a good medium in which to multiply. If the nature of the infection becomes thus plain, the duty of the dairyman, under these new revelations of science, becomes no less clearly defined. His business more than ever will demand strict attention being paid to the health of the cows under his charge. Armed with the knowledge of Dr. Klein's discoveries, it should be an easy matter for the veterinary inspector of the dairy to isolate at once from the vicinity of healthy cows all animals presenting the diseased appearances described. While it will be incumbent on the dairy man to see that the milk of such animals is not allowed in any way to be used for human or indeed animal consumption.

A case was shown recently in a patient who, whilst under the internal administration of phosphorized cod-liver oil, his hair, which was prematurely grey, returned to its original color. G. O. M.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Charities and Correction—Entertainment for the Insane—Bartley Campbell—Industrial Education Association.

The Commissioners of Charities and Correction are contemplating some important changes in the accommodation of the city's criminals, paupers, sick, idiotic and insane, of which they have charge. The penitentiary on Blackwell's Island, having for a long time been overcrowded, instead of enlarging the buildings there, it has been decided to erect an entirely new structure elsewhere, and two years ago, under a special act of the Legislature, empowering them to make the purchase, the Commissioners bought Riker's Island for the purpose. They propose to have there an enormous model penitentiary, ample in size to serve for many years to come, and have now practically secured from the Board of Estimate and Apportionment the sum of \$100,000 with which to commence the work. There was some legal obstruction to this appropriation, but this is believed to have been removed by a recent decision of the Court of Appeals.

In order to relieve the overcrowded asylums under their charge, the Commissioners last year purchased a thousand acres of land near Central Islip, on Long Island. The present population of these institutions is reported as follows: Men in city insane asylum,

Ward's Island, 1,944; women in asylum on Blackwell's Island, 1,879; women in branch asylum, Ward's Island, 614; women in homœopathic hospital (insane), 150; epileptics and idiots in institutions on Randall's Island, 650; total, 5,237. It is prepared to inaugurate, under the direction of Dr. A. E. MacDonald, general superintendent of the city asylums for the insane, the cottage system, which has been so successfully carried out in Germany and Switzerland, on this tract on Long Island, which is conveniently situated on the railroad and is said to be admirably adapted for farming purposes. Many attractions and home-like cottages will be erected there, in which will reside small families of the non-violent insane, both men and women, and it is believed that with the labor of the able-bodied among them they will at once care for themselves at a lower rate of current expenditure than under the present system, which, by means of the various favorable influences thus brought to bear upon them (which will be so different from those of the ordinary lunatic asylum), the percentage of recoveries will be largely increased. For a considerable time, between six and seven hundred insane men have been employed in useful labor, principally in farm and garden work, on Ward's Island, while many of the insane women on Blackwell's Island are constantly occupied in womanly work there; and the results from the plan have been very satisfactory.

By the removal of the penitentiary to Riker's Island, Blackwell's Island will be left exclusively devoted to the relief of the suffering poor. As long as it remains there, the hospitals and asylums will, to a certain extent, continue to be associated in the popular mind with the penal institution. As has been said, the shadow of the penitentiary rests upon all the noble works of charity on Blackwell's Island, and by its association with crime in an official way, a new disgrace is imposed upon helpless poverty, and soon a stigma cast upon the victims of physical suffering and mental alienation. Among the other recent improvements on Blackwell's Island is the abandonment of the hospitals for small-pox and other contagious diseases there. Patients suffering from these afflictions have now been transported from the care of the Commissioners of Charity and Correction to that of the Health Department, and about six months ago the new hospital for infectious diseases was opened on North Brother's Island, under the auspices of the latter, which also has charge of the new reception hospital at the foot of East 16th street.

The former small-pox hospital building, thus left vacant, is charmingly situated on the extreme southern point of Blackwell's Island, and as it is substantially built of stone and architecturally one of the handsomest structures among the city institutions, it was decided not to destroy it, but to fit it up for the residence of the corps of trained nurses engaged in the care of the sick in the neighboring great Charity Hospital. As a preliminary to this conversion, everything but the stone walls was torn out and burned—trams, flooring, wainscoting, rafters and roof—and the interior was completely reconstructed, so as to adapt it in the most perfect manner possible to its new uses. The fifty young women of the Charity Hospital train-

ing school have just taken possession of their palatial quarters, and it is altogether probable that no set of hospital nurses has ever before been so luxuriously housed. On the ground floor a spacious corridor runs through the building (which is eighty feet long), from end to end, with a connecting hall as long as the width of the building (forty feet), and on either side the large parlors and reception rooms, are the office and apartments of the lady superintendent. The floors above are devoted to the sleeping rooms of the nurses, which are large, lofty and admirably lighted and ventilated, and it is needless to say that the young women are highly delighted with their new quarters. Among the other attractions of the place is a beautiful bathing beach just at the doors.

In Bellevue Hospital, one great trouble with the old and badly constructed buildings of which has always been the difficulty of receiving an adequate supply of fresh air, the Commissioners have decided to introduce a new system of ventilation, the working-power of which is applied by an electric motor; and it is claimed that by it the air in a ward will be entirely changed every thirty minutes, and may be in each fifteen minutes if it is required that the temperature should be maintained, absolutely without fluctuation, at any desired point. The working of the fans in the tubes at the top of the buildings will be entirely automatic, and the electric motor will not require attention more than once a month.

Dr. MacDonald and his assistants have recently introduced at the Female Insane Asylum on Blackwell's Island a form of entertainment which it is thought will prove highly beneficial. Instead of having the patients entertained by musical or dramatic performers by parties from outside, as has been commonly the custom, the idea is to have the patients give the whole performance themselves, and the first of these took place on the 22d of September. The programme was made up of vocal and instrumental music, recitations and dramatic and negro minstrel sketches, and was most keenly enjoyed both by the audience and those who took part in it. The costuming is said to have been very amusing, and a part of the wardrobe was supplied from that of a disbanded theatrical company, which Commissioner Brennan, who always has a large heart for the unfortunates under the care of the Department, recently purchased for the patients. These entertainments will be repeated as often as practicable, as the physicians find their effect exhilarating and healthful.

The wife of poor Bartley Campbell, the playwright (who has been for some months an inmate of the Bloomingdale Asylum), having applied for the appointment of a committee of his estate and person, Judge Andrews, of the Supreme Court, has granted a writ *de lunatico inquirendo*. In his testimony concerning the condition of the patient, Dr. Charles H. Nichols, one of the physicians of the asylum, states that he continues to show the characteristic indications of progressive paralysis of the insane. In his hallucinations he imagines that he frequently holds communications with Shakespeare, Wagner, Queen Victoria, King Humbert, of Italy, President Grévy, and other notable personages, living and dead,

whom he is supposed to meet in heaven. At other times he fancies that many persons are pursuing him for the purpose of taking his life, and that among them are his two sons, from whom he especially beseeches to be protected; while sometimes, again, his delusion is that certain persons, one of whom is Oliver Cromwell, are engaged in combat with each other within his body.

The large and commodious building on University Place, formerly occupied by the Union Theological Seminary, has been secured for that excellent institution, the Industrial Education Association, which, since the exhibition of children's handiwork last spring, has greatly extended its work and has been placed upon a permanent basis. During the last summer the experiment of opening vacation schools has had a good effect in showing the advantages of seeking to establish in children the habit of cheerful industry, and a number of classes of boys and girls have been profitably trained on Long Island, Staten Island and other localities. In its new quarters the Association will enjoy extended facilities for carrying out its work. The former chapel has been converted into a lecture hall, and the library will be used as a permanent exhibition for juvenile industries. Many useful and ornamental kinds of handicraft will be practically taught, and the courses of instruction also include a Kindergarten and a training school for female servants.

P. B. P.

MISCELLANEOUS.

THE PASTEUR INSTITUTE.—The municipal council of Paris has ceded to the Pasteur Institute, the ground on which it is built. The official statement just made by the directors of the institute shows: The whole number of persons treated by Pasteur is 1,656 (of these, 15 have died); 1,009 of these were French (3 of them died); 182, including 50 bitten by rabid wolves, were Russians (3 of these bitten by dogs, and 8 by wolves, have died); 20 were from Roumania, with one death; of the others, 59 were from England, 17 from Austria, 74 from Algeria, 18 from America, 2 from Brazil, 42 from Belgium, 58 from Spain, 7 from Greece, 8 from Holland, 25 from Hungary, 105 from Italy, 20 from Portugal, 2 from Turkey, and 2 from Switzerland. Of these not one has as yet died.

THE DETECTION OF MORPHINE TAKING.—PROFESSOR BULL, of Paris, says that the morphine-taker may be detected by examination of the skin or the urine. The skin will be covered, usually on the thighs, with little dark spots which are situated in the centre of small indurations; these are made by the hypodermatic needle. If the patient refuse an examination, the urine may be examined. By adding a few drops of tincture of iron to the urine, a blue tinge will be presented if morphine be present.

DEATH OF MR. SAMPSON GAMGEE.—We regret to have to announce the death of Mr. Gamgee, which took place on September 18.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 25, 1886, TO OCTOBER 1, 1886.

Major Dallas Bache, Surgeon, granted leave of absence for 25 days, to take effect on or about Oct. 2, 1886. (S. O. 143, Div. of the Atlantic, Sept. 24, 1886.)

Capt. Daniel M. Appel, Asst. Surg., assigned to duty at Fort Davis, Texas. (S. O. 133, Dept. Texas, Sept. 22, 1886.)

First Lieut. Philip G. Wales, Asst. Surg., leave of absence extended to include Nov. 5, 1886. (S. O. 226, A. G. O., Sept. 29, 1886.)

First Lieut. Charles M. Gandy, Asst. Surg., assigned to duty at Fort Concho, Texas. (S. O. 131, Dept. Texas, Sept. 18, 1886.)

First Lieut. Chas. F. Mason, Asst. Surg., ordered for temporary duty at Fort Verde, Arizona Ter. (S. O. 90, Dept. Arizona, Sept. 20, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE TWO WEEKS ENDING OCTOBER 2, 1886.

P. A. Surgeon D. M. Guiteras, to Rec'g Ship "Franklin," for temporary duty, Oct. 3d.

Asst. Surg. A. R. Wentworth, detached from Navy Yard, League Island, and to the U. S. S. "Galena," Oct. 1st.

Asst. Surg. H. B. Scott, ordered to Navy Yard, New York, Oct. 1st.

P. A. Surgeon Richard Ashbridge, detached from the U. S. S. "Swatara," Oct. 1st, granted six months leave.

Asst. Surg. T. A. Berryhill, detached from the Museum of Hygiene and ordered to Rec'g Ship "Minnesota."

P. A. Surg. Geo. Arthur, detached from the Navy Yard, New York, and ordered to the Museum of Hygiene.

P. A. Surg. H. T. Percy, detached from the U. S. S. "Galena," proceed home and await orders.

Asst. Surg. Joseph Shafer, detached from the U. S. S. "Minnesota," and ordered to the U. S. S. "Swatara."

P. A. Surg. J. M. Steele, detached from Naval Academy, and granted six months leave.

P. A. Surg. Clement Biddle, ordered to Naval Academy, Annapolis, Md.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED OCTOBER 2, 1886.

Bailhache, P. H., Surgeon, granted leave of absence for thirty days, Sept. 25, 1886.

Vansant, John, Surgeon, granted leave of absence for thirty days, Sept. 24, 1886.

Bratton, W. D., Asst. Surgeon, relieved from duty on Revenue Steamer "Corwin," ordered to duty at Marine Hospital, San Francisco, Cal., Sept. 20, 1886.

Purviance, Geo., Surgeon, granted leave of absence for twenty-five days, Sept. 30, 1886.

Stoner, G. W., Surgeon, granted leave of absence for twenty-three days, Oct. 1, 1886.

Carter, H. R., Passed Asst. Surg., to proceed to Galveston, Texas, as Inspector, Sept. 30, 1886.

Ames, R. P. M., Passed Asst. Surg., granted leave of absence for thirty days, to take effect when relieved, Sept. 30, 1886.

Wasdin, Eugene, Asst. Surg., ordered to examination for promotion, Sept. 30, 1886.

Brooks, S. D., Asst. Surg., granted leave of absence for thirty days, to take effect when relieved, Sept. 30, 1886.

Williams, L. L., Asst. Surg., relieved from duty at Mobile, Ala., ordered to Marine Hospital at Wilmington, N. Carolina, Sept. 27, 1886.

Perry, T. B., Asst. Surgeon, relieved from duty at San Francisco, Cal., ordered to Marine Hospital, St. Louis, Mo., Oct. 1, 1886.

FIBRO- OR SPINDLE-CELLED SARCOMATOUS TUMORS, WITH THE REPORT OF A CASE AND PRESENTATION OF THE SPECIMEN.¹

BY B. A. WATSON, A.M., M.D.,

SURGEON TO CHARITY, ST. FRANCIS, AND CHRIST HOSPITALS, JERSEY CITY, N. J.

Various names have been employed by modern authors to designate these tumors, and such appellations are commonly expressive of their structural composition or pathological peculiarities. We accordingly find Mr. Paget speaking of them as "recurrent fibroids;" Lebert, as "fibro-plastic tumors;" Müller, "fasciculated carcinoma;" Gluge, "albuminous sarcoma;" Cornil and Ranvier, "fasciculated sarcoma;" Follin, "plasmona;" Bennett, "fibro-nucleated tumors;" Lancereaux, "spindle-celled sarcomatous tumors;" while the same morbid condition is discussed by Billroth under the head of "spindle-celled sarcoma or fibro-sarcoma." These tumors vary greatly in size and may not be larger than a filbert in one instance, while, in other cases, the dimensions occasionally exceed those of the adult human head.

These neoplasms were first described by Lebert under the name of "fibro-plastic tumors." They are very common and may be developed in various regions of the body. They are most frequently found in the skin and subcutaneous structures, but likewise frequently occur in the deep seated connective tissue, aponeuroses, mammary gland, testicles, and also, occasionally, in the muscular tissue. The disease may also originate in the periosteum and by some authors it is thought possible for it to find a starting point even in the endosteum of the long bones. These tumors are never uniform in their external appearance, inasmuch as the form of the growth is commonly dependent on the surrounding tissues, and it is a well known fact that development will go on most rapidly in the direction in which it meets the least resistance. These growths are generally rounded or lobulated and firmly attached to the surrounding tissues, and even a casual examination after their removal, shows them to be firm, tough, and irregular. A transverse section of the tumor having been made, brings into view a pale red, pale pink, or clear grayish-white tissue, and the surface has a

streaked appearance as if from the presence of fibrous bands and bundles of fibrous tissue variously arranged, sometimes straight, sometimes curved, at other times parallel or even crossing each other, and occasionally found in concentric layers, similar to that which is observed on the section of uterine myoma. There is not seen, on the freshly cut surface of these tumors, any juice, or at least only a very small quantity of a transparent fluid, but in those tumors which have been left exposed to the air after their removal, until decomposition has set in, it will be observed that if incisions are now made in them, there soon appears on the cut surfaces a whitish, milk-colored fluid, which, however, is less in quantity than that commonly exuded under the same circumstances when some of the other varieties of sarcoma are incised during the stage of decomposition.

The cell formation of the spindle-celled sarcoma is copied very accurately after the spindle-celled tissue of recent cicatrices, as the microscopical examination of these tumors shows that they are made up of a short and narrow spindle-cell with an elongated, roundish nucleus, with or without nucleoli, enlarged in the middle and terminated in two fine points; it is also this peculiar form which has caused them to be compared with the spindle; this peculiarity supplying the explanation why the name of spindle-cell has been given to these elements and the name, spindle-celled sarcoma applied to these morbid growths. The spindle-cells vary greatly in size, and this fact has caused Rindfleisch to designate the spindle-celled sarcomatous growths as the "small spindle-celled sarcoma," and the "large spindle-celled sarcoma." This distinction possesses but little value since all the intermediate sizes are found in our pathological examinations; nevertheless, it may be well to remember that the small spindle-cells characterize a tumor which is more dangerous to life—more prone to return when it has been removed. It therefore seems that the large spindle-cells represent a more favorable condition of the elements—the prognosis is less grave, and consequently from the clinical stand-point, it is not a matter of entire indifference whether the cells are large or small. Besides these spindle-cells, there is frequently found a certain number of round cells, similar to those observed in cases of encephaloid sarcoma. The latter are sometimes very limited in number, whilst, on the contrary, they may be very numerous. In these instances the surgeon is dealing with a mixed form of sarcoma, intermediate between the encephaloid and the spindle-celled.

¹Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

The arrangement of the fibrous bundles in the spindle-celled sarcoma is very simple, the fusiform cells being placed side by side in such a manner that the enlarged portion of one cell is in contact with the slender part of its neighbor, and these are firmly united by an intercellular substance. The uniting, or intercellular substance is hyaline, more firm and less abundant than in cases of encephaloid sarcoma. The vessels in these tumors possess few peculiarities; the larger are observed running in the same direction as the large fasciculæ, but the smaller do not conform to this rule. The tissue of the spindle-celled sarcoma is more dense than that of the encephaloid, and consequently interstitial hæmorrhage is more rare. In the encephaloid variety it has been observed that fatty granular changes, mucous transformation, etc., are frequent occurrences which are not seen in cases of the spindle-celled sarcoma.

It is highly important that sarcoma should be carefully studied in connection with the tumors of the female breast, and although these sarcomatous growths may be either encephaloid or spindle-celled, it is, nevertheless, highly important, from both a diagnostic and prognostic standpoint, that the surgeon should be able to make a differential diagnosis of sarcoma and carcinoma of the breast. This difference consists of well marked pathological characteristics, which I shall attempt to portray in the following diagram.

DIFFERENTIAL DIAGNOSIS OF SARCOMA AND CARCINOMA OF THE BREAST.

SARCOMA.

1. Commonly develops very slowly, especially at first; may remain stationary for years.
2. Rough, lobulated, or lumpy; lump may be as large as a hen's egg; tumor finally attaining great size and becoming pediculated.
3. Skin involved after a long interval; morbid growth approaches the integument, which is gradually thinned as by an abscess, and also frequently marked with large veins.
4. Nipple does not retract and is not often changed in appearance.
5. Ulceration occurs after the lapse of a long period; skin gives way, owing to pressure on its internal surface by the lumps which belong to the morbid growth, but the ulcerated border of the integument is thin, loose and not adherent to the tumor.
6. Consistence of the tumor varies in the different stages of the disease; first hard, later soft spots may be found, and even liquid parts from the cysts within it.
7. The mammary gland remains distinct from the tumor; consequently it is not destroyed, but simply flattened and atrophied.

CARCINOMA.

1. Commonly develops very rapidly and may terminate fatally within a year.
2. Slightly roughened; no large lobules; tumor usually small and flattened on the chest.
3. Skin becomes quickly attached to the morbid growth, is retracted, drawn in, thus giving rise to the appearance of a quilted cover; large veins not seen, but in their stead there may be observed white lines, sometimes called lymphatic varices.
4. Nipple retracts and its end seems to be absorbed.
5. Ulceration occurs at an early date; skin is invaded by the morbid growth, and destroyed; border is thickened, hardened and adherent to the tumor.
6. Consistence of the tumor never varies in the different stages. Generally firm.
7. This morbid growth, from the first, fuses with the mammary gland and soon destroys it.

8. Sarcoma does not become adherent to the deep-seated parts.

9. Does not involve the lymphatic system in the early stage of the disease, and rarely, even in the late.

10. The morbid growth returns in the majority of cases, commonly in the same organ, and these relapses indicate a finally fatal termination of the disease.

11. The general health of the patient often remains quite satisfactory, even after the tumor has been removed several times.

12. The progress of the disease is rarely attended with much pain.

8. Carcinoma adheres quickly to the deep-seated parts, especially the pectoralis muscle.

9. Involves the lymphatic system in the early stage of the disease, which is always steadily progressive.

10. The morbid growth will surely and speedily return; usually in some other part of the body and a fatal termination rapidly supervenes.

11. The general health is quickly impaired, the cachexia becoming very marked in the early stage of the disease.

12. The progress of the disease is attended with severe pain.

Having pointed out the most essential differences between sarcoma and carcinoma of the breast, I shall now consider briefly, the chief characteristics of the former disease in this organ. It should, however, be remembered that while speaking of the morbid growths in the mammary gland, I do not confine myself to the spindle-celled sarcoma, but also include all the varieties of sarcomatous growths found in this organ. I have taken this liberty in order that I might be enabled to draw a dividing line between sarcoma and carcinoma.

The sarcomatous growths found in the breast were designated by Rindfleisch by the following names: cysto-sarcoma fibrosum, cysto-sarcoma mucosum, sarcoma peri-caniculare, sarcoma peri canaliculare diffusum. The sarcoma which is developed in the mammary gland is accompanied by a proliferation of cells of the lactiferous ducts. Cornil and Ranvier, who have studied very carefully these morbid growths have designated two forms, one in which the sarcomatous tissue is developed in the lobules at those points where the lactiferous ducts are the most numerous distributed, or, as is thought by some, within these minute canals.

In the other form of this disease, the granulating sarcomatous tissue which is supposed to originate within the lactiferous canals, pushes back their walls, extends into them in the form of simple papillæ, which distend these tubes and frequently become attached to them by a narrow pedicle. This growth is distinguished from the former by a more rapid development of the tumor and also by a more luxuriant proliferation of the foliated and papillar excrescences into the lactiferous ducts.

This condition becomes more marked when, besides the distention and distortion of the lactiferous ducts, there is also a collection of mucoid secretion within them, which gives rise to irregular sacs in which fluctuation may be detected. These sacs are the lacunary cysts which are so frequently mentioned by the various authors in their writings on sarcomatous tumors of the breast. Billroth has described this variety under the name of adenoid sarcoma, and many other authors have classified it with adenoid tumors, thus accounting for the fact that many morbid growths, so-called adenoids, have returned after their removal by operation.

The symptoms of the spindle celled sarcoma differ somewhat from those which have been described in the above. This morbid growth, when it makes its appearance in the breast, is commonly indicated by roundish nodules, which have their origin in the connective tissue surrounding the lactiferous ducts.

The pathological and microscopical appearances of the spindle celled sarcoma of the breast is very similar to those presented by the same morbid growth in other parts of the body. Rindfleisch's¹ sarcoma peri-canalicular diffusum is "an entirely uniform, yet mostly spindle-celled sarcomatous mass, within which the lactiferous ducts are distorted and distended into widely gaping clefts. This tumor also begins in the surroundings of the ducts, thence, however, passes over the entire interstitial tissues." The spindle-celled sarcoma of the skin, where this neoplasm is common, frequently shows itself in the form of a small tumor, a mere excrescence, which soon involves the entire thickness of the integument, and its breadth may exceed its thickness. This growth sometimes ulcerates at an early day, presenting a raw surface, covered with granulations which readily bleed, and soon become covered with a scab which falls off and is renewed from time to time. There is a form of spindle-celled sarcoma which takes its origin in the connective tissue beneath the skin, possessing many of the characteristics of the encephaloid sarcoma, although its consistence is more decidedly firm, occasionally even hard, where one observes fewer blue veins zig-zagging under the skin on the surface of the tumor and about its periphery. The skin, in some of these cases, remains a long time intact, when the disease is primary in its character, much longer than in cases of encephaloid sarcoma. The tumor, likewise, possesses a marked degree of mobility, but should this morbid growth happen to be attached to the aponeurosis it will then become almost immovable. Therefore, when a spindle-celled sarcoma originates in the periosteum it is naturally immovable. In these cases there is felt a mass which seems to be incorporated with the bone, even though only a lateral projection from it, while in other cases it envelops the whole surface of the bone like a cushion.

These tumors are commonly attended with little or no pain. They also develop very slowly, in fact their action is more torpid than that of the spindle-celled sarcoma of the soft parts. It is likewise thought that this tumor, when it has its origin in the periosteum is much more fatal than when it is confined to the soft tissues, a result which may, *in some measure be due* to the fact that owing to the severe character of the operation required to remove the morbid growth it is commonly postponed so long as to fail in accomplishing the object sought. The constitutional infection in the case of any spindle-celled sarcoma unquestionably takes place through the circulatory system, the blood carrying with it the contaminating juices of the tumor while the lymphatic vessels take but little or no part in this morbid process. It therefore follows that there is seldom found an enlargement of the lymphatic glands during any stage of its progress.

The spindle-celled sarcoma destroys life by a con-

tamination of the general system, or by its pressure on important organs. When a spindle-celled tumor is removed, it may without doubt be reproduced, in fact this is the usual course which this disease takes; but in some patients the health remains good in spite of a multiplicity of relapses. Birkett has cited a case in which sixteen operations were performed within nine years, and where the general health remained unimpaired. A fact worthy of mention, but one that is also observed in other kinds of tumors, is the unfavorable action arising from a traumatism involving morbid growths, in which it is not unfrequently the case that an essentially harmless and chronic disease may take on a very rapid and unfavorable action in consequence of a severe blow or concussion. In connection with this statement it is not difficult to comprehend the effect produced by incomplete operations on various tumors, which, by these operations, are caused to take on a high state of activity, frequently with a fatal result; thus a harmless fibro-polypoid growth situated in the nasopharyngeal cavity, frequently becomes sarcomatous following an incomplete operation for the removal of the primary tumor.

When the spindle-celled sarcoma is reproduced after its removal the secondary tumor may consist of essentially the same texture as the primitive; but there is a marked tendency in these growths to become more and more embryonic in their nature, thus precipitating the progress of the malady. The practical lesson taught by these observations is the avoidance of incomplete operation.

The ganglionic engorgement, which is rarely observed in cases of spindle-celled sarcoma, is merely irritative, and consequently entirely disappears after the removal of the morbid growth. The absence of this ganglionic engorgement is a peculiar characteristic and constitutes a marked difference between the encephaloid and spindle-celled sarcoma, ganglionic infection being rather common in the former, but exceptional in the latter.

It must be confessed that our knowledge of the etiology of the spindle-celled sarcoma is very limited and unsatisfactory. If we can believe statistics, the spindle-celled sarcoma of the soft parts is much more common among women than among men, the proportion being about two to one; but the order of frequency of occurrence in the sexes is reversed when this disease attacks the long bones. This disease occurs in all classes and at all ages, but most frequently in the middle period of life. It is very rare in children; nevertheless a case has been reported by Schwartz in which the disease attacked the tibia in a young infant. There are also reported cases of well-marked spindle-celled sarcoma of the skin which were discovered at birth, and it is also believed that the existence of excrescences or slight defects in the integument present weak points which predispose to this degeneration. In addition to these etiological conditions, there should be mentioned the effects of repeated or continuous irritations, bruises, or contusions which have a definite action in the origin and development of sarcomatous growths, especially the spindle-celled sarcoma. There are in-

¹A Text-book of Pathological Histology, p. 595, Trans. Phila., 1872.

numerable cases cited in support of the views expressed in the preceding sentence, and it is impossible to deny their importance. It has likewise been clearly shown, that, if a sarcoma which already exists, be subjected to a traumatism, this action may become the cause of much greater activity in the morbid process. Inflammation, suppuration, and other unfortunate complications may now arise in rapid succession, hastening the disease to a fatal termination.

The diagnosis of spindle-celled sarcoma cannot be based on any pathognomonic signs. It is by carefully weighing the symptoms as a whole that we are able to diagnosticate the malady. Even a very careful examination of all the symptoms, in many cases, does little more than supply a serious presumption in favor of its nature, without enabling the surgeon to say positively that the tumor before him is a true spindle-celled sarcoma. Thus when this tumor it developed within an aponeurosis *e. g.*, in the fascia lata or some other fibrous tissue, it is rendered immovable, a fact which, when considered in connection with our knowledge of the nature of this neoplasm establishes a presumption in favor of its character. The same, or even greater difficulty, may be experienced in establishing a correct diagnosis in cases of spindle-celled sarcoma when it takes its origin from the periosteum, where it may be readily mistaken for an exostosis, whilst in other localities the question of an enchondroma may lead to a similar difficulty. In certain organs, the breast for example, the spindle-celled sarcoma may be mistaken for a scirrhous carcinoma, or even an encephaloid cancer. However, it should be remembered that the spindle-celled sarcoma develops more slowly, that it maintains a more independent existence, does not attach itself so firmly to the surrounding tissues, the skin which covers the morbid growth remains a long time intact; finally, enlargement of the glands in the axilla never takes place in the early stage of the disease, and very rarely even in the late. A small sarcoma in the skin may be readily mistaken for an epithelioma, but, if the subject is young, the age of the subject should be regarded as presumptive evidence in favor of the sarcomatous nature of the growth. It would seem that there should be very little trouble experienced by a surgeon in diagnosticating a secondary sarcomatous growth appearing in a cicatrix following the removal of the primary disease; but even this may at times be very embarrassing. It is well known that a cicatrix may become reddened and thickened at various points, showing hard excrescences which are properly designated as cicatricial keloids, and that these are commonly regarded as inflammatory products. This peculiar growth frequently marks the former site of every suture employed in the treatment of the wound, or more accurately stated, these keloids form on every suture cicatrix. It may therefore become difficult, in some rare cases, to decide whether the morbid development appearing on a cicatrix is really a sarcomatous growth or not, but the surgeon need not long remain in doubt in these cases. The spindle-celled sarcoma will continue to grow steadily, but the keloid will soon come to a perfect halt and finally shrink and shrivel up.

The prognosis of spindle-celled sarcoma, is without doubt, very grave. Abandoned to itself it advances steadily, and ultimately leads to a fatal termination, either by the general contamination of the system, or local organic disturbance of important vital functions. Furthermore, the fact should not be lost sight of that the spindle-celled sarcoma soon returns after its removal, that it may ultimately become constitutional, and likewise multiply in various organs of the body; notwithstanding all this, the prognosis is much less grave than in cases of carcinoma, or even of encephaloid sarcoma, its progress being slower and the surrounding tissues much less rapidly involved.

It is undeniable that the well-being of the patient is served by an early operation. A considerable number of patients on whom operations have been done under favorable circumstances have remained perfectly well for many years and finally died from other causes. The prognosis, whether favorable or otherwise, must depend largely on the locality of the tumor and the performance of an early or late operation—the former giving the patient the better chance for recovery and long life—while the complete removal of the morbid growth gives the highest degree of safety attainable in these cases; therefore any obstacle in the way of the full accomplishment of this object must influence, unfavorably, the opinion of the surgeon in the question of prognosis.

The treatment of the spindle-celled sarcoma is necessarily entirely surgical; and the earlier the operation is performed the better will be the chances of the patient. It should be carefully remembered that every surgical operation, when possible in these cases, ought to be made before there is involvement of the lymphatic glands or impairment of the general health. Another very important rule in the management of these growths is, that *every particle of the tumor should be removed; let not a single morbid cell remain behind;* if a long bone is involved, amputation is the only effectual remedy. This operation should be performed eight or nine centimetres above the apparent limit of the disease, as shown in the bone substance—better still, where practicable, to amputate through an articulation, above the morbid growth, because there is frequently found in the medullary canal sarcomatous cells at a much higher point than in the bone. The performance of the complete operation is recommended by the following observations: First, ganglionic enlargement, when it exists, is promptly relieved by this procedure; secondarily, the contaminating juices stored up in the morbid growth, as well as the danger arising from its pressure on important organs, is completely removed, and the development of constitutional symptoms is postponed. Incomplete operations should not generally be performed; since this procedure accelerates the development of the morbid growth and gives it, in many instances, a malignant character; but there are unquestionably some cases in which the incomplete operation is absolutely necessary and consequently justifiable, thus, impending suffocation caused by a sarcomatous tumor would justify this procedure.

In connection with this paper I desire to report a

case of spindle-celled sarcoma, and, likewise to present the pathological specimen, which, I think, will be accepted as typical of the disease; but my chief interest centres in the complications rather than in the tumor itself.

C. F. H., school boy, æt. 12, born of healthy parents, nervous temperament, somewhat delicate, accustomed to complain of headache while in daily attendance at school, fond of athletic sports but rather easily fatigued, had passed safely the diseases of childhood; health equally as good after an attack of scarlatina, occurring when the child was about 9 years old, as it had been previously. The tumor was discovered by the mother about November 1, 1885. It was then about the size of a goose egg, and was situated posterior to the middle third of the left femur. The patient, notwithstanding the dimensions to which the growth had already attained, had never complained of any pain or other inconvenience that could be attributed to the tumor. The family physician was finally called and continued in charge of the case until the patient died, which occurred Jan. 5, 1886. In this case there was observed, about the 1st of December, a mottled appearance of the integument, covering some parts of the tumor, which at first consisted of a few isolated red spots. These continued to increase in number and also to enlarge their dimensions. Soon there was observed a change in their color—the spots which primarily were red, slowly turning to a bluish-brown, then to a brownish-black; and inasmuch as new spots were continually making their appearance the parts presented a variegated and mottled aspect. These changes in the skin took place without any apparent elevation of the spots above the surrounding integument. I saw the patient in consultation with the attending physician, about the 20th of December. The tumor was then about four-fifths as large as when I removed it, January 4. The entire surface of the integument covering the morbid growth was mottled as already described. The tumor occupied at this time about the same relative position on the thigh as when first discovered by the mother, although it had increased considerably in size.

I did not see the patient again until the day that the operation was performed. The tumor, in the meantime had changed in form (being less oval than it was), had increased in size, and had descended—the upper border being one inch lower than it was when I made my first examination, and the mottled surface of the integument was now three times greater than at my first visit. The superficial veins covering the tumor were not much enlarged. The patient was anesthetized—a linear incision was made of sufficient length to enable me to remove the entire morbid growth which was found imbedded in the deep connective tissue—its anterior surface approaching closely to the periosteum of the femur, the sciatic nerve passing through one-third of its lower portion, grooving deeply the upper two-thirds of the posterior surface.

The operation was speedily accomplished and attended with very little loss of blood. There was some traction made on the sciatic nerve while liberat-

ing it from the tumor; it was also slightly incised at one point, and was completely detached from all the surrounding tissues throughout the entire length of the tumor.

The operation was performed under strict antiseptic precautions—the nerve was placed within the wound—drainage tubes introduced and the wound closed with iron wire sutures. The shock caused by the operative procedure was apparently slight and the patient reacted very well; but within a few hours it was observed that the mottled appearance which has been previously mentioned was extending very rapidly over the limb; and within thirty hours after the completion of the operation the gangrene had reached the toes and abdomen. The patient survived the operation about thirty-four hours.

I sent the tumor for examination to Dr. Frank Ferguson, pathologist of the New York Hospital, who reports as follows: "My Dear Dr. Watson: I send you the following statement of the tumor received from your office on Saturday last. The tumor measures, vertically, 12 centimetres; laterally, 8; and in its antero-posterior measurement, 6 centimetres. It weighs 304 grammes. Tumor is lobulated, and grooved in the median line posteriorly, to the depth $2\frac{1}{2}$ centimetres, where it received the trunk of the sciatic nerve.

"It is limited by a delicate fibrous capsule except at the point of attachment of muscles. In these locations the tumor is directly continuous with the fibrous tissue of the muscles. It is composed of numerous small spindle-cells and much fibrous tissue. The vascular supply is abundant and the vessel walls are composed of tumor tissue. Diagnosis: Fibrosarcoma. Yours sincerely, Frank Ferguson."

The chief interest in this case attaches to the involvement of the sciatic nerve in the morbid growth which unquestionably caused the vaso-motor disturbances and ultimately the gangrene following the operation.

PNEUMONIA IN THE OLD.¹

BY F. H. PATTON, M.D.,

NATIONAL MILITARY HOME, OHIO.

It was formerly taught that the very robust were peculiarly liable to lobar pneumonia. It is now generally conceded that a strong and healthy constitution protects against the disease. Many recent writers have called attention to the liability of persons suffering from cachectic, carcinomatous, diabetic and other chronic exhaustive diseases, as well as those suffering from severe acute diseases, to be attacked with pneumonia. Diett, in his statistics of 750 cases of pneumonia, found only 18 per cent. to have occurred in previously healthy persons. Alcoholism, climate, chilling of the body, and other causes, have entered prominently into the discussion of the etiology of the disease, and some writers have referred to the debility of age as an exciting cause. Day, in his "Diseases of Old Age," published in 1849, gives a

¹ Read in the Section on Practice of Medicine at the Thirty-Seventh Annual Meeting of the American Medical Association

table of "Causes of Death in 1000 persons over 60 years;" 285 died of old age, 79 of bronchitis, 35 of consumption, and only 27 of pneumonia; but in the next page he contradicts this table and says "there is in all probability an enormous error in it," and gives pneumonia the highest per centage of deaths in diseases of the respiratory organs in the old; and gives a table of examinations of bodies of 390 persons who died at the age of 60 or beyond. One hundred and forty-nine of these died of diseases of the respiratory organs, and of this number 77 died of pneumonia, 26 of pleurisy, 18 of consumption, 10 of asthma, 8 of bronchitis, 4 of pulmonary congestion, and 3 from asphyxia. From the time of this book until Loomis's recent work, I have not consulted any author who gives special prominence to senility as an etiological factor in pneumonia.

Jürgensen says: "In the aged the symptoms are often so latent that the disease may very readily be overlooked;" also, "that he who loses many of his patients from senile debility may rest assured that many of these cases have been pneumonia." But in his comments on his English statistics, he says "that from the fifth to the seventy-fifth year the ratios do not exhibit very marked variations." Reynolds quotes Gunsburg's statistics of 5000 cases of pneumonia, which gives the largest number of cases (17 per cent.) between 20 and 30 years of age; next largest (16 per cent.) between 30 and 40; 7 per cent. from 60 to 70, and 11 per cent. from 70 to 80; he observes on these statistics, that the disease is comparatively frequent from 20 to 40, less so from 40 to 60, and very frequent and very fatal after 60 years of age. Aiken does not refer to its frequency in the old.

Quain and Niemeyer speak frequently of the latent form of the disease in the old, and the absence of pronounced symptoms, but nowhere refer to its frequency. Bartholow scarcely refers to it in the old, and Flint says: "No period of life involves either exemption from or a notable proclivity to the disease." His tables comprise none over 60 years, and he only observes that cases are not infrequent after that age. Nathan S. Davis is of the opinion that "It occurs more frequently in middle period of adult life, that is, from 20 to 40 years of age, than either earlier or later in life." Loomis, in his "Practical Medicine," third edition, says: "Some of the most reliable modern authorities state that nine-tenths of the deaths after the seventh-fifth year are from lobar pneumonia." He gives as his own opinion that 90 per cent. of deaths beyond the sixty-fifth year are from this cause, and that it is the most common cause of sudden death in the old. I have not been fortunate enough to find the authorities he refers to, but his statement caused me to look more carefully into the cause of death in the aged members of the institution under my professional care. At the Central Branch National Home for Disabled Volunteer Soldiers, there died last year 289 members at the average age of 60 years. It will be seen that there are here unusual advantages for observing the diseases of the old. It is not intended in this paper to discuss the pathology or treatment, or say much

about the etiology of pneumonia in the old, but give some statistics. clinical and autopsic observations. I do not recall a single case that can be attributed directly to exposure, to inclement weather, or chilling of the body. In two or three cases men who were exhausted by a debauch took pneumonia and died promptly. With over 5000 old soldiers belonging to this "Home," it is not surprising that several hundred are of dissipated habits. In scores of cases men have been brought in, thoroughly chilled, who had been lying several hours exposed to winter storms; many have lain out over night, and we have had numerous instances of frosted and frozen feet and hands, but it has been the constant observation of the medical attendants that these men did not take pneumonia. Our cases have usually originated in the barracks or hospital, where the men are well housed, clothed and fed, and, with the exception of indifferent barrack ventilation, their hygienic surroundings are all that could be desired. In the last seven months there have been treated in the hospital, including about 250 permanently chronic cases, 610 members over 60 years. Of this number 63 had acute lobar pneumonia, 36 of whom died, 14 recovered, and 13 still remain under treatment. In the same time there were 53 deaths from all other causes, of persons over 60 years of age: 13 of consumption, 7 of senile debility, 5 of cancer, 4 of valvular disease of heart, 3 of apoplexy, of Bright's disease and exhaustion each 2, and of 17 other diseases each 1. In three of the cases of senile debility pneumonia was suspected in the closing hours, and it may have likewise occurred in some of the other cases and not have been detected where there was no autopsy. I must admit that in the autopsy of doubtful cases pneumonia was discovered in nearly all. In 35 autopsies pneumonia was discovered in 24 cases; 7 cases were double pneumonia, and in 15 different parts of the lung were invaded at different periods; of these 13 showed the disease to have begun at the base of the lung. In four cases only had the stage of gray hepatization been reached, and in no case was there abscess or gangrene.

The latency of the symptoms is the most striking feature in the history of pneumonia in the old. The ordinary symptoms are prominently absent, and the fatal malady will only be detected by the most careful examination. Chill is the ordinary precursor of pneumonia in earlier life. Niemeyer says: "Except in intermittent fever and septicaemia we nowhere encounter chills of equal violence." In the above recorded cases a history of chill was obtained in only five or six. Pain, cough or expectoration were not usually present, and in but a very limited number of cases were they distressing symptoms. A flush of face, slight rise of temperature, some increase of pulse and respiration were found in the majority of cases, but in only a few sufficiently striking to attract attention, if you had not been looking carefully for symptoms of febrile action. The temperature was usually about 100, the respiration rarely beyond 30, and in no case did I observe that distressing battle of the respiratory organs so common, especially in double pneumonia in young persons. In fact, our

patients usually died suddenly and unexpectedly, where there occurred double pneumonia or secondary invasion of a single lung.

Pneumonia has been the final cause of death in patients exhausted from softening of the brain, cerebral hæmorrhage, organic disease of the heart, pyelitis, cancer of the stomach, *fistula in ano*, and other diseases in patients between 45 and 60. My observations so far indicate that persons exhausted from phthisis have a greater immunity from pneumonia than any other class of patients equally debilitated. There are many old persons who have pneumonia of one lobe and are so little ill that they do not send for a physician. Many of our cases have been detected in old men coming to ordinary morning "Surgeon's Call," complaining only of feeling generally unwell. In these cases sometimes another lobe is invaded, and they usually die quickly.

Secondary invasion is often attended with a prostration, almost like shock from severe concussion of the brain. An instance of this: A man, aged 60, apparently in his usual health, went from camp to the city (three miles by train) one morning. At noon he was taken suddenly and violently ill at the house of a friend, and within two hours was sent to the City Hospital. The attending physician reported that he was received unconscious, cold extremities, rapid breathing, temperature 103, and almost moribund. He died within six hours of the attack. Autopsy revealed: Lower right lobe passing into stage of gray hepatization, indicating that the disease had existed here for several days; whole of left lung and middle lobe of right were œdematous and engorged with recent pneumonia. In a limited number of cases we have had stupor, mild delirium, slight elevation of temperature, lasting 24 to 48 hours, without any lung symptoms, when suddenly the lung would be overwhelmed and the patient die between night and morning visits, without attracting enough attention for ward-master or nurse to call a physician. I will give a brief clinical history of two cases, illustrating the fact that it is a common cause of sudden death in the old. It has been, in the last few months, the *most common cause*. Except in pneumonia we have had only two sudden deaths, one from hæmorrhage of the lungs, and in the other the aortic valves were thickened, immovable, calcareous masses.

Case 1.—G. M., a large, well nourished man, æt. 76, in good health (with the exception of feeble, irregular action of heart, with slight apex beat near epigastrium, which had been diagnosed as dilatation of the heart), had been feeling rather unwell without any pronounced symptoms but general lassitude, was walking to his meals, etc. I carefully examined his lungs on the evening of the 10th and could discover nothing wrong. Temperature 99½. At the morning visit on the 11th the nurse reported the old man restless since five o'clock. His temperature was now 100, pulse 105 and feeble, respiration 28. Complained of distress in epigastrium; no cough, but physical examination discovered dulness over middle and lower lobe of right lung, and scarcely any air entering that part of the lungs. General appearance did not indicate any immediate danger. He was or-

dered stimulants and beef tea, which he took with relish, rested quietly for an hour, when he raised up, called the nurse, and suddenly expired.

Autopsy.—Almost entire right lung œdematous and engorged with blood. Dilated heart with fatty degeneration.

Case 2.—Patient 78 years old, was exhausted from genito-urinary disease, occasioned by an old stricture. He was able to walk around the ward and ride out in a carriage for an hour on fine days. I saw him at 5 P.M.; he complained that he had some colic, which he attributed to the too sudden arrest of a diarrhoea which had been troubling him for several days. He was sitting up and gave no evidence of being worse than usual. Without carefully examining him I ordered an enema, which was given at 6 o'clock, after which he was reported more comfortable, but continued restless during the first part of the night. He would not allow the nurse to call the physician, as he said, for a little colic. (I might add that he was a man of more than ordinary intelligence.) At midnight he called for the commode, got up, sank back into bed, and almost immediately expired.

Autopsy.—Middle and lower lobe of right lung engorged with blood, which was doubtless the immediate cause of death.

Our patients are all men well advanced in life and more or less disabled by wounds or diseases incident to the exposures and hardships of soldiers in active service.

The records of our Hospital for the last six months show that 48 per cent. of deaths in persons beyond 70 were from pneumonia, and 36 per cent. of those from 65 to 70 were from the same cause. If autopsies had been held in all cases the probability is that the per centage would have been higher. Day, in his old book, says: "It is, I fear, too often the case that in old persons this disease is first detected in the dead-house, and if not sought for there is altogether unrecognized." With modern methods of exploration and diagnosis, there is less excuse for the patient dying with the disease not diagnosticated; but I am convinced that the utmost vigilance of ordinary skill will not always detect the latent symptoms of this disease, which seems so prone to attack the old, especially when weakened by any debilitating cause, and which so often becomes the primary element in producing death, instead of the more chronic, more slowly developing and debilitating malady which invited it.

THE VALUE OF AN ATTEMPT AT ENUCLEATION OF A NEUROMA, WHICH SEEMED TO DEMAND RESECTION OF A NERVE.

BY MOSES GUNN, M.D.,
OF CHICAGO, ILL.

If to my colleagues in the Surgical Section, the resection of a so considerable portion of the trunk of an important nerve as to prevent approximation and suture of the ends is as repugnant as it is to me, I

¹ Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

shall need to offer no apology for the introduction of the following case, which illustrates how completely lost in neoplasm nerve fibrillæ may become without impairment of their conducting function, and, also the possibility, in some instances, of enucleating the adventitious growth, without injury to the nerve.

C. B. H., age 36, admitted to the Presbyterian Hospital on August 10, 1885. Fourteen years ago the patient noticed a small lump on the inner aspect of the right arm at the union of the middle with the upper third, which was firm in structure, movable and painless. It increased slowly in size till two years since, when it had attained about half its present dimensions, which are three and one-half, longest, by two and one-half inches, shortest diameter. Three years ago it began to be tender on pressure, but the tumor itself had been always free from pain except that which had been excited by handling in the various examinations to which it had been subjected. Within the last two years he has experienced increasing pain in the ulnar side of hand extending to the little finger and ulnar side of ring finger. The pain is dull and aching, accompanied by numbness, and occasionally by a sharp and burning sensation. Pain, at first, was nocturnal, but has become constant, and so severe as to greatly interfere with sleep. Appetite is good, and his bowels are regular in their action; but the patient is losing flesh persistently. The tumor is extremely tender to the touch, exquisitely so at its upper portion where the nerve enters the mass. From the lower end of the tumor the nerve can be easily traced as it takes its course towards the notch behind the epitrochlea. Exsection of the mass by nerve resection was advised and consented to.

On August 11, operation was commenced by an incision four and one-half inches in length down upon the mass; the dissection was prosecuted, freeing the tumor from adjacent tissues down to the base and exposing the entrance and exit of the nerve. The nerve fibres became lost in the mass at three-fourths of an inch from upper, (apparently spreading out on the surface) and reappeared at about the same distance from lower end of the tumor. At this step of the operation the thought occurred to me to explore the mass by a longitudinal incision, before resection. I had, a few years previously, enucleated a considerable cyst from the trunk of the median, the fibres of which completely enveloped it. I, therefore, made a slight incision on the surface of the tumor, and at the depth of a couple of lines I found that I could easily separate a capsule of this thickness from the central mass; extending the incision through the whole length of the tumor, I was enabled to rapidly enucleate the adventitia proper from the capsule which was composed, principally, of neoplastic tissue involving and obscuring completely the widely separated nerve fibres. After the enucleation, we had, attached to the bottom of the general wound, from which it had not been dissected, a collapsed bag or capsule, continuous above and below, with the ulnar nerve. In this capsule, except at either extremity, no trace of nerve fibre was recognizable, so completely had such fibre been occulted by neoplastic structure. The wound was irrigated, and was drained by three

tubes, one in the capsule and one on either side of it. The wound healed rapidly and kindly, the patient being discharged on September 1, free from all pain and impairment of nervous function in the parts to which the ulnar nerve is distributed.

The enucleated mass was subjected to thorough microscopic scrutiny by Dr. Ochsner, of the Physiological laboratory, and was pronounced "distinctly fibrous."

At this stage of our report we may pause to consider certain interesting features which challenge our attention. A tumor is developed in the centre of a nerve trunk separating the nerve fibrillæ from one another as the mass increases in size. Conservative instinct, so to speak, in life force springs to the relief of the over-strained nerve tissue and effects that relief by recruiting neoplastic tissue which increases with the demand till at the time of our observation the new element outmeasures the nerve, by at least, forty to one, completely occulting the nerve fibrillæ, yet in no wise interfering with nerve function. Conduction in both directions, and pain referred to ultimate distribution, caused by pressure of the tumor, exists. The pressure is overcome by removal of the tumor, pain ceases, function becomes normal, and gradual absorption of the neoplastic tissue takes place. This adaptiveness of nerve tissue to altered circumstances which we here observe, has its parallel in certain forms of spina bifida, where the arrest of development in the vertebral arch is, probably the result of the outward pressure of the sac which has had its origin in the anterior sub-arachnoidal space, and to which, as the sac is developed, the spinal cord becomes attached, spread out and attenuated, and with which it is at last more or less intimately blended.¹ Such attenuation and blending of the chord and nerves with the sac impairs in no way the transmission of nerve force in either direction. Such cases of spina bifida, and the case which I have here related, show that nerve tissues are capable of undergoing gross changes while they preserve their special characteristics and consequently their function.

Of what value this fact may prove to the practical surgeon in dealing with tissues on or in nerves remains to be seen. In the present case the result which immediately followed the operation and which seemed to promise so much, was not ultimately realized. The patient, after enjoying immunity for a time, and engaging in farm labor, returned on the 30th of November, a little less than four months from the operation with a reappearance of the disease in its former site. The tumor was yet small, but the pain had become considerable. It involved the same length of nerve as before, but the tumor was rather less than an inch in diameter. On careful examination and consideration I determined to resect the nerve, which operation I made next day.

An examination of the specimen showed a reproduction of the fibroma, which on splitting the nerve, was readily enucleated, leaving a sac of nerve and neoplastic connective tissue, as after the first operation, only much smaller and with a much less propor-

¹ For anatomy of spina bifida see London Lancet, No. xiii, 1885. — Prof. Humphrey.

tion of new elements. The connective tissue had largely disappeared so that Dr. Ochsner, who made sections of the specimen, says: "The amount of connective tissue is increased, and the nerve fibres are not so near each other as in the normal nerve, but further than this there is no change in the nerve structure."

The question may suggest itself whether a repetition of the former operation would not have been better practice than resection. That such an operation could have been made as readily as in the first instance, there is no doubt; but a neoplasm which recurs after complete removal, is not prone to cease in its habit of recurrence; on the contrary it usually recurs at shorter intervals, thus demanding radical measures. The possibility, however, of enucleation in cases where we should, from the general appearance of the mass, deem it impossible, should be borne in mind, and an attempt in that direction should be made before resorting to the more radical procedure. Such, I think, is the lesson taught by the above case.

DR. STAPLES, of Minnesota, inquired if the function was restored after the second operation and resection?

DR. GUNN answered that function was destroyed by the second operation, and that with a hope of restoring it, he had opened the sheath of the median nerve, separating its fibres so as to engraft the distal end of the ulnar nerve upon it, and that the function was being gradually restored; in explanation of this fact, he expressed the belief that the restoration of function in a severed nerve was not necessarily dependent upon the reunion of the particular fibres severed, that the fibres could interchange function, and that function was determined rather by the machinery at the ends of the nerve than by the fibre itself.

A LARGE PHARYNGO-LARYNGEAL FIBROMA— CURED.¹

BY E. FLETCHER INGALS, A.M., M.D.,

PROFESSOR OF LARYNGOLOGY, RUSH MEDICAL COLLEGE, AND PROFESSOR
OF DISEASES OF THROAT AND CHEST, WOMAN'S MEDICAL
COLLEGE, CHICAGO.

E. G., farmer, aged 47, was sent to me January 7, 1886, by Dr. Chas. Enfield, of Scranton, Iowa. He was supposed to be suffering from a fibrous tumor of the larynx.

The patient stated that about two years previously he had begun to experience some difficulty in swallowing, which had been gradually increasing until deglutition had become almost impossible, in consequence of which he had emaciated, having lost about fifty pounds, and had become very weak. Recently there had been much difficulty in sleeping on account of choking spells. A few months before I saw him a physician, whose name I did not learn, had removed a portion of the tumor, which, upon micro-

scopic examination, he had pronounced fibrous in character. The patient had experienced considerable relief after the operation, but the tumor had continued to grow and for some months another physician had made ineffectual attempts to reduce its size by means of caustics.

The tumor was not visible by depressing the tongue, but on a laryngoscopic examination I found a large growth filling the laryngo-pharynx and vestibule of the larynx. It rested against the epiglottis in front and rose as high as its upper edge. The tumor completely hid from view all the larynx except the epiglottis; but a welt which ran downward, backward and inward from near the left margin of the epiglottis had so much the appearance of the ary-epiglottic fold that I at first supposed it to be that tissue with the tumor projecting externally and internally below it.

A small ulcer on the upper surface of the growth seemed to have resulted from some caustic applications. With great difficulty I succeeded in getting the epiglottis thrown forward enough to show that the growth was not attached to it.

A small lobe about half an inch in diameter presented on the right side of the larynx, in a position apparently just above and internally to the ary-epiglottic fold. This I secured and removed with little difficulty by the steel wire *écraseur*.¹

Bleeding was not excessive, but it prevented further operations at the time. The piece was examined by Dr. A. J. Ochsner, of the Presbyterian Hospital, of Chicago, who pronounced it fibroid in character, though not entirely fibrous. The next day I passed the wire loop of my *écraseur* carefully between the larger part of the tumor and the epiglottis, and then twisted one side of the loop around the end of the growth and along the posterior pharyngeal wall, and thus engaged a mass which, as it presented in the throat, appeared about an inch in diameter. I pulled the wire taut, securing a firm hold of the growth, and then gradually tightened the loop by means of the milled screw. The growth proved to be so hard that I finally broke the steel wire (No. 5 piano wire) before it was entirely detached; but I loosened the *écraseur* and fastened to the end of the broken wire a new one, which I succeeded in drawing down about the tumor. The *écraseur* was then slipped over the wires and its end passed down into the throat. The wires were fastened tightly, and after a few more turns of the milled wheel I had the satisfaction of removing about three-fourths of the entire growth. This was irregularly nodular in form, had a smooth surface, was hard to the touch, and measured $1\frac{1}{8} \times \frac{3}{8}$ inches in diameter.

There was very little bleeding, and immediately afterwards I could plainly see the ary-epiglottic fold of the left side, and most of the epiglottis, but the whole vestibule of the larynx, with the exception of a very small chink along the epiglottis, was filled with

¹ The instrument which I use for this purpose is a modification of what is frequently termed Jarvis snare, made for me by Sharp & Smith, of Chicago. It has upon the handle a slide to which the wires are attached, which enables the operator to tighten the loop quickly without the aid of the milled wheel, which is subsequently screwed down to complete the cutting off of the tissue. It has several tubes of different lengths and shapes, any of which may be easily attached to the handle.

¹ Read in the Section on Ophthalmology, Otology and Laryngology at the Thirty-Seventh Annual Meeting of the American Medical Association.

a portion of the tumor, which also covered the right ary-epiglottic fold and pressed against the pharynx on that side. The large mass removed at this time was found by Dr. Ochsner to be a typical fibrous growth.

On the day following the operation the whole mass in the vestibule was hidden from view by dark clotted blood. Three days later it had a grayish, gangrenous appearance, and emitted an offensive odor. At this time I succeeded, after one or two attempts, in engaging the mass in the snare and cutting it off. I then found that the vocal cords could be easily brought into view, and that the whole lower and left lateral portions of the larynx were in a healthy condition; but a mass of the growth the size of a large chestnut still pressed upon and partly hid the right ary-epiglottic fold.

The mass last removed measured about three-fourths of an inch in diameter, and its surface to the depth of nearly an eighth of an inch had a gangrenous appearance. This was examined microscopically by Dr. N. S. Davis, Jr., who found it mostly fibrous.

Two days later I removed another piece the size of a chestnut, and at the next sitting was enabled to see the small remnant of the tumor's pedicle, which was about half an inch in diameter and grew from the right side of the pharynx about half an inch below the upper margin of the right ary-epiglottic fold. I removed this with the snare, and subsequently thoroughly cauterized its root with the galvano-cautery.

Three weeks after the first operation the patient returned to his home thoroughly cured, having gained ten pounds in weight.

Dr. Enfield recently informed me that the patient has no signs of a return of the growth. Tumors of this kind are very rare in this situation, though small papillary growths are not infrequently met with at the upper part of the pharynx. The successful operations in this case well illustrate the wonderful adaptability of the steel wire *écraseur* for the removal of tumors from cavities difficult of access, and the efficiency of the laryngoscope in enabling us to lengthen the span of human life. Without the snare I doubt if the growth could have been removed; without the laryngoscope the snare would have been of no use and this patient must soon have succumbed to his disease.

64 State Street.

CASES IN WHICH IRIDECTOMY PERFORMED FOR GLAUCOMA IN ONE EYE CHECKED THE GLAUCOMATOUS PROCESS IN THE OTHER.

BY M. LANDESBURG, A.M., M.D.,
OF NEW YORK.

Clinical experiences have taught us to regard glaucoma as one of the diseases which, after it has attacked one eye, will, with few exceptions only, sooner or later also affect its fellow. For this very reason, and for the well established fact that in a certain percentage of cases iridectomy, performed for glaucoma

in one eye, is apt to be followed by the sudden development of acute glaucoma in the fellow-eye, which had not shown before any symptom whatever of the disease, Fienzel felt justified in proposing preventive iridectomy on the healthy eye in every instance when the other had to be operated upon for glaucoma. Abstraction made from all other objections against such a far-reaching proposition, I emphatically am at issue with the latter, as my observations tend to show *that there are cases in which iridectomy successfully performed for glaucoma in one eye may check the glaucomatous process and bring about permanent recovery in the other, which has not been treated.*

I am perfectly aware that I have to deal with a subject which has no counterpart in the whole ophthalmic literature, and which seems to have escaped the notice of the most prominent oculists, as I had occasion to learn from the personal intercourse with the latter during my recent trip through Europe.

In the following cases I record facts as they have occurred to me in my practice, and which I have studied with the careful attention and the unbiased mind so as to exclude any possible source of error. The cases are as follows:

Case 1.—Mrs. K., 63 years of age, presented herself with a typical acute glaucoma in her right eye. The left eye showed ocular tension pathologically increased. Pupil sluggish and slightly dilated. Anterior chamber shallow. Spontaneous arterial pulsation and pronounced venous engorgement of the retina. Emmetropic refraction with vision $\frac{1}{16}$. Near point greatly receded. Marked loss of sensibility to light in the peripheric parts of the upper inner quadrant of the visual field. The eye had remained healthy until seven months ago, when it experienced for the first time the phenomena of a colored halo around a flame, and obscuration in the visual field, which are the pathognomonic symptoms of the prodromal stage of the glaucomatous process. The attacks were at first transitory and recurred after long intervals of perfect health, but in the last weeks they have become more frequent and of longer duration. For the last few days, since the outbreak of acute glaucoma had taken place in the right eye, a sensation of pressure and tension has become permanent in the left one.

Iridectomy successfully performed upon the right eye had the effect to influence in the most favorable manner the condition of the left eye, the complete restoration of which was accomplished in the second week after the operation. No morbid alteration whatever remained, no relapse occurred, and no morbid sensation was ever experienced by the patient during a further observation of eight years and a half.

Case 2.—Mrs. B., 49 years of age, came under my notice with the following condition: *Right eye*, typical acute glaucoma. *Left eye*, ocular tension increased; pupil slightly dilated, very sluggish; anterior chamber shallow; cornea hazy; background of the eye veiled; pulsation of the retinal arteries easily produced by pressure on the eyeball; marked venous hyperæmia of the retina; with the naked eye vision $\frac{1}{16}$, with the help of concave 18 vision $\frac{1}{16}$; light perception dulled in the peripheric parts of the upper

half of the visual field. The subjective complaints are: Pressure and tension in the eye, and perception of flashes of light and of fire-balls in the visual field. No similar attacks had preceded, and only the appearance of colored halos around a flame, with temporary cloudiness in the visual field, have been experienced during the last month.

I performed iridectomy first upon the right eye, with perfect success, deferring the operation upon its fellow for the next day. During the interval such a marked improvement took place in the left eye that I did not feel justified in proposing the intended operation, to which patient would hardly have consented. The restoration of the left eye to normal condition and refraction was accomplished on the third day after the operation. The result remained permanent during a further observation of nearly eight years.

Case 3.—Merchant D., 53 years of age, applied to me with sub-acute glaucoma in the right eye. The left eye showed: M. $\frac{1}{2}$, S. $\frac{1}{2}$. Field of vision normal; pupil sluggish, slightly dilated and somewhat irregular; ocular tension increased; marked venous hyperæmia of the retina; veins dark and tortuous. The prodromal attacks of glaucoma have repeatedly occurred during the last six months, and vision has slightly decreased in the last weeks.

Iridectomy successfully performed on the right eye had the effect to bring about complete restoration in its fellow. All functions became normal and remained in this condition during a further observation of five years.

Case 4.—Mrs. L., 47 years of age, somewhat prematurely old, emphatically denies having ever had any trouble with her eyes until the day before, when, a few hours after great mental trouble had preceded, symptoms of inflammation suddenly developed in her left eye, which were accompanied with rapid loss of vision. After the paroxysm had somewhat abated by topical and internal remedies, patient noticed that a morbid change had also taken place in the right eye. About fifteen hours after the attack I ascertained the following condition: *Left eye*, acute glaucoma, with intense symptoms of inflammation. *Right eye*, slight pericorneal injection; central haziness of the cornea; pupil sluggish and somewhat dilated; ocular tension increased; background of the eye veiled and markedly hyperæmic; arterial pulsation effected by pressure upon the eyeball; one upper venous branch excessively tortuous; vision greatly diminished.

I proposed iridectomy on both eyes, but was only allowed to have it performed on the left one. The operation was followed by immediate relief in either eye. The next day showed the right eye absolutely free from any morbid alteration and vision, according to the statement of the patient, as good as ever before. Normal conditions and functions were ascertained on subsequent examination. The result remained stationary during a further examination of nearly five years.

Case 5.—Mrs. S., 58 years of age, came under my notice with subacute glaucoma in her right eye. The left eye presented the following condition: Hm. $\frac{1}{2}$,

vision from $\frac{1}{8}$ to $\frac{1}{2}$; no power of accommodation; perception of light diminished in the upper peripheric parts of the field of vision; refracting media normal; pupil sluggish, slightly dilated; ocular tension pathologically increased; marked venous hyperæmia of the retina. Periodical obscurations, perception of flashes of light and of colored halos around a flame have been repeatedly occurring during the past few weeks.

Full recovery took place in the left eye after iridectomy had successfully been performed on the right one. The result remained stationary for thirteen months, when the old complaint reappeared after a relapse had occurred in the right eye. Sclerotomy made upon the latter had a beneficial effect upon either eye. Normal functions were restored in the left eye and were maintained during a subsequent observation of nearly five years.

40 W. 34th Street, New York.

MEDICAL PROGRESS.

CIRCUMCISION UNDER COCAINE.—DR. E. R. PALMER, of Louisville, says that, desiring to perform circumcision under cocaine, he determined to use Corning's method of sequestration. "The patient, a young man, 20 years old, with a complete congenital phimosis, was seated in a chair, and the penis was seized by my assistant and drawn upon firmly. A Martin bandage, seven-eighths of an inch wide and a yard and a half long, was next applied, the first turn being made behind the scrotum to prevent slipping, and the bandage being then wound tightly back and forth from the symphysis pubis to the corona and back again. An ordinary hypodermatic syringe was next filled with a 6 per cent. solution of cocaine, and the needle, directed toward the extremity of the penis, was passed at four different points through the skin over the glans, a fourth of the contents of the syringe being discharged each time into the subcutaneous tissue. No attempt was made to introduce the drug from the mucous surface. In about three minutes I began adjusting a Rogers clamp, occupying as many more minutes in getting it placed to suit me and screwed down. The prepuce was removed with one stroke of a pair of long curved scissors, and the clamp removed. The dorsal artery was found not bleeding; the frænum was not cut. The mucous membrane was split up, and some eighteen sutures leisurely introduced. The bandage was now removed and, contrary to expectation, no hæmorrhage ensued. Less than a drachm of blood was lost during the entire operation. The wound was dressed loosely with absorbent cotton wet with equal parts of listerine and water. Not a twinge of pain was felt after the last needle-puncture had been made. The young man, of nervous temperament, was at first quite pale, but later assisted in the stitching, and as he washed his hands after the operation remarked that his penis still felt dead. The wound healed in forty-eight hours by first intention.

"The advantages of the bandage are several. It wholly controls bleeding, it localizes the action of the

cocaine, and it increases the facility with which the penis can be handled during the operation. The reverse direction for application, that is, from behind forward, will be found the best, because the easiest, and fully effectual."

Dr. Palmer adds that he performed the operation a second time in the same manner with equally good results as regards anæsthesia. But the continuous suture was used, and although perfect coaptation was accomplished, some trouble was experienced later from swelling and from syphilitic induration of the parts. It was attempted to remove the suture, but this was found impossible, and the writer thinks it would have been better had interrupted sutures been employed. The case is now doing quite well, however, and the result will be good.—*Medical Record*, September 25, 1886.

TREATMENT OF WHOOPING-COUGH BY NASAL INSUFFLATION.—In an extensive epidemic of this disease, in February of this year, which was particularly prevalent among very young children Dr. GUERDER treated his cases, at first, by disinfecting the sick rooms with carbolic acid and then using a syrup composed of

Syr. diacodii,	
Syr. belladonnæ, aa.	gr. 50.00
Acidi phenici.50
Potassii brom.	4

This was administered in doses of a coffee spoonful once or several times a day, according to the age of the patient. Only a moderate degree of success attended this treatment, and when the medicine was suspended the number of paroxysms became as great as before. The continued use of belladonna was also found very undesirable in young children, as it produced decided dilatation of the pupil, delirium, and a condition of narcosis which it was deemed imprudent to continue for long periods of time. The nasal catarrh which accompanied the disease, the injection of the nasal mucous membrane, and the probable parasitic character of the disease suggested the idea that the paroxysms of cough and asthma were of a reflex character, and might be susceptible to a similar course of treatment to that which has been found efficient in hay fever. A powder was therefore made of equal parts of boric acid and burnt coffee, and blown upon the nasal mucous membrane morning and evening. Thirty children were thus treated, seven being under one year of age, seven between one and two, six between two and three, ten between three and eight. Seventeen of these received almost no treatment except the insufflations, while the others had already received some benefit from the use of the syrup, the formula of which has been given. In all the cases benefit began to be apparent in from two to six days, the paroxysms of coughing becoming less frequent and less intense, the vomiting, the epistaxis, and the nasal catarrh diminishing or disappearing. The general condition also improved, and in fifteen or twenty days the patients were apparently well. This result is the more satisfactory since the cases occurred among poor people surrounded by bad hygienic conditions, and the children were out of doors much of the time in cold and

wet weather alike. In those cases in which the insufflations were practiced at the beginning of the disease, the course was invariably a mild one, and a cure was effected in eight to fifteen days. Powdered benzoin which was recently recommended by Michael, of Hamburg, for this disease, to be used also by insufflation, gave good success, but not so satisfactory as the mixture of pulverized boric acid and pulverized roasted coffee.

Dr. J. BACHEM, of Bonn, has treated sixteen cases by blowing into the nostrils a mixture of quinine muriat (3 parts) and pulv. acaciæ (1 part) once or twice daily. Three weeks was the average time of cure.—*Archives of Pediatrics*, August, 1886.

MICROSCOPICAL DIAGNOSIS OF A NEPHRO-INTES-TINAL FISTULA.—Nephro-intestinal fistulæ are certainly rarer. Dr. R. WERNICKE, who publishes his observations in the *Anales del Círculo Médico Argentino*, has only met with three cases in literature, and so believes his to be the fourth. In May last he was asked by Dr. Montes de Oca to examine a sample of urine in a flask. The color was yellow and there was some turbidity, also a copious yellow sediment containing grey clots of irregular shape. The reaction was alkaline, and the liquid after filtration contained albumen. The turbidity was evidently due to putrefactive microbes and leucocytes. The sediment on microscopical examination showed the presence of leucocytes, red blood-corpuscles, vesical epithelium, caudate or pyriform epithelial cells from the pelvis of the kidney, granular casts, particles of fatty matter (highly refracting and of a yellow tint), quantities of small aggregations of granules (highly refracting, some of the granules being attached to one another, and some surrounded by a yellow, structureless envelope, being in fact coagulated milk); and lastly, a number of striated muscular fibres, stained with biliary pigment, the strigæ being more or less obliterated, according to the stage of digestion which had been reached. As there was no question that the whole of the contents of the flask had been passed from the urethra of a man, there could be no doubt that a communication existed between the urinary and digestive passages. The cause of this ulceration was also diagnosed by further microscopical examination of the sediment, which revealed the existence of tubercle bacilli, which were so clearly recognized both by their form and their behavior with reagents as to leave no doubt in Dr. Wernicke's mind of their precise nature. The case not being under his care, no clinical details are given. It is seldom, however, that the microscope alone enables so much of a diagnosis to be made in a rare and intricate case such as this.—*Lancet*, August 21, 1886.

NARCEINE FOR INFANTS.—LABORDE reports that in many diseases of children narceine is superior to morphine. It induces sleep and diminishes bronchial secretion. It is very advantageous in whooping-cough and nocturnal coughs. As an analgesic it has not the power of morphine. It is administered in syrup or in suppositories.—*Journ. de Méd. de Paris*, July 25, 1886.

THE

Journal of the American Medical Association.

PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, OCTOBER 16, 1886.

THE TRANSMISSION OF YELLOW FEVER BY MOSQUITOS.

In the *American Journal of the Medical Sciences*, of October, 1886, is a most interesting article on this subject by DR. CHARLES FINLAY, of Havana, who is already known to readers of Spanish medical literature as having contributed some interesting articles on subjects connected with yellow fever. Five years ago he put forward the view that whereas yellow fever is not spontaneously transmissible by infection through the air nor by contact, it can be communicated by inoculation; and in searching for a natural agent capable of communicating the disease by inoculation he fixed upon the *Culex* mosquito, which is common in Havana, as the most likely agent. This insect has also been described as the *Culex fasciatus*. "Although great differences are observed in the duration of the successive phases of development of the *Culex* the following may be taken as a fair average: Every mosquito that stings may be considered as a fecundated female, and will probably lay eggs within a few days after its bite, provided it can find water upon which to lay them. In water-jugs standing in bedrooms, the insect is often found depositing its eggs either on the sides of the jug or upon the water. The eggs are commonly hatched, producing minute wrigglers, between the second and fourth day, in summer; some are delayed much longer, and those that are deposited outside the water may remain a long time in the dry state without losing their vitality. The wrigglers grow more or less rapidly according to the nutritive material contained in the water, the temperature, etc., but they probably pass into the pupa stage within twelve or fourteen days. This

stage is always short, not lasting more than two or three days, the fully developed mosquito emerging from its aquatic case a fortnight or three weeks after the egg was laid." This much natural history seems necessary to a proper understanding of how one infected mosquito conveyed to a healthy place, if the temperature and altitude be suitable, might, on Dr. Finlay's theory, inoculate the disease on a healthy subject who might be bitten by it, "and, according to the usual rate of incubation, at the end of a fortnight or three weeks, the consequent attack of yellow fever would be at its height. In the meantime the imported insect would have produced a whole brood of its own species, probably in the vicinity of the place where the patient is lying; thus providing the necessary conditions for the subsequent propagation of the disease."

From careful investigations and experiments Dr. Finlay finds that the insect under consideration, when suddenly transported to heights above 3,000 or 4,000 feet, must find it difficult to exert its functions, and that it would never, of its own accord, seek elevations which render its flight difficult." From his experiments he finds it probable that the limits of functional activity for this insect (the *Culex fasciatus*) are: as regards temperature, between 60° and 100° Fah., though it will revive after having been chilled to 32°, or warmed to 105° F.; as regards altitude, from the level of the sea to 3,000 or 4,000 feet. "Now the limits which most observers assign to the propagation of yellow fever are temperatures ranging from 60° to 90° F. ('Barton's Reports,' 1852, pp. xiii and 283); a general temperature of 32° F. having, however, proved ineffectual to prevent the recurrence of the disease (in the case of the 'Plymouth'), when a tropical temperature was produced. As regards altitudes, the highest limit at which it has been observed seems to be 400 feet above the level of the sea." There are some mosquitos which are entirely nocturnal, and these necessarily lead a more stationary existence, than those which come out in the day, as the latter often have to follow an intended victim from the house, or to some distance in order to accomplish their object. When it succeeds in stinging a person it will generally take up its quarters at that place, as its digestive act may require two days or more, and will there lay its eggs.

For a further comprehension of this subject it is well to say that the sting of the *Culex* mosquito is a slender hollow needle from $\frac{1}{10}$ to $\frac{1}{4}$ mm. broad and 2 mm. long, with its sides roughened by a series of transverse ridges and its point armed with teeth. "This needle penetrates through the skin until it

reaches one of the capillaries of the corium, generally to the depth of 1 to 2 mm., remains in position during a space of from one to five minutes, and, after being withdrawn, will continue protected by its sheath until the insect's next bite. I have been able to prove that the sting often retains spores of microscopical fungi, which may be made to develop by keeping the proboscis in a sterilized cell, and I once found upon the side of the sting a finely developed bunch of spores like those observed in yellow fever blood cultures by Dr. Sternberg, . . . whence it is to be inferred that it may likewise retain upon its outer surface or inside of its sheath, such minute disease germs as are generally believed to occasion most of the zymotic diseases. If so, the sting of the mosquito having been impregnated with the animal juices during the operation of stinging, may constitute an appropriate soil for the preservation or even for the culture of those germs; might it not, indeed, be the 'intermediate host' necessary for some phase of their development?"

Dr. Finlay's account of his inoculation experiments is very interesting, and it is to be regretted that he had not more time at his disposal, and more yellow fever patients and mosquitos—for, strange as it may appear, the two last are not always to be readily obtained at the same time, even in Havana. Twenty-four persons have been inoculated by him since June, 1881. One of these has died of yellow fever: he was inoculated in November, 1883, without any visible result, and was attacked in June, 1884, with a malignant form, which was the result of contagion. Two of those inoculated left the country and were lost sight of the first summer after the inoculation. Twenty-one remained under observation for from one to four full summers. Six were followed, within from five to twenty-two days, by an attack of fever, the exact counterpart of mild attacks of yellow fever, and which were proved afterwards, by observation, to have conferred immunity. Eleven inoculations, though not followed by morbid manifestations within the limits of incubation, appear likewise to have conferred immunity. In four cases, not followed by immediate manifestations, a mild attack of yellow fever was observed at the end of several months. It is upon the six successful cases that he relies in order to prove the aptitude of the *Culex* mosquito for transmitting yellow fever. "If this be once admitted, it must follow that the disease is actually so transmitted, since it must constantly happen, in a place like Havana, that unacclimated subjects are stung by mosquitos which have previously bitten yellow fever patients." Dr. Finlay concludes that

while yellow fever is incapable of propagation by its own unaided efforts, it may be artificially communicated by inoculation, and only becomes epidemic when such inoculations can be verified by some external agent, such as the mosquito. A careful study of the habits and natural history of the mosquito shows a remarkable agreement with the circumstances that impede or favor the transmission of yellow fever. From Dr. Finlay's observations, and information, the disease is incapable of propagation wherever tropical mosquitos do not or are not likely to exist, ceasing to be epidemic at the same limits of temperature and altitude which are incompatible with the functional activity of this insect; and it spreads readily wherever they abound. Hence he thinks it may be inferred that these insects are the habitual means or agents of its transmission; though, of course, there may be other factors. It is at least a remarkable coincidence, if nothing more, that in the summer of 1885 mosquitos, especially the diurnal species, were scarce in Havana, but became more numerous during the autumn months; and there was a remarkable scarcity of yellow fever cases during the summer months, which were unusually hot, but the cases became more numerous in October and November, in which the weather was rather mild. Dr. Finlay's paper is worthy of great attention, especially in view of the proposed Yellow Fever Commission, which, it is to be hoped, will thoroughly investigate the subject.

THE HAIR AND TEETH OF THE FUTURE.

There seems to be an inherent morbid tendency in some people which leads them to frighten their fellow men. Every little while some one appears on the literary horizon and frightens us into hysterics by predicting something awful that is to happen to our thirty-fourth century descendants. Scarcely do we recover from some professor's prediction as to the fate of American medical colleges and doctors before those of us who are so unfortunate as to be subject to malaria sink in a sea of despondency because we are told that the *bacillus malariae* and the *phyloxera scientiae* are one and the same. The rigor caused by this news has scarcely passed into the febrile stage before a monster earthquake is predicted.

And now come MR. VIRGIL G. EATON and DR. WILLIAM A. HAMMOND to tell us that our descendants (of some time about the year 3500) will be innocent of hair and teeth. We cannot dismiss this prediction by asking "How do you know?" Inasmuch as they have declared that such will be the case we must, of course, believe that they have some se-

cret and special information on the subject; that they have been to the roots of the matter (of both hair and teeth), and have obtained facts which cannot be controverted. After having such aspersions cast on our thirty-fourth century posterity, it is all the more galling, to those who retain their hair and teeth, that these writers should insinuate that baldness and toothlessness are the results of higher education and cultivation, and advanced civilization. And to those who live in the West the dregs of this cup of bitterness will be found in the following sentence: "Bald-headed men are most plentiful in New York and Boston. After these come Philadelphia, Washington, and the Western towns."

Will this be an unmitigated evil to posterity? The dental colleges will then live only in history, and the barber, like Othello, will find that his "occupation's gone." The medical literature of that day will perhaps contain a short reference to a disease mentioned in the infant history of medicine as "Toothache;" and doubtless some medico-historian will show that its disappearance from the earth was caused by a change in the meteorological conditions of the planet in the year 2900. The Professor of the History of Medicine will no doubt lecture learnedly on the fatal affection of the nineteenth century known as "dentition," and will ascribe its disappearance to improvements in sewer pipes and house drainage. He will look up *alopecia* in the medical dictionary, and finding that it is so called because *foxes* were supposed to be afflicted with it, will marvel greatly that even so late as the twentieth century the doctors could not cure *fleas*. The archaeologist will perhaps find an old toothbrush, and straightway construct the wondrous animal which possessed such a tail. And what a very treasure it will be to him when, in excavating the site of an ancient barber-shop, he finds a bottle with the curious inscription: "Scalpine; positive cure for baldness." Perhaps some daring scientist will try some of it on a cubic centimetre of his own glossy scalp—and regret it the remainder of his days. False teeth, teething rings and hair-pins will be deposited in honorable positions in museums. No doubt Paracelsus will then get the credit of having invented the dental engine, and given it a name which, like many others of the nineteenth century, has no signification, and no other merit than length. In that day an infant King of Spain will not have a dentist appointed for him before he has taken leave of the last three inches of his umbilical cord. Roast beef will be a thing of the past, and the Earth will be dotted over with mush factories.

May we not, therefore, accept this fate of posterity

with perfect resignation? After all, the prospect of our thirty-fourth century descendants rising up and reviling us for having worn hats and cooked our food will not fill us with dismay—for it is asserted that such will be the causes of their baldness and toothlessness. It is entirely possible that in that day and generation there will be no need for hair and teeth; and if some one then living chances to find in the *Medical Record*, of October 2, that "Mr. Eaton's curious observations tend to confirm the view that the per cent. of baldness is in direct proportion to the amount of education and cultivation," it will probably be considered "bad form" to be guilty of one single hair. To show that Mr. Eaton and Dr. Hammond are not far from the truth, the foreign journals announce that President Grévy, now almost 80 years of age, lost his first tooth a few weeks ago. Possibly the heraldry of that day will be somewhat changed, and some blue-blooded doctor will proudly wear on his gynecological case the inscription: *On a scalp hairless, a decayed molar rampant.*

THE PNEUMATIC CABINET AGAIN.

Some weeks ago, in an editorial article on the Pneumatic Cabinet, we suggested that the rental of the Cabinet was too high for many physicians who might be perfectly competent to use it intelligently, and that there was no good reason why the Cabinet should not be sold outright to those who could furnish satisfactory assurance to the Board of Managers that it would not be used in an unprofessional manner. We have just received a communication from the Pneumatic Cabinet Co., saying that, mainly on our suggestion, the Directors have determined to sell the instruments. During the early period of its existence and trial of test and experiment, the possibilities for misdirection of the instrument, and perhaps fatal injury, made it necessary that the greatest caution should be exercised in selecting those who should bring its merits and demerits before the profession. The Directors now say that no reason for a restrictive policy remains, and they have resolved to accept our editorial suggestions, and sell the Cabinet. We will now further suggest that the same caution be used in selling the instrument as was used in renting it. It has been but a short time since a daily paper of this city contained an interview with a professor of *chemistry* in a Homœopathic college, who claims to have one of these machines, and manages to pose before the public as the next thing to a raiser of the dead. Whether he really possesses the instrument under consideration we do not know; but this shows that

some people should not be trusted with the instrument.

Our editorial comment of a few weeks ago was not written with the purpose of bringing the instrument into disrepute, but to bring about just what the Directors have determined to do. Now that they have taken this course, and if the price of the Cabinet be within the reach of men of moderate means, there is no further cause for complaint. As we have said before, we believe this instrument to be a very valuable addition to therapeutics. No claim has been made for it that it will cure every or many diseases. It has been honestly investigated by competent men, and its dangers as well as its advantages pointed out. In the hands of a careless or incompetent person it may do very great injury, but this is no more than may be said of any therapeutic agent. Under these circumstances, and so long as the Directors wisely restrict its use to reputable physicians, not advertising it to the public, it deserves the careful attention of reputable physicians. It has been objected to it that it was not invented by a professional man, and that it is made under a patent. The same objections, which are not objections, could be brought against other articles in constant use by physicians in the practice of their profession.

MILK INSPECTION IN CHICAGO.

On Tuesday, October 12, Health-Commissioner DeWolf, of this city, put in effect an order, which he had previously issued, prohibiting the sale of milk from infected distillery sheds. Besides the presence or danger of pleuro-pneumonia in these sheds, those who have looked into the matter assert that the distillery sheds are in a most filthy condition. And beyond the question of the presence of disease in the sheds, the swill milk business, which has existed in Chicago, is illegal and criminal. There are two Sections (1410 and 1731) which are sufficiently explicit in this matter. The former prohibits the keeping or selling, bringing or sending into the city swill milk, or milk from cows or other animals that for the most part have been kept in stables or that have been fed on swill, or milk from sick or diseased cows or animals. The latter Section provides that "Milk produced from sick or diseased cows and all milk obtained from cows kept in distillery yards or pens and fed on distillery slops or waste shall be deemed impure and unwholesome." And further than this, the Health Department of Chicago is vested with authority to abate the filth of distillery sheds.

There is nothing, in the way of food, that has such

a direct bearing on the health of the community as the purity of milk. The fact that a large number of persons have their fortunes invested in the business of distributing impure milk has no bearing on this question. If they suffer loss from being in an illegitimate business they have only themselves to thank, and their money should not be placed in the scale with the lives and health of hundreds or thousands of people who subsist wholly or in great part upon milk.

SOCIETY PROCEEDINGS.

AMERICAN GYNÆCOLOGICAL SOCIETY.

The Eleventh Annual Meeting, held in the Hall of the Johns Hopkins University, Baltimore, Md., September 21, 22, and 23, 1886.

(Concluded from page 417.)

TUESDAY, SEPTEMBER 21, FIRST DAY.

AFTERNOON SESSION.

DR. T. ADDIS EMMET, of New York, read a paper entitled

PELVIC INFLAMMATIONS; CELLULITIS VERSUS PERITONITIS.

In this country, the term cellulitis has come to signify pelvic inflammation without reference to the special form, but its origin is supposed to have been in the connective tissue. So close is the relation between the connective tissue and the peritoneum, that it seems impossible for inflammation to be present in one without affecting the other. There are situations, however, as between the uterus and bladder, and between the uterus and rectum, where cellulitis might exist without involving the peritoneum. Inflammation in these situations tend to resolution and so the tissues soon regain their healthy condition if suppuration does not take place. After septic poisoning, the peritoneum rapidly becomes inflamed and adhesions occur, the circulation in the blood vessels becomes more or less obstructed and the action of the absorbents is greatly impeded. Finally a condition is produced which remains long after the symptoms have subsided and one not prone to change or amenable to treatment. In such cases a fresh attack is provoked by slight causes.

It has been objected that when the abdominal cavity is opened for the removal of the ovaries, very slight evidences of inflammation are found. In a recent case I expressed the opinion from the vaginal examination that a thickened and shortened left broad ligament would be found, at the operation no broad ligament was found, but there was an enlarged tube lying against the side of the vagina. Similar cases have been noted. I should explain these cases in this way. If there is an inflammation between the folds of the broad ligament, it must involve the peritoneum. As a result of the inflammation, the con-

nective tissue disappears and adhesion of the opposing surfaces takes place. The broad ligament is flattened out so that Douglass' cul-de-sac disappears on that side. The vaginal wall is raised up so that it and the tube lie in contact. This is the condition found by the surgeon when he operates for the removal of the diseased fallopian tubes. In all these cases I feel satisfied that there has been inflammation of the connective tissue. I think that the inflammation has been secondary to the cellulitis in every instance except where the primary inflammation was the result of gonorrhœa. If my observations are correct they would prove that the connective tissue never regains its integrity after having been once inflamed. If the surrounding tissue has restored the loss the part will return to its normal condition. If the loss can not be replaced, nature can only repair the injury by a process of adhesive inflammation of the parts involved.

I have used the term thickening of the broad ligament, but I have not meant to imply that there is a deposit of lymph between the layers of the broad ligament. The enlargement is I think due to the dilated state of the veins. The condition is one easily aroused to activity.

It is still a moot question as to the way in which the tube has become involved where gonorrhœa is not the cause of the inflammation. In septic poisoning after surgical injuries, I believe that the connective tissue of the veins and lymphatics first become involved and that the inflammation of the peritoneum is secondary. There is no evidence to prove that the inflammation passes into the uterine canal and thence to the tubes, except in such cases where the process is due to gonorrhœa.

The prognosis as to the result to be gained by local treatment is doubtful in those cases due to gonorrhœa, in those cases where the pelvic inflammation is of long standing without reference to the cause and in those with a history of frequently recurring attacks. In cases which can secure every attention, a cure by local treatment can sometimes be effected, but a long time is required. In cases which have to gain their own living, we may seriously consider the advisability of an operation after having gained the consent of the patient after a true representation of the operation and its results. We should enter a protest and the profession should demand a recognition of the responsibility of those who are indiscriminately operating for the removal of tubes and ovaries. It requires an expert to determine when the operation is necessary, and still more experience and skill to do it with safety to the patient. It should only be done as a last resort after other measures have failed. In a number of cases in private practice I have succeeded in restoring the patient to health by local treatment, for whom the operation had been strongly urged. If we could get accurate statistics I think that it would be shown that the average amount of benefit gained does not compensate for the amount of risk. I believe that the operation is done too often even by those who have the least death-rate. I predict that five years will not pass before it will be almost necessary to offer an apology when this operation is proposed.

DR. ROBERT BATTEY, of Rome, Ga.: From my experience it has seemed to me that the pelvic cellulitis which gives so much trouble was in a large proportion of these cases secondary. So far as disease affecting the tubes is concerned, I believe that if we throw out of consideration gonorrhœal cases, the primary disease starts in the ovary. I regard most of these serious inflammations of the pelvic cellular tissue as dependent upon cystic or cirrhotic disease of the ovary. With reference to the frequency with which this operation is done, I must confess that I am largely in sympathy with the speaker. I think that the operation is done too often. I do not believe that every case of organic disease of the ovary requires operation.

In reply to a question of Dr. Fordyce Barker asking him to state the grounds on which he would advise removal of the tubes and ovaries, Dr. Battey said, that every case must be determined for itself. If I had a poor miserable patient without the means of comfortable subsistence, suffering with ovarian or tubular disease, I would operate. If I could put such a patient under suitable surroundings and under a prolonged course of treatment, I might not think of the knife, but we have to look at the cases as they exist. I do not require in my cases an absolute diagnosis of disease of the tubes or ovaries prior to operation. It is sufficient for me to know that the general health is broken down by reason of the perverted function of her ovaries, that she is utterly miserable, that there is no reasonable hope of restoration to health by other means and that there is a reasonable prospect of restoration by removal of the ovaries. Under such circumstances I unhesitatingly operate and contrary to my former view, I do find that the ovaries are diseased.

DR. R. STANSBURY SUTTON: I believe that when the ovary is diseased and can not be cured by ordinary means, when it is interfering with the health of the woman and her duties in life, it should be removed. If the ovary is diseased and is a burden to the woman, it is as much the duty of the surgeon to remove that ovary as it is to remove a diseased eyeball. I agree that the operation is being done too often; not, however by competent men, but by incompetent men. The conditions which require the operation are not always clearly understood before the abdomen is opened. I do not believe that a man is compelled to be positively certain of what he is going to find before operating. The speaker then presented several specimens and described the cases from which they were removed.

DR. T. C. BUSEV, of Washington: I think that if pathologists will return to the histological basis, there will not be the difference of opinions which now exists. I believe that it is now held that the cellular tissue is really a vast lymphatic stricture and that the peritoneum is a large lymphatic sac. Instead of discussing nice distinctions between pelvic cellulitis and pelvic peritonitis, it would be better to classify as pelvic lymphangitis, these different varieties.

DR. J. SCOTT: I might mention some of the cases bearing upon this point which I have seen. One was a patient supposed to have fibroid tumors. The ab-

domen was opened and both ovaries found to contain pus. They were removed and patient recovered. In a second case the patient presented a tumor in the right side. The temperature record was kept for two months, during which time it did not vary half a degree. On opening the abdomen, the ovary was found to contain ten ounces of pus. The right ovary was removed, but the left appeared to be healthy and was left in position. During the operation the bladder was opened. This was sutured and the patient made a good recovery. Five weeks later the patient complained of pain in the left side and on examination, I found an enlarged left ovary. This was removed and the patient promptly recovered. In a somewhat similar case, one ovary was removed. In a short time the other enlarged, but the operation was postponed and the woman died of rupture of the abscess.

DR. MATTHEW D. MANN, of Buffalo: I wish to allude to the possibility of one tube and ovary being diseased without involvement of the other. There is no reason why it should be so. I have in several cases where the disease appeared to be limited to one side, removed but one ovary and the result has been a perfect cure. This operation avoids some of the objections urged against the removal of both ovaries.

DR. H. P. C. WILSON: I believe that where there is a general cellulitis, there is more or less pelvic peritonitis. These two affections are often associated. In the early stages, the inflammation is often controlled by active treatment. If it is not controlled, it may go on to the formation of abscess. The pus may be discharged and the patient recover. Occasionally the abscess occurs in the tube or ovary and these are the cases in which laparotomy is often called for. I agree that the operation is done too frequently. The point which Dr. Mann has raised that it is not always necessary to remove both ovaries is a very important one.

DR. JOHN C. REEVE, of Dayton, Ohio, reported a

CASE OF ABDOMINAL SECTION FOR CHRONIC SUPRATUBAL PERITONITIS.

A. D., aged 19, living as if married, was healthy until November last. She had never been pregnant. She was attended by a physician who found abdominal inflammation. On January 18th, she was seen in consultation by the speaker, at which time she presented the evidences of chronic peritonitis, but no history of a gonorrhoeal origin could be obtained. One month later she began to pass pus by the rectum. After other measures of relief had failed, laparotomy was offered in April, but declined. The patient was not seen again until June 20th, when she desired the operation, as she had suffered with hectic. The menstruation had ceased since January and examination of the urine showed no albumen. There was great tenderness and hardness all over the abdomen, pus being still passed with the stools. By vaginal examination, no definite hardness could be detected. By the rectum there was ill-defined resonance high up on the left side. No opening into the rectum could be detected, although frequent examinations for this purpose were made. The patient was greatly ema-

ciated, the weight having fallen from 125 pounds to seventy pounds.

The operation was performed June 23, there was great difficulty in the administration of the ether. On opening the peritoneum, all the parts were matted together. The abdomen was washed out by allowing water to run into it from a pipe and then syringing out what remained. Finally a cavity was reached in the left lumbar region. It was impossible to attach the walls of this cavity to the abdominal wound and as the condition of the patient was by this time alarming, a drainage tube was introduced and the abdominal incision closed with sutures. In the course of several hours, the patient gradually rallied from the operation. The temperature did not go above 100. The cavity was washed out with a solution of iodine in tincture in water. The upper two-thirds of the abdominal wound failed to unite. On the fourteenth day a large quantity of fecal matter came through the wound. This has continued to recur. In July, evidences of Bright's disease were detected. Since then there has been some improvement in the general health. I think that if the patient had consented to the operation when first proposed, the result might have been different. One of the principal objects of the paper has been to ascertain if, as has been stated, fecal fistula is an invariable consequence of laparotomy for abdominal inflammation in cases where pus has already escaped by the rectum.

DR. J. SCOTT: I would mention the following case: A patient was admitted to the hospital with prolapse, inflammation of the ovaries and cellulitis. After three months' treatment without improvement, removal of the ovaries was recommended, but declined by the patient. The patient was kept under treatment for six months longer, when enlargement of the right ovary began. Later pus discharged by the rectum and subsequently the abscess opened into the bladder. The patient then consented to operation. The abdomen was opened, an opening made into the vagina and a drainage tube introduced. The improvement was not marked and in the course of two months the patient was as bad as ever. The removal of both ovaries and tubes was then performed. Four or five days after the operation faeces appeared in the wound. During the five months succeeding the operation, the fecal fistula has closed, the patient has gained ten pounds and is able to walk about.

DR. WILLIAM GOODELL, of Philadelphia: The only case which I have had at all similar to the one reported was one of pelvic abscess opening into the rectum and bladder. I performed laparotomy with the intention of opening the abscess and stitching its walls to the abdominal wound. The abscess had been so constantly drained, that it was not larger than a pear. By compressing the abscess sac, I was able to make it prominent in the vagina, and forced into it a closed pair of scissors, which were then opened and the opening gradually enlarged, and a drainage tube inserted. This case gradually recovered, both the rectal and vesical openings closing in the course of time.

DR. C. C. LEE, of New York: I think that the rule will come to be established that in chronic suppurative peritonitis, laparotomy is not only justified, but the procedure to be adopted.

DR. R. S. SUTTON: In a case of pelvic abscess as large as a cocoanut, I performed laparotomy and then stitched the peritoneum at the edge of the incision to the peritoneum covering the abscess, which was then opened and a drainage tube introduced. The patient recovered.

DR. J. TABER JOHNSON, of Washington: I would suggest that in such cases as the one described by the author, where time is a matter of importance, much can be gained by adopting the procedure employed by Drs. Bantock and Tait. In washing out the abdominal cavity they pour the water into the cavity with a pitcher, using gallons at a time. In this way the cleansing is rapidly accomplished.

WEDNESDAY, SEPTEMBER 22, SECOND DAY.

MORNING SESSION.

DR. JOHN GOODMAN, of Louisville, Ky., read through the Secretary, a paper on

ERGOT AFTER LABOR.

The administration of a full dose of ergot immediately after the completion of labor has become a general practice. It is claimed that it promotes involution, prevents after pains and tends to prevent post-partum hæmorrhage. Some years ago the author administered a full dose of ergot after a perfectly normal labor. In fifteen minutes, severe pain appeared and increased. The tenderness in the uterus continued for a week. There was no milk and the patient, previously prolific, never again conceived. The trouble was attributed to inflammation of the muscular coat of the uterus produced by the action of the ergot. In a second case treated in May, 1886, ergot was given after a forceps delivery. On the seventh day the patient had a chill followed by a temperature of 104. The next day a clot was washed out of the uterus and the temperature fell to 99. Well marked septicæmia developed and the patient died one week later. In this case the retention of the clot was attributed to the spasmodic contraction of the uterus preventing its escape. The author had seen other cases in which injurious effects were produced by the administration of ergot.

Dr. Goodman claimed that ergot did not assist involution, which was a natural process and required a certain length of time for its completion. That we have in ergot a remedy capable of arresting after-pains, can not be doubted, but it does so by exciting a mode of muscular action at variance with all physiological laws. After-pains are conservative and it is better to wait until they become of abnormal severity before resorting to treatment. Ergot is capable of preventing hæmorrhage, but its use is attended with such dangers that it should not be employed except under exceptional circumstances. It should be an inviolable rule not to give ergot at the close of the third stage of labor, unless hæmorrhage is imminent. It should then be used by hypodermic injection.

THE PRESIDENT: I have in process of preparation a paper in which I enter my protest against routine practice of the administration of ergot after the third stage of labor. This conclusion is based upon my experience and upon a study of the action which is claimed for the drug. The contractions produced by ergot are unlike those of nature. The contraction of ergot is persistent, while the normal contraction is intermittent. If the contraction is persistent, the circulation of the uterine wall can not reach a healthy state, and thus the process of it not only retains what is in the uterine cavity, but it interferes with the process of involution and lays the foundation for sepsis and inflammation. I think that in the course of the next five or ten years, the practice of obstetricians in this matter will be revolutionized.

DR. WILLIAM GOODELL: The author of the paper states that it is only since last May that he has given up the use of ergot. I think that he has not had sufficient time to form such positive opinions. In the first case, I think that there must have been a fibroid tumor. The second case was a clear instance of septicæmia. I do not think that after-pains are conservative, as a rule we do not see them in primipara. These pains are in a great measure the result of weakness induced by civilization. I do not believe that every woman who has given birth to a child needs ergot, but we do not know the cases which do require it. In twenty-five hundred cases of labor, I have always given ergot after the completion of labor and I have never seen any harm from its use. I do not believe that one dose of ergot has much effect in favoring involution. Involution is the result of fatty degeneration, and the greater the contraction, the greater the interference with the circulation the more rapidly should this change take place. I have used ergot for two purposes, one was to prevent hæmorrhage and the other to prevent the absorption of septic matter. Since the introduction of antiseptics, which I think should be used in every case of labor whether public or private, the use of ergot to prevent septic infection is not so important. I think that it does not do the harm which has been mentioned.

DR. GEORGE J. ENGELMANN: I hold in the main the views which the President has expressed. I use ergot much less than I did a few years ago. I believe that we have equally effective measures in the hot antiseptic douche and in the faradaic current. After the contents of the uterus have been expelled ergot will in certain cases always be a useful and effective remedy. I would not venture to say that after labor ergot is out of place, but I think that I may say that before the contents of the uterus are expelled, it should not be used at all.

DR. THEOPHILUS PARVIN, of Philadelphia: The effect of ergot varies with the dose. A small dose acts simply to increase the normal uterine contractions. I must object to the assertion that ergot should never be given before the completion of labor. Statistics show that those who are most successful in the treatment of placenta prævia are the men who use ergot. Again, in a multipara with the os dilated,

where a sudden rupture of the membranes has taken place with a cessation of labor, 15 or 20 grains of ergot causes a rapid completion of the labor. After a protracted labor, there is a weariness of the uterus and a failure to enter upon the normal retraction which is a preventive of hæmorrhage and tends to promote involution. As long as in the third stage of labor we assist nature in the expulsion of the placenta, why should we not assist nature in securing normal retraction of the uterus after the completion of the third stage. In some experiments which I made at the Philadelphia Hospital, to determine the rapidity of involution of the uterus in women who had received ergot and in those who had not, it was found that in those who received ergot after delivery, uterine involution seemed to take place more rapidly.

DR. ALEXANDER J. C. SKENE, of Brooklyn: I do not think that in the cases reported, the ergot had anything to do with the production of the effects. All rational men use ergot as any other remedy, when it is necessary or may possibly become necessary. If there is any doubt whether or not it is needed, it is better to give the patient the benefit of the doubt.

DR. P. C. WILLIAMS, of Baltimore: I have never yet regretted the use of ergot in any case, but I have regretted not using it. The great danger under the use of anæsthetics is hæmorrhage. To avoid this the use of ergot seems to be the proper thing. I admit that ergot is abused, but the abuse of ergot is no argument against its proper use.

THE PRESIDENT: The profession is not taught that ergot should be given in diseased conditions, but that it shall be given in all cases after labor as a routine practice, and it is only against this use of it that I raise my voice.

DR. THADDEUS A. REAMY, of Cincinnati, then delivered

THE PRESIDENT'S ADDRESS.

He first referred to the prosperity of the Society during the past ten years, and spoke of the great advance of abdominal surgery and ovariectomy during the same time. The speaker thought that the less satisfactory results obtained in America as compared with other countries might be due to climatic and constitutional conditions and to the fact that the operation was performed by too many operators. The operation of removal of the ovaries for beginning cystic troubles and for other conditions is performed in many cases which could be relieved by other and less serious measures. The practice of leaving the undiseased ovary was recommended. The success of ovariectomy has led to the performance of laparotomy in other conditions, as suppurative peritonitis, with satisfactory results.

The use of electricity as a therapeutic agent is attracting much attention. It is the safest and most effective remedy in extra-uterine pregnancy, and it is coming into use in many other conditions.

The treatment of extensive fibroid disease was next taken up. Medical treatment is, in the main, unsatisfactory, although in some cases, good results have followed the use of ergot and electricity, especially the latter, which is perhaps the most effective thera-

peutic agent in these cases. The operation of hysterectomy should not, as a rule, be performed in these cases. Spaying has met with more favor and success than any other surgical procedure. There are a few cases where on account of the large size of the tumor or its fibro-cystic character, hysterectomy probably affords the best hope.

Pelvic deformities as influencing labor were next considered. In the lesser degrees, premature labor, with the use of appropriate forceps applied with proper skill were recommended. With reference to operative procedures, the mortality in the United States has been very great. An important reason for this is the failure to recognize the importance of early interference. It has also been shown that, other things being equal, the danger is increased by doing the operation after the death of the child.

Total extirpation of the uterus for cancer has been steadily growing in favor. So far as the speaker had examined the clinical proof the evidence as to its utility had not been convincing. While patients have recovered from the operation, it is not yet proven that the operation is justifiable, except where the disease is confined to the body of the uterus or the cervix and the vagina is free. While the view that epithelioma of the cervix is due to traumatism is not generally accepted, he believed that traumatism of the cervix was conducive to the development of epithelioma. If for no other reason, Emmet's operation is warranted on the sole ground of a preventive.

The speaker in referring to the *uterine curette* stated that he had recently had alarming symptoms following its use, and in one case where the instrument was used immediately after dilatation with sponge tents, death resulted. Peritonitis had not been developed in a single case where the dilatation had not immediately preceded the operation. Rapid dilatation is alleged to be comparatively free from the dangers attendant upon the use of tents, but he has recently had a high degree of peritonitis following dilatation by this method where the curette was not used.

The following case was then described: A married woman aged 32, the mother of two children, had suffered with severe menorrhagia during the past year. There was an old laceration of the perineum, but no laceration of the cervix. The uterus measured $3\frac{1}{4}$ inches and was not tender. No pelvic tenderness could be detected. Treatment directed to the general condition was ordered, and under it the anæmia improved and menorrhagia decreased. Some months later the blunt curette was used with the woman in the lithotomy position. No dilatation was required. A large amount of the fungous tissue was removed from the posterior wall and the curette was then passed over the anterior wall. During the manipulation, no roughness being employed, the instrument passed through the uterine wall. It was at once withdrawn, and a sound being introduced, it readily passed its whole length and its extremity could be felt externally above the umbilicus. Forty drops of laudanum was administered by the rectum and an ice bag was placed over the abdomen. The ice bag was kept on continually for five days. The

accident caused no symptoms whatever. The perineum was subsequently restored and the woman's health is much improved. The menorrhagia has disappeared.

In concluding the President referred to the proposition looking to the organization of a Congress of American Physicians and Surgeons, and hoped that the action of the Society would be favorable to such an alliance.

DR. FORDYCE BARKER, of New York, read a paper on

THE INFLUENCE OF MENTAL IMPRESSIONS ON
THE FÆTUS.

The belief that maternal impressions may affect the nutrition and development of the fœtus *in utero* has existed from the earliest periods of which there are any records. Medical writers with hardly an exception down to the beginning of the eighteenth century, express the belief with more or less distinctness that fœtal marks and deformities are due to the emotions, desires or shocks of the pregnant mother. Reference was then made to numerous papers written within the past twenty years in which this theory was strongly controverted. Those who disbelieve in this doctrine base their skepticism on what they regard as physiological reasoning, and chiefly on the assertion that there is no direct nerve connection between the maternal and fœtal systems. Deformities, they urge, are due to arrest of development; but no one has brought forward sound physiological reasons why this arrest of development may not have been caused by mental impressions affecting the fœtal nutrition by their influence on the maternal blood. Extremely rare as is the occurrence of cases which prove the result of this influence, he considered the fact is so well proved by sufficient authentic evidence as to make it as certain as any other fact which cannot be explained by science. The term "mental impressions" should include those which have a physical as well as a psychical origin. Five cases coming under the author's observation were described.

Case 1 was that of a young lady who at the age of 18 had for the first time been taken to the theatre and had seen Sothorn, the actor, play "Lord Dundreary." From this time she spent her whole time in writing to Lord Dundreary and she thought and talked of nothing else. This continued for several months, and under treatment and change of scene, gradually wore away. She subsequently married, and four years after her attack of insanity, her first child, a boy, was born. As the child became able to talk he exhibited peculiarities resembling those of Lord Dundreary. He walked with a little skip, had a slight stammer in his speech, and his left brow was drawn down with the lids practically closed.

Case 2 was that of a lady, a typical brunette, who was first married to a gentleman, a typical blonde. She was never pregnant by him. Subsequent to his death she married a gentleman as marked a brunette as herself. Her first child was a decided blonde. Both her own and her husband's relatives are all brunettes. The lady has since had three children, all brunettes.

Case 3 was that of a lady who during the first month of pregnancy had been much worried over her oldest daughter, who had had her ears bored for rings. The ears became inflamed and caused much trouble. When the child was born, both ears presented the appearance of having been pierced for rings, and through at least one of the lobes, a thread could be passed.

Case 4 was that of a lady who at a very early period of pregnancy was much impressed by seeing three ladies, all of whom had hare-lips. When her child was born it had a double hare lip.

Case 5. Mrs. X., married but a few weeks, was at the theatre with her husband. Something vexing him, he placed the point of his elbow on her hand and held it so firmly that she could not draw it away. Not wishing to make a scene, she bore it until she fainted. The fingers were much swollen and painful for several days. She never lived with her husband afterward. Thirty-five weeks and three days after the theatre incident, she gave birth to a son. On the left hand, the first and second phalanges of all the fingers and thumb were absent, looking as if they had been amputated. During her pregnancy, she had never thought that her child would be born with any deficiency.

DR. WM. GOODELL: I have been very skeptical on this subject, but I have seen one case which seems to bear out the theory. A physician was called upon to assist at the operation of circumcision. His wife, who was in the early months of pregnancy, was much interested in the operation and insisted upon having all the details. The operation occupied much of her thoughts. When her child was born, a boy, it was found that the glans was exposed, the prepuce well retracted with granulation edges, showing an appearance very similar to that of a recent circumcision. I have recently seen an almost identical condition in a child, which could not be accounted for by any impression on the mind of the mother.

DR. SAMUEL C. BUSEY: While I have no positive convictions to present, I believe that there is some relation between mental impressions and fœtal deformities. Any prevalent and concurrent belief must be based upon an element of truth. This belief has prevailed since the time of Jacob. In the physical world there is no effect without a cause and in the world of life the rule is the same. If we can demonstrate in any single instance connection between the deformity and the mental impression, we must concede that such a thing can again occur. Dr. Barker has cited some instances and Dr. Goodell has given another case. In still another case the mother while pregnant saw a man with an opening in his trachea from which a tracheotomy tube had been removed. The child when born exhibited a depression in the same position. Another case is reported where the mother received two distinct impressions and the child was born with two distinct deformities corresponding to the separate impressions received. In another case, the father had removed, in the presence of the mother, a metacarpal bone of one of the fingers. When the child was born it exhibited a corresponding deformity. A consideration of these

cases can bring us to but one conclusion. The earlier in pregnancy the impression occurs the more frequently does the deformity follow and the greater is the correspondence between cause and effect.

The discussion was then postponed until the afternoon session.

AFTERNOON SESSION.

DR. FORDYCE BARKER, of New York: In all the cases I have reported there is no evidence that the period since conception had been more than six weeks. I have rejected all cases in which conception occurred three or four months before the mental impression was produced.

DR. JOHN BYRNE, of Brooklyn, read a paper on
THE TREATMENT OF PROCIDENTIA UTERI BY GALVANO-CAUTERY.

In February, 1872, Mrs. H., the mother of four children, presented herself with the entire womb and vesico-vaginal wall protruding. She was 35 years of age. The cervix was ulcerated from the friction. She was treated by applications of glycerole of tannin and irrigation for two months. The cervix was then removed with the galvano-cautery loop. The patient recovered without a symptom. Five weeks later, there was no bulging of the vesico-vaginal septum and the uterus could just be reached with the finger. No reasonable amount of force by means of a vulsella forceps could draw it down. The patient was discharged cured and has continued well.

The whole number of cases treated with the galvano-cautery has been nine, but in three only has the cervix been removed. In six of the cases, linear cauterizations were required.

Case 2 was a patient with procidentia who had been treated with pessaries for a long time. The cervix appeared to be healthy. A double tenaculum was introduced into the cervical canal and the whole mass pushed into the pelvic cavity and lifted to show the line of vaginal insertion. A groove sufficiently deep to admit the loop was then cut around the cervix close to the vaginal vault. The hot loop was then adjusted and the cervix cut through to the depth of one-fourth of an inch. The wire was then removed and tampons of glycerole of tannin inserted. Two weeks after operation, the uterus resisted all reasonable efforts to depress it. Two years after operation no perceptible change was observed. The health had never been better and menstruation was regular.

In *Case 3* the parts were returned and the line of vaginal insertion marked in spots with the cautery knife. The entire mass was then drawn down and a deep fissure three-eighths of an inch in depth made along the circumference of the cervix. Then three incisions were made in the vagina, one central and the others diverging, and the whole mass was then returned. The recovery was complete. In none of the cases has there been any peritonitis of any account. The speaker highly recommended further trial of the galvano-cautery in these cases.

DR. GEORGE J. ENGELMANN, of St. Louis, read a paper on

ELECTRICITY IN GYNÆCOLOGICAL PRACTICE.

After referring to the confusion which had surrounded this subject he referred to the following points which should govern the use of electricity as a therapeutic agent: The formation of strict indications for the use of the galvanic and faradic currents, a differentiation between the varying forms and modifications of the galvanic and faradic currents, differentiation between the active and indifferent poles, the localization and concentration of the current, the precision of the dose, the use of stronger currents continued for a short time. He has used the galvanic or faradic current in the reduction of the size of neoplasms, fibrous polypi, cystic growths and urethral caruncles; also in chronic pelvic inflammation, in chronic ovarian inflammation, in stenosis of the os, for the relief of the engorgement accompanying subinvolution, in prolapse when due to relaxation of the tissues. It is an aid in the correction of various forms of displacement, in metrorrhagia when due to inflammation and relaxation, in certain forms of amenorrhœa and for the relief of many annoying reflex symptoms. In obstetrics it is useful in uterine inertia during or after labor, in cases of weak and irregular labor pains, in post-partum hæmorrhage, in delayed involution, in paralysis of the urethra or bladder after labor and in the interruption of extra-uterine pregnancy.

The only contraindication to the use of electricity is the presence of severe acute inflammation. It may be used in sub-acute inflammation. In the more acute pelvic inflammations care is required in its use.

A number of cases were then referred to showing the beneficial effect of electricity in diminishing the size of fibroid tumors and in other conditions.

At the business meeting the following were elected

OFFICERS FOR THE ENSUING YEAR:

President—Dr. A. J. C. Skene, of Brooklyn.

Vice-Presidents—Dr. John C. Reeve, of Dayton, O., and Dr. Elwood Wilson, of Philadelphia.

Secretary—Dr. Joseph Taber Johnson, of Washington.

Treasurer—Dr. Matthew D. Mann, of Buffalo.

Council, additional members of—Drs. W. H. Baker, of Boston, C. C. Lee, of New York, T. M. Drysdale, of Philadelphia, and A. Reeves Jackson, of Chicago.

NEW MEMBERS.

Drs. Charles M. Green, of Boston, A. F. A. King, of Washington, E. C. Dudley, of Chicago, A. W. Johnstone, of Danville, Ky., J. E. Janvrin, of New York, H. Marion Sims, of New York, B. F. Baer, of Philadelphia, and W. Gill Wylie, of New York.

It was decided to hold the next meeting in New York, beginning September 15, 1887.

A communication with reference to the organization of a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS was presented.

DR. JOHN C. REEVE, of Dayton, O., offered the following:

Resolved, That this Society expresses an opinion favorable to the formation of the proposed Congress, but that the committee be instructed not to favor any plan looking towards a surrendering of its distinctive title, character, or to interfere with the full and entire management of its own affairs in every respect.

The following amendments were offered and accepted:

1. That this Society does not favor meetings of the Congress oftener than biennially.

2. That the committee opposes, as far as possible, meetings in the month of June.

Resolution, as amended, adopted.

The committee consists of Drs. Samuel C. Busey, of Washington, Fordyce Barker, of New York, T. A. Emmet, of New York, J. R. Chadwick, of Boston, and Joseph Taber Johnson, of Washington.

THURSDAY—THIRD DAY.

MORNING SESSION.

DR. W. H. BAKER, of Boston, read a paper on

ELECTROLYSIS IN GYNÆCOLOGICAL SURGERY.

The speaker referred more particularly to the use of electrolysis in cases of fibroid tumor. He laid down the following rules for the performance of the operation: It should not be employed within a week before or after menstruation; an anæsthetic should be administered; it is better to use electrolytic needles for both the positive and negative poles; the operator should be absolutely sure of the cleanliness of his needles; the needle should be deeply buried in the tumor in order that the current shall be insulated from the parts outside of the growth; the insertion of the needle should be made at the most prominent part of the growth, whether that is in the vagina or in the abdominal wall; the needles should not be too nearly approximated; if both needles are properly placed the position of the two poles makes no difference; the circuit being completed, the number of cells should be gradually increased from four to twenty or thirty (a more exact means of determining the strength of the current would be the galvanometer, but this had not given him accurate results); the length of time during which the application is continued should be from ten to twenty minutes, and should be determined by the character of the pulse; when the pulse becomes slower and weaker than normal the number of cells should be diminished or the current discontinued; the current should be diminished gradually, and the wires should be disconnected at the battery before the needles are removed; the application should not be made at the surgeon's office; after the application the patient is to be put to bed, where she is to remain for one week.

With such precautions, the speaker had never seen shock after the operation. A single treatment is often all that is necessary. He had never found it necessary to make more than three applications, and the latter number in only one case. There should be an interval of at least from one to three months between each application.

The use of electrolysis is also of service in the treatment of inflammatory effusions. Before resorting to electrolytic puncture the application of the galvanic current should be tried, as it does not require an anæsthetic, and avoids the slight risk which accompanies even small wounds.

The author presented the following conclusions:

1. Electrolysis is a useful agent in the treatment of certain cases of fibroid tumors of the uterine walls and of chronic circumscribed peri-uterine effusion.

2. When applied to fibroid tumors of the uterus, electro-puncture is a most reasonable and efficient method.

3. In the treatment of fibroid tumors by this agency, it is unnecessary to apply it often.

4. Cases of perimetritic effusion to be treated by this method should be selected with care, in reference to the absence of all acute symptoms.

DR. JAS. R. CHADWICK, of Boston: I tried electrolysis in one case of fibroid tumor, introducing the needle through the abdominal wall. This caused a smart attack of peritonitis. During the following year there was no decrease in the size of the tumor.

DR. GEO. J. ENGELMANN: By puncturing through the vagina and if possible through the tissue of the uterus we avoid the dangers of inflammation which accompany abdominal puncture. I believe that the same results can be accomplished without anæsthesia and with less danger by one electrode in the tissue and concentrating the total effect upon that electrode, by using a large electrode in connection with the other pole.

DR. JAMES B. HUNTER, of New York: My experience with this method of treatment has been limited, but I can not say that I have seen one case of fibroid tumor permanently relieved by electrolysis.

DR. MATTHEW D. MANN, of Buffalo: I have employed this agent in one case, plunging one needle into the tumor from behind through Douglas's cul-de-sac, with a sponge electrode over the tumor on the outside. The current was kept up fifteen minutes. Six applications were employed. The size of the tumor much diminished and the tenderness and pain were lessened. The patient is now able to attend to her duties.

DR. JAMES B. HUNTER, of New York, read a paper on

PERSISTENT PAIN AFTER ABDOMINAL SECTION.

Pain before operation may be due to various causes. It may be located in the ovaries, when it will be increased by menstruation. Disease of the tubes is a cause of pain in a large number of cases. The pain of peritonitis is of great importance. Acute peritonitis may be limited to the region of the ovaries and tubes, and the pain caused by it may be periodical in character. The presence of adhesions interfering with the mobility of the intestines and other organs is a frequent cause of pain. A severe form of pain may also be caused by displacements of the uterus.

Abdominal section is performed for the relief of pain, and the organ at fault is successfully removed and the patient recovers, but the pain continues. If

there is no marked relief at the expiration of twelve to eighteen months, if the patient has been favorably situated, the operation may be pronounced a failure so far as the patient is concerned. Such pain may be due to former peritonitis, to peritonitis following the operation, or to some defect in the abdominal wall. Peritonitis following the operation is a cause of pain in a certain number of instances. A slight amount of peritonitis often occurs after abdominal section, and it may leave some slight adhesions interfering with the mobility of the viscera. Inflammation in the region of the stump often causes its attachment to the abdominal wall and thus cause pain. Pain may result from defective union of the abdominal incision, allowing a ventral hernia. Pain in the cicatrix may occur, as in other situations.

In the way of prophylaxis, the utmost precaution should be taken to prevent the development of peritonitis. Antiseptic precautions should be adopted. The stump should be tied with aseptic silk. The early and judicious use of drainage and irrigation will go far toward preventing inflammation. The cold coil with antipyrin should be resorted to if there are any indications of peritonitis.

In the treatment of the pain, blisters, vaginal injections and the use of iodine may be resorted to. The internal use of opium is usually demanded. Such treatment can, however, scarcely be expected to cure the pain. Rest in the horizontal position is perhaps better than any medicine. If all palliative measures have been tried, and at the end of twelve or eighteen months there is no improvement, a second operation may be warranted. The dangers of operative procedure and the uncertainty of the operation causing any improvement, must be stated to the patient.

The following conclusions were drawn:

1. All cases of abdominal section done for the relief of pain should be carefully followed up for at least two years, and not counted as cured simply because the operation has not been fatal.
2. Peritonitis following operation is to be dreaded as much for its remote consequences as for its immediate danger.
3. Extreme caution is demanded when the operation is undertaken where there exist the physical signs of chronic peritonitis.
4. Secondary operations, as a rule, are of no value, although occasionally they may afford relief.
5. Where the operation is done for the relief of pain, a guarded prognosis should be given. There are certain chances that a perfect cure will not result, even if the operation itself is entirely successful.

DR. A. J. C. SKENE: Among the causes of pain after laparotomy I would place the ligature. In tying the pedicle after removal of the ovaries, some traction must be made upon the broad ligament and the nerves must be drawn upon. That form of pain may disappear. Another cause of pain is the application of the ligature just tight enough to arrest hæmorrhage without destroying the nerves. I think that we have more pain after the use of the ligature than after the use of the cautery clamp. The cautery as a means of treating the pedicle has never been thoroughly tried in this country.

In regard to what constitutes success after abdominal section, I would say that many of the cases which I have reported as failures have subsequently turned out to be most successful.

DR. W. GILL WYLIE, of New York: With reference to peritonitis, I would say that I regard it as a condition behind which there is some disease. In chronic peritonitis, there is often some cause which keeps renewing the inflammation. In many of the cases that suffer after operation, the pain is due to imperfect operation. Sometimes a small portion of diseased tissue is left. I have taken the precaution to destroy the diseased tissue that may be left beyond the ligature, either by carbolic acid or preferably by Paquelin's cautery. This has lessened the mild attacks of peritonitis. Sometimes the inflammation is centered around a ligature, leading to abscess and the formation of a sinus. In some of these cases the trouble can be cured by dilating the sinus and fishing out the ligature. In many cases the peritonitis is due to the bursting of a small cyst. Again, in cases where there is chronic inflammation of the lining membrane of the uterus this is not always cured by removal of the tubes and ovaries. This may cause pain not only in the uterus, but reflexly in other parts of the body. These pains can often be cured by dilating the uterus and applying carbolic acid.

DR. ROBERT BATTEY, of Georgia: I have had some little experience with the difficulties alluded to by Dr. Hunter. We are all familiar with the neurotic women. As a result of a carious tooth, an intense neuralgia may be set up which may continue for years and not be relieved by the removal of the diseased tooth. This is probably due in an alteration in the nerve tissue itself. The explanation that these pains persisting after abdominal section were due to inflammation and adhesions has been carefully considered by myself, but I have wholly failed to find a satisfactory explanation in this quarter.

The speaker has said that at the end of twelve or eighteen months, we should give up these cases as failures: I would qualify that statement by more than doubling the limit. Some of the cases which were most unsatisfactory at the end of a year have achieved the most gratifying cure by the lapse of time. Among the causes which produce the neurotic condition, I am inclined to rank in the first place, an acquired neurotic habit from long suffering. In looking for causes, I have been much struck by one point, that alluded to by Dr. Skene—that is the use of the ligature, and especially a rather loosely tied ligature. Dr. Skene suggests the use of the cautery and clamp. I formerly used a method which has not been alluded to, and that is the separation of the ovary from its attachments by the *écraseur*. In these cases I did not have any of these troublesome neuroses, and there was no hæmorrhage. I have seriously been considering a return to this method of treatment.

With regard to treatment by a second opening of the abdomen, I would call attention to the fact that by a simple opening of the abdomen, purely for diagnostic purposes, unaccompanied by any great disturbance of the parts, the condition of the patient is often greatly improved, especially as regards pain.

I think that after removal of the ovaries and tubes, the uterine trouble will get well, but the cure may be hastened by applications to the interior of the uterus of a solution of iodine in carbolic acid.

DR. H. P. C. WILSON, of Baltimore: I am satisfied that while cases do occur where the pain after laparotomy continues as a result of local adhesions, yet the majority of cases belong to the class of cases described by Dr. Battey where the condition is due more to the neurotic element than to the operation. Most of these are long standing cases where the mental condition has become so morbid that the patient is almost insane on the subject of her ovaries and tubes. Even if these organs are removed, the neurotic condition may remain for a long time. Where the woman has to work and has not time to think of herself, these pains more rapidly disappear than where she is pampered with every luxury. Nothing is so good for the relief of these pains as exercise by walking.

DR. JAMES B. HUNTER: The neurotic condition has been referred to, but I think this is secondary. As regards chronic metritis, I think that usually after removal of the ovaries nothing more is required. I am willing to admit that my limit was too short and should be extended to two or three years. I think that it is not well to expect any improvement after removal of the ovaries and tubes for at least twelve months. I think that it takes that long for the system to become accustomed to the changed condition.

DR. JAMES R. CHADWICK read a paper entitled

THE BLUE DISCOLORATIONS OF THE VAGINAL ENTRANCE AS A DIAGNOSTIC SIGN OF PREGNANCY.

The speaker had tables of 440 cases examined. He had divided the discolorations into four groups: first, doubtful, where it was so faint that he could not be certain of its presence; second, suggestive, where it was more marked; third, characteristic, where the discoloration, though faint, is confined to the anterior wall of the vagina and more particularly to the urethra, just below the meatus and on either side of the meatus. In every instance where this was present the woman was pregnant with one exception; and fourth, marked, where the congestion has become deep and exhibits the appearance constantly seen during pregnancy. He did not claim that the characteristic discoloration is seen in every case, but if carefully looked for, it would be found quite pronounced in the majority of cases. The color varies from a violet to a dark, dusky, almost black color. When present, this sign is of decided value in the early months of pregnancy, but its absence should not be accepted as a positive proof against pregnancy. Cases were cited in which the discoloration had been observed in the seventh or eighth week of pregnancy.

DR. H. P. C. WILSON: I consider this one of the most valuable means of diagnosing pregnancy in the early stages. It is invaluable in cases where women wish to deceive you.

DR. A. J. C. SKENE: This has seemed to me to be a most reliable sign in the early months of pregnancy. I believe that it is an illustration of the

physiological hyperæmia of the formative stage of development.

DR. JOSEPH TABER JOHNSON: Some years ago, I referred to this point, and the discussion which followed seemed to indicate that the discoloration was a congestion produced by interference with the return of the venous circulation by the pressure of the enlarged uterus. It was held that the same discoloration could be produced by any other tumor which would have the same effect as the pregnant uterus.

DR. WILLIAM H. PARRISH: In regard to the continuance of the discoloration after labor, I have noted that in primiparæ where involution of the vagina takes place completely, the discoloration disappears with corresponding rapidity. Where there is subinvolution, the blueness may continue for a longer time. In multiparous women where the blueness was marked, I have associated it with a condition of subinvolution of the vagina.

AFTERNOON SESSION.

DR. R. STANSBURY SUTTON exhibited the SPECIMENS FROM THREE CASES OF SUPRA-VAGINAL HYSTERECTOMY AND MADE SOME GENERAL REMARKS ON THE OPERATION.

DR. W. GILL WYLIE: In many cases of fibroid tumor, however, where hysterectomy has been performed for hæmorrhage, I think that curetting the cavity of the uterus would have obviated the necessity for the operation. With the curette, not only may the hæmorrhage be brought to a normal standard, but I have seen the tumor diminish in size. We meet with some cases, however, in which if hysterectomy is not performed the patient will die as the result of the hæmorrhage.

THE PRESIDENT: I think that if Dr. Wylie uses the curette in cases of fibroid tumor, he must, notwithstanding the adoption of all antiseptic precautions, have a certain number of cases of septicæmia. Curetting is much more likely to be followed by septicæmia when there is a fibroid tumor of the uterus than when the operation is done for ordinary fungous granulations.

DR. WYLIE: I have had no trouble whatever. I invariably use antiseptics before the operation and douche out the cavity afterwards. I have never had septic poisoning in any case of curetting in my practice. I use the bichloride solution one to two thousand in the vagina and one to five thousand in the uterus.

DR. H. P. C. WILSON: Where we have excessive hæmorrhage from a fibroid tumor, I believe that there is no remedy so efficient as the curette. I have never seen any evil results from its use.

DR. JOHN C. REEVE, of Dayton, Ohio: Have any of the members had any experience with incision of the cervix in the treatment of fibroid tumors? This was highly recommended some years ago.

DR. SUTTON: I have tried division of the cervix and have stopped the hæmorrhage, and have seen rapid fatty degeneration of the tumor occur in one case.

DR. WILLIAM H. PARRISH, of Philadelphia, read a paper on

THE HIGH MORTALITY OF THE RECENT CÆSARIAN OPERATIONS IN THE UNITED STATES, WITH REPORT OF A CASE.

S. M., married, was admitted to the Philadelphia Hospital while in labor, September 20, 1885. She was the mother of two children, the last of which was born twelve years previously. Labor had begun on September 18, the membranes soon rupturing. She was seen by two physicians who had her sent to the hospital. The cord had prolapsed and the pulsations ceased before she was sent to the hospital. On admission she was found much exhausted with the cord protruding from the vagina. The resident physician not recognizing the gravity of the case, Dr. Parrish was not summoned until some hours after her admission. At this time the uterus was in a tonic spasm; the patient was etherized. The vaginal examination revealed merely a rigid condition of the cervix. The pelvic canal was roomy. The hand was introduced into the vagina and two fingers into the uterus. This examination showed two hard intramural fibroid tumours about the internal os. The author concluded that Cæsarean section should be performed without delay and three of his colleagues were sent for in consultation. They all agreed that attempts at enucleation should not be made, but they did not agree as to the necessity of Cæsarean section. They were in favor of craniotomy. The skull was perforated, but it was found impossible to grasp and crush the head. Various instruments were tried without avail. The necessity for Cæsarean section was then conceded by all. The uterus had then been emptied of its waters for at least forty hours. The vagina and lower part of the uterus were washed out with a solution of corrosive sublimate. The cervix was closed by tying around it a rubber drainage tube. The abdomen was opened and the section of the uterus made. At once a very offensive gas escaped. A large child was removed. The placenta was not in line of the incision. Antiseptic precautions were employed during the operation. Deep and superficial sutures were introduced into the uterus and the abdominal incision closed. A hypodermic injection of ergotin was at once administered. After the operation the tube around the neck was removed. The patient died twelve hours later from exhaustion and rapidly developing septicæmia.

At the autopsy the lips of the uterine incision were found in contact. Three dense intra-mural fibroid tumors were found.

Dr. Parrish then referred to the great mortality of this operation in the United States, and presented the statistics of Dr. Robert P. Harris, of Philadelphia. The following rules were then given for the performance of the operation.

1. Carefully determine the degree of obstruction and operate early in labor, as soon as the os is sufficiently dilated to permit drainage, and before the rupture of the membranes.
2. Operate with full antiseptic precautions, but the spray over the abdomen is unnecessary.

3. Control hæmorrhage by compression of the cervix either with a rubber tube or manually, preferably by the latter means.

4. Introduce numerous deep and superficial sutures so as to approximate accurately the muscular walls of the uterus, but do not carry the sutures into the endometrium. Removal of a section of the muscular wall is unnecessary.

5. Protect the peritoneum from the discharges, and if it become soiled, it should be carefully cleansed.

6. Ergotin should be administered at the beginning of the operation.

THE PRESIDENT: In three thousand cases of labor I have never made a Cæsarean section nor any of its modifications. It is only now that the people are coming to recognize that craniotomy is not to be performed in any but the rarest instances, and that the sacrifice of life is unjustifiable. The explanation of the better results in other countries is not so much in the skill of the operators as in the condition of the cases when operated upon.

DR. PARRISH: I agree with the president that craniotomy should be an operation of exceeding rarity. The people are not yet ready in this country to accept Cæsarean section, but one of the great troubles is with the general medical profession who regard this as an operation almost necessarily fatal.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Oct. 20, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. CHARLES WARRINGTON EARLE entertained the Society with a very interesting account of his recent trip abroad, referring more particularly to observations made in the

HOSPITALS OF PARIS AND THE LABORATORY OF M. PASTEUR.

He first visited the Hospital Lariboisière, which has an outside and inside obstetrical department in which 3500 women were confined last year. This hospital has 875 beds, and the several pavilions are disinfected by carbolic acid, and thoroughly washing everything in them with solution of bichloride of mercury. But the favorite antiseptic is the biniodide of mercury. An interesting feature in this hospital is the contrivance for keeping up the body heat of prematurely born infants. It is a square box so constructed as to prevent the loss of heat, the top of which is covered with glass. In the upper part is placed a thermometer and a little basket with soft clothes, in which lies the baby. In the lower part of the box is an arrangement for the introduction of hot air, either from the heating apparatus of the building, or by heating air by gas or hot water bottles. For infants younger than seven months the temperature is maintained at 100° to 105° F. Between seven and eight months the temperature ranges from 85° to 100° F. The children are fed with breast milk when possible, and are not handled or exposed except when absolutely

necessary. By using this incubator they save a large number of the lives of the prematurely born infants. The Maison de Accouchements is Tarnier's private hospital. Although not a modern hospital, asepsis is aimed at, each patient being isolated and having her own irrigator, the permanganate of potash being the favorite antiseptic. Carbolic acid is sprayed in the wards continually. In turn he visited the Hospitals Bichat, Tenon, and Hôtel Dieu, in all of which the rule is cleanliness and disinfection. Dr. Earle said his most interesting visit was to the dispensary and laboratory of M. Pasteur. The dispensary was smaller than the number of patients demands, and here Pasteur spends his forenoons exercising a supervision over the treatment of the scores of unfortunates who go daily to be inoculated for hydrophobia. Nearly every country on the globe has sent patients here. Dr. Earle then explained the mode of preparing the virus. He said, also, that the majority of scientists on the continent are satisfied that M. Pasteur is honest in his endeavors to prove that he has discovered a cure for hydrophobia, and that they are simply waiting for time to prove if such be the case. They have great confidence in Pasteur, and believe that at the proper time he will announce the truth.

DR. CHARLES F. SINCLAIR read a paper on

THE RELATION OF CERTAIN FORMS OF DEFECTIVE
VISION TO HEADACHE IN YOUTH.

He said that the headaches arising from defective vision are very numerous. They possess certain definite characteristics according to the degree and character of the ametropia. Thus, instead of the usual classification, the ophthalmologist might furnish a terminology of his own based upon the condition of the eye. The pain in these cases increases as the errors of refraction become more complicated. A woman had suffered with intensely painful headaches for fifteen years who was found to have mixed astigmatism, and here properly adjusted lenses effected a cure.

It is in childhood and youth especially that these different forms of ametropia manifest themselves in headache. Dr. W. H. Day, of London, however, in his work on the "Nature and Causes of Headache," in which he devotes a lengthy chapter to the headache of childhood and youth, does not mention ametropia as a possible cause.

Nevertheless the eye, among school children, is frequently the cause of all the head trouble. Among American children one form of ametropia is exceedingly common and very disastrous in its effects. It is difficult to detect. It may in certain cases simulate different forms of ametropia, and even normal vision. He referred to a case in which occurs a slight degree of astigmatism under one dioptric.

Maud W., a school girl 14 years old, had suffered with severe headaches. On examination excellent vision was found, but minus lenses improved it and made it normal. After the use of homatropin, however, half a dioptric of hyperopic astigmatism was found, which was corrected and the headache cured.

Emily R., 15 years old, had suffered with constant headache for a year. On examination, .50 D mani-

fest hypermetropia was found, and only this corrected, as patient would not submit to the use of atropia. This patient returned in a few days saying that her headaches were as bad as ever, when homatropin was used and a small degree of hypermetropic astigmatism was found. This being corrected, a cure of the headache was effected.

In another case there were constantly recurring attacks of vertigo and dizziness, together with severe unilateral headache caused by astigmatism, and which properly adjusted cylindrical lenses cured.

These are types of an exceedingly large number of cases where headache can be cured by a weak cylindrical lense. These cases are interesting not only because of their marked consequences, but because of their tendency, in certain cases, to exactly simulate other conditions, and they certainly suggest the advisability, in every case of severe headache, to examine the eye only when under the influence of atropia.

DR. W. FRANKLIN COLEMAN said that in an examination of the eyes of pupils in Boston, in eighty-nine cases of defective vision fifty-nine were traceable to over-study. Out of this number twenty-five to fifty per cent. of the cases of headache which occurred were relieved by supplying suitable glasses. Another class of cases in which headache occurs is when there is weakness of the recti muscles. By supplying proper prismatic glasses this weakness may be overcome, and the headache disappears. Other factors in producing headache are improper light and too low desks, thus causing the pupil to strain the eyes. So far as artificial light to read by is concerned, the incandescent electric light is probably the best, as it most nearly resembles sunlight, and is free from heat, dust and flickering.

DR. F. C. HOTZ said he believed the authors of such papers as this often exaggerate the importance of their observations. The result is, patients are often instructed to go to oculists, but do not do so on account of the expense, or for some other reason, and the patient therefore receives no treatment. But he has been surprised to see how few cases of defective vision come to him complaining of headache. He has not found it a prominent symptom. In looking looking over his record of cases he finds a great many cases of astigmatism, hypermetropia, and ametropia, in which the symptoms complained of are difficulty of vision, but not headache. Children often complain of not being able to see the figures on the blackboard, and consult the oculist for that trouble directly. But if a large number of cases of the eyes of children are examined, it will be found that in youth a normal eye is often far-sighted, and yet such persons are able to do the work required. However, in cases of defective vision, accompanied by headache, the defect of vision should be corrected.

DR. J. E. COLBURN related his personal experience with astigmatism, stating that not only had he headaches, but he could not study well, and these difficulties disappeared with the using of proper glasses.

DOMESTIC CORRESPONDENCE

"CHLOROFORM AS AN ANÆSTHETIC."

TO THE EDITOR OF THE JOURNAL:

Dear Sir: THE JOURNAL of September 25, contains an article by T. J. Hutton, M.D., on "Chloroform as an Anæsthetic." Although the vast majority of American surgeons have discarded chloroform, it is not well to allow some statements contained in this paper to pass unchallenged; especially, when coming from a careful practitioner, and based on a large number of observations.

Dr. Hutton states, that "ether could never fill the place of chloroform;" and gives amongst his reasons, "the huge quantity of ether required" to produce anæsthesia, "its louder, all-pervading odor," and "the indefinite time required for etherization." There are good and bad methods of administering ether, and the want of success which is often reported, must be ascribed to a failure in appreciating the fundamental principles, which govern the use of these two agents. It is not safe to compel inhalation of an atmosphere containing more than 4 per cent. of chloroform, whilst air saturated with ether vapor, can be inhaled with practical impunity. Anæsthesia by any agent, is the production of the lethal effects of that agent, to an extent corresponding with the degree of anæsthesia; and as insensibility deepens, the patient is brought nearer to a possibly fatal termination. It therefore follows, that chloroform should be given largely diluted with air; and ether with the least possible admixture. For these reasons, a good chloroformist is generally a bad etherist, and *vice versa*. To fulfil the foregoing indications, the best apparatus for use with chloroform, is Dr. Hutton's "rag," which is safer than any mechanical appliance. Where ether is employed, the conditions are so opposite, that for efficient administration, an inhaler is absolutely necessary. I lay down this proposition, because I do not intend to take the results obtained with paper cones, towels and sponges, napkins, etc., which support Dr. Hutton's position; but those where a good instrument delivers concentrated ether vapor, without appreciable waste by diffusion. Under these circumstances, the average time required to produce anæsthesia will be two minutes, and the average quantity of ether employed 1 oz.; the amount consumed in maintaining anæsthesia for thirty minutes, under 3 oz. The odor during the operation is perceptible, nothing more. After some years experience in Hospital, and private practice, I have failed to meet with a case which I could not anæsthetize. There are several instruments which will give these results; with some the quantity of ether varies, but is always under 2 ozs. Professor Müller, of Philadelphia, reports an administration with insensibility in thirty seconds, I have succeeded in obtaining unconsciousness in forty seconds. Would any careful physician attempt to do that with chloroform? I hope not. Having gone over this subject so many times, I do not care to occupy space by recapitulating what can be found elsewhere; and will only add that these statements can be proved from good authority, or demonstrated at any time.

"Finally, as to safety, *the greatest of all considerations*," (the italics are mine). Dr. Hutton has never seen ill results from chloroform, in about 3000 cases. Elsewhere there has been 7000 consecutive administrations without a death; but deaths have occurred, and the average by the latest statistics is enormously in favor of ether. This is not alone sufficient, for a much more important fact, which seems often to be lost sight of, should be emphasized. The doctor, in enumerating the "limitations" under which he uses chloroform, says: "Fourthly, with one hand I administer the chloroform, and with the other I hold the pulse. Any change is instantly noted and I act accordingly—desist or push to completion." If anyone will carefully read the list of chloroform fatalities, recorded in Professor Lyman's work on anæsthetics, he will be struck by the fact, that in many cases the only change noticed was from life to death. Without any previous warning the heart's action has ceased, and efforts at resuscitation have been fruitless. I do not think that any similar case will be found where ether was used.

Care and experience are essential in administering chloroform, but such men as Snow, Clover, and Simpson, have reported deaths; and I am fully convinced that in comparing fatalities from ether and chloroform, we are safe in concluding in the majority of cases, that where ether was used the administrator was to blame, while with chloroform the anæsthetic is culpable. Yours truly, JAS. H. PARKINSON, L.R.C.S.

Sacramento, Cal., October 4, 1886.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 2, 1886, TO OCTOBER 8, 1886.

Major Jos. R. Gihon, Surgeon, granted two months' leave of absence, from Sept. 25, 1886, on surgeon's certificate of disability, in lieu of the unexpired portion of the ordinary leave of absence granted him in S. O. 158, A. G. O., July 10, 1886. (S. O. 227, A. G. O., Sept. 30, 1886.)

Major Wm. H. Gardner, Surgeon, ordered from Dept. Texas to Dept. of the East. (S. O. 227, A. G. O., Sept. 30, 1886.)

Capt. Washington Matthews, Asst. Surgeon, granted leave of absence for one month and twelve days, with permission to go beyond sea. (S. O. 232, A. G. O., Oct. 6, 1886.)

First Lieut. W. W. R. Fisher, Asst. Surgeon, leave of absence extended one month. (S. O. 230, A. G. O., Oct. 4, 1886.)

First Lieut. Wm. C. Borden, Asst. Surgeon, relieved from temporary duty at Ft. Bridger, Wyo., and ordered to return to his station, Ft. Douglass, Utah. (S. O. 126, Dept. Platte, Oct. 2, 1886.)

First Lieut. Wm. P. Kendall, Asst. Surgeon, granted leave of absence for one month. (S. O. 81, Div. Pacific, Sept. 24, 1886.)

Col. John F. Hammond, U. S. Army (retired), died at Poughkeepsie, N. Y., Sept. 29, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING OCTOBER 9, 1886.

Suddards, James, U. S. N., Medical Director, will convene Medical Board, Oct. 6, 1886.

Browne, J. Mills, U. S. N., Medical Director, ordered to report to President Medical Board Oct. 6, 1886.

Dean, R. C., U. S. N., Medical Director, ordered to report to President Medical Board, Oct. 6, 1886.

THE INCISION, DIGITAL EXPLORATION AND DRAINAGE OF LUMBAR ABSCESES.¹

BY EDMUND ANDREWS, M.D., LL.D.,

PROFESSOR OF CLINICAL SURGERY IN THE CHICAGO MEDICAL COLLEGE.

Lumbar abscesses in their own intrinsic nature are not more dangerous than others. They are rendered especially perilous only by the inefficiency of our explorations and by the consequent incompleteness of our local treatment. When thoroughly explored and kept completely disinfected, they rarely cause death.

The first step towards safety is the exploration. Here we are confronted by the published opinions of some of our ablest men, especially of the older class, insisting that the opening of lumbar abscesses and even the aspiration of them is fearfully dangerous. The limits of this paper do not permit an elaborate discussion of this antiquated opinion, which was true under old methods, but false under new ones. I shall assume that the nine cases related in this paper, as well as other established facts of antiseptic surgery, prove that where a lumbar abscess can be freely opened and kept thoroughly disinfected, there is positively no danger in the procedure. There is no hectic, no exhaustion, no pyæmia nor septicæmia. On the contrary the patient rebounds towards health, as if relieved of a great depressing influence. He grows plumper and ruddier, and makes in many instances a good recovery. I grant that certain cases are best treated at the outset by repeated aspiration, but if this fails, or is inapplicable from the abscess being already open, then the open method with regular disinfection is necessary.

Assuming this to be true, the thorough exploration of the interior of the abscess is a prime necessity, and it cannot be accomplished without the use of the surgeon's finger. Treves, of London, publishes three cases of digital exploration, and Erichsen quotes them with approval; but most authors seem not to have thought of it, and apparently would be horrified at the very proposal of such a thing.

The time to be selected is the earliest one at which a diagnosis can be made. A lumbar abscess at the outset is a simple sac, without any complicated pouches, but as it gets older, the pus sometimes bur-

rows to far distant parts, greatly increasing the difficulty of exploration and of disinfection and drainage.

The steps of the operation vary with the locality. Where the abscess points behind in the lumbar region, the following anatomical arrangement almost always exists: The original sac is inside the body, but behind the peritoneum. A small orifice at the outer border of the common mass of the *erectores spinae* muscles conducts the pus outward to another broad sac which expands beneath the integuments. This double arrangement is an effectual barrier to any efforts to disinfect the abscess by antiseptic injections thrown merely into the outer sac. The great interior fountain itself must be opened, explored and tubed. The first step is to open the external sac widely. The second is to examine the floor of the cavity with the finger, and if necessary with a large probe, until we find the opening leading to the interior sac, which orifice is usually in the groove just outside the border of the common mass of erector muscles, but sometimes lies in the angle where the crest of the ilium approaches the spine. These openings vary in size from an eighth of an inch to three-quarters of an inch in diameter. Dilating the orifice, with the aid of an incision if necessary, the finger is inserted to examine the interior. Passing inward the spinal column can be examined to search for necrosed portions, or for excavations whence sequestra have previously exfoliated. In the lower parts of the sac pieces of the exfoliated bone are sometimes found. Passing upward beneath the ribs one often finds the kidney lifted out of its bed, and pressed forward with other tissues. Still higher the sac may terminate in a rounded pouch behind the liver, or extend upward behind the edge of the diaphragm, requiring a long bent probe to complete the examination. Below, it may terminate in a rounded hollow, or extend down into one or both iliac fossæ, or passing into the lesser pelvis make its escape by the sciatic notch into the thigh. Still oftener it burrows beneath Poupart's ligament into the front of the thigh. Probes and flexible bougies are valuable in tracing extended channels, but the touch of the finger is indispensable in exploring the short pouches, and in finding the entrances to the longer ones.

When the abscess points in the angle between the crest of the ilium and the spinal column a wide opening should be made into the external sac, and as before said, the narrow opening into the inner one must be enlarged. The finger then readily explores the cavity. Often it runs forward along the internal

¹ Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

iliac fossa towards Poupart's ligament, where another free opening must be made. At other times it runs upward behind the kidneys, and sometimes sends pouches in three or four directions.

When the abscess points above Poupart's ligament, it presses away the peritoneum so that there is usually no danger in opening it a little above the ligament and in front of the anterior superior spinous process of the ilium. If it opens below the ligament, a free incision must be made to admit the finger. If the finger is too short, or too large, a Britannia metal sound is bent to proper form and carried upward under the ligament, if possible. If the great length of the lower channel prevents this, we must cut down upon it just below the ligament, and pass the sound under it into the pelvic section, and then cut down upon it as before. The finger being introduced shows the size and form of the sac at that part. Next let the metallic sound, or what is often better, a flexible Mercier's *sonde coudée*, be used to trace the channel upward and backward into the lumbar region. If this is successfully accomplished, the next step is to turn the patient on his face or side and cut down upon the sound by an incision much like that of lumbar colotomy, only keeping more towards the spine and passing into the cavity through the groove along the external border of the common mass of erector muscles. The incision may be either longitudinal or transverse at pleasure. Motions of the sound made by an assistant will help the surgeon's finger to identify the exact position of the abscess, especially if the instrument be pretty large and firm. The finger should now be inserted into the lumbar cavity and made to search the whole interior exactly as in cases where the first pointing is in the lumbar region. Every opening must be tubed, and the cavities all be kept well disinfected. As the upper tube will take away the pus at its source, and prevent it flowing down to the lower cavities, the latter can be healed without difficulty, thus reducing the dangerous size and complexity of the cavern, and giving us a comparatively small and simple abscess to deal with.

The following cases from my own experience illustrate the subject:

Case 1.—A woman of middle age entered Mercy Hospital with a fluctuating tumor four inches in diameter on the right lumbar region. Coughing caused succussion as in hernia. The exploring needle brought out pus. The patient being anæsthetized, I incised the tumor freely and evacuated the fluid. The floor of the sac was on the external surface of the muscles of the trunk. In the groove along the external border of the common mass of the erector muscles, I found a hole about a quarter of an inch in diameter leading through the abdominal walls. Enlarging this with a bistoury I inserted my finger and found a large interior cavity, some seven inches long and three inches broad. The inner border was formed by the spinal column. The vertebræ were exactly normal in form, there was no naked nor ulcerated bone, and the bony surfaces were covered with a thin healthy periosteum. The upper end of the cavity was a rounded *cul-de-sac* behind the right lobe of the liver. The kidney and the ascending colon were lifted

forward and inward by the pressure of the abscess. The inner surfaces of the lower ribs were examined and found healthy, and the lower end of the abscess was a simple *cul-de-sac*, like the upper. Neither the finger nor the probe could detect any diseased bone, nor any pouches or passages leading to other parts. It appeared to be purely an abscess in the cellular tissue, and though large, it was very simple in form. It was very thoroughly washed out with antiseptics, a large drainage-tube inserted, and the patient under daily antiseptic injections and dressings rapidly improved in health, and is now nearly well.

Case 2.—A married woman, aged about 33 years. She had a fistulous orifice in the right lumbar region, which had been discharging several months. Potts' disease caused by a fall existed with protuberance of the second lumbar vertebra. She was thin, rather weak and very nervous, but able to keep about the house. Ether was given and the patient placed on the left side, and a free opening made through the skin. The outer sac was found to be small. The opening from the outer to the inner sac was about a third of an inch in diameter. This was enlarged, and the finger inserted. The inner cavity was ovoid in form, about six inches in length and two and a half inches in breadth. Two small pieces of bone lay loose within it, and several others had previously been discharged. The affected vertebra lay directly opposite the opening and was easily examined with the finger. The periosteum was thickened and the form of the body of the bone somewhat changed by the effusion of provisional callus, as well as that of the vertebra below. On the side of the body of the bone was a concave excavation like the bowl of a teaspoon, but there was no longer any naked ulceration of bone to be felt. Apparently the ulcer was healed, and a smooth periosteum lined the hollow. Neither the finger nor the probe succeeded in touching carious bone anywhere. Apparently the caries had become spontaneously cured and only the abscess with the two loose pieces in it remained. These were extracted, a large drainage-tube was inserted, and antiseptic injections regularly kept up. The patient did well as long as she remained within reach of observation, but I lost sight of her, and do not know her present condition.

Case 3.—A boy aged 7 years, much emaciated and weak. A bad Potts' disease existed at about the first lumbar vertebra, with very great deformity. A lumbar abscess pointed on the left side behind. I aspirated the tumor about three times, in hopes to obtain one of the cures which sometimes reward this method of treatment. After the last aspiration, the pus ulcerated its way out along the track of the puncture. Knowing very well the disasters impending from sepsis unless met by prompt measures, I anæsthetized the patient and opened the external sac, which was about three inches across. The opening to the inner sac lay in the usual position alongside the common mass of the erector muscles, and was over half an inch in diameter. The inner sac was very large, some parts being beyond the reach of the finger. This being my first case of digital exploration of lumbar abscess, I was more timid than

I am now, and did not examine the bodies of the vertebræ, but withdrew my finger, inserted a large drainage-tube, and instituted a daily wash-out with a $2\frac{1}{2}$ per cent. solution of carbolic acid. No hectic followed; on the contrary the patient gained greatly in health and strength, and was obviously relieved of a deadly depressing influence. As the patient lived at a distance, I did not learn the subsequent history, and do not know whether the antiseptic measures were steadily followed up, but so long as kept under observation, the improvement in his condition was immense.

Case 4.—An exceedingly complex case. The patient was an adult male aged about 42 years. He came from a distance with the belief that he had a hip disease with an abscess pointing on the outer side of the left thigh. It was a remarkable instance of a lumbar abscess burrowing a long distance, and requiring several openings to explore and disinfect the cavity. The external tests, such as rotation of the femur, etc., failed to prove any true hip disease, but I found, much to the patient's surprise, a moderate but perfectly distinct Potts' disease with the usual deformity affecting the ninth dorsal vertebra. There was a small contracted fistula yielding only a slight discharge at the angle where the crest of the ilium approaches the spine. On the middle of the outer side of the thigh there was a large fluctuating tumor some six inches in diameter.

Having anæsthetized the patient, I opened the tumor freely and evacuated the pus. It extended upward and backward far beyond the reach of the finger, but a long probe traced the cavity through the sciatic notch, and into the pelvis, where its crookedness prevented further progress of the instrument. I now passed a director into the small fistula above the crest of the ilium, opening the external sac, which was very small, as was also the opening leading to the inner sac. Enlarging the orifice the finger was inserted, and three channels were found, one leading downward through the pelvis towards the sciatic notch, and thence out of the notch and down to the abscess on the thigh; the second led forward into the iliac fossa and terminated near the anterior superior spinous process of the ilium. I opened this widely above Poupart's ligament, and was able by putting an index finger in to touch the index of the other hand inserted at the posterior opening. The peritoneum seemed thickened and firm, making a strong barrier between the fingers and the intestines. The third channel was rather small, and led directly upward along the psoas muscle, and behind the kidney. I inserted a finger and cut down upon it just below the twelfth rib, where, inserting a probe, I traced the abscess still onward behind the diaphragm towards the body of the deformed ninth dorsal vertebra. All the cavities were tubed and disinfected and treated with daily antiseptic injections.

Doubtless by exsecting about two inches of the shafts of the ninth and tenth ribs, the finger could have been inserted directly upon the carious body of the affected vertebra, and perhaps a successful scooping of the bone effected, but I desisted for these reasons: Across the body of each dorsal vertebra

winds a pretty large intercostal artery, whose ligation in such a locality would be rather difficult. I judged it best, therefore, to try every other measure, before encountering this danger. I have proved by abundant experience that a daily irrigation of a weak solution of muriatic acid conveyed through a catheter close to a carious bone will often completely dissolve the dead osseous tissue in a moderate time, and effect a permanent cure. Having therefore provided a route by which this plan could be put in operation, the patient returned to his home with a letter of advice to his physician counseling that measure, as well as the regular disinfection of the channels below. No shock or hectic fever followed the operation, and at the last advices the patient was steadily improving.

Case 5.—A boy 5 years of age with Potts' disease causing decided projection of the tenth dorsal vertebra. He was much exhausted, and unable to walk about the room. An abscess was pointing on the right lumbar region. Being freely opened under anæsthesia the external sac was found to be about three and a quarter inches across. The opening leading to the inner sac was in the usual location at the outer border of the erector muscle, and was of a size barely sufficient to admit a pencil. Enlarging it partly by notching with a bistoury and partly by dilatation with the finger, the index was freely inserted. The inner sac was smaller than the external. A prolongation extended to the affected vertebra, but neither the finger nor the probe after a very careful search could detect any really naked or carious bone. The cavity was disinfected, a large drainage-tube inserted, and daily injections of antiseptics instituted. A spinal brace was applied, and the patient returned to his home and to the care of a skilful family physician. He progressed well. No hectic nor septicæmia occurred. The discharge diminished to a mere trifle, the patient became fat and strong, and the spinal inflammation disappeared so as to allow of free and active motions without pain. Several months have now elapsed and the tube is still kept in as a matter of prudence, but the child runs freely about the house, and has grown so tall as to necessitate a new spinal brace.

Case 6.—This is an instance of an abscess breaking in the lumbar region; though really iliac in its origin. The patient is a woman aged about 26. Hereditary syphilis was suspected in the case, but not proved. Some months prior to my visit an abscess pointed and broke in the left lumbar region in the angle between the ilium and the spinal column, and discharged freely. She fell into hectic fever, which, however, subsided after a time. At the time of my visit there was no fever and the discharge was small, but the patient was very thin and feeble. Opening the outer sac, I found a small orifice leading to the inner cavity, which I enlarged and inserted my finger to explore the interior. To my surprise I found no lumbar cavity, but an elongated and irregular sac lying in the iliac fossa and reaching nearly to the anterior superior spinous process. The cavity was tubed and disinfected, and placed under full antiseptic treatment, in the hands of a skilled family physician. She improved in all respects and continued to

gain for two months, when inflammation occurred to some extent near the anterior superior spinous process of the ilium, which is doubtless due to the anterior portion of the abscess sac being imperfectly drained and disinfected. I judge that complete success will require an anterior opening, as well as a posterior one.

Case 7.—Male, æt. 36. No evidence of Potts' disease present. A tumor gradually formed in the right iliac fossa, extending laterally further than is usual in perityphlitis, as it could be felt above the crest of the ilium. Fluctuation was very evident above the outer third of Poupart's ligament, and upward to the anterior superior spinous process of the ilium.

I anæsthetized the patient, opened the sac freely and evacuated the pus. The peritoneum was already pushed well aside by the pressure of the abscess, so as to require no special care. A very large reservoir of pus occupied the iliac fossa, but the finger detected no caries of the ilium. The upper and posterior part extended beyond the reach of the finger, but a flexible metal sound passed readily into the lumbar region to a distance proved by measurement to reach above the kidney. The sound was left in this position and the patient turned on his side. I then made an incision in the groove along the outer border of the common erector mass of muscles, and dissected down to the sound. Inserting the finger, I found that the cavity extended well up behind the kidney, but was much narrower than that in the iliac fossa. No other prolongations were discovered, and the patient did well at first. However, in a short time a hard inflammatory swelling appeared in the iliac fossa of the opposite side of the body. The temperature rose, and the patient fell into delirium. The swelling increased in size, but presented no fluctuation. However, after a little delay I opened it above Poupart's ligament and found deep in, and covered with a thick mass of inflammatory deposit, a large cavity of putrid pus, which was evacuated, and the cavity tubed and disinfected.

A day or two later the old channel of communication from the original abscess to this one, which seemed to have become blocked by the swelling or clots, re-opened, so that injections could be thrown across from one iliac abscess to the other. The delirium continued and the patient died of a cerebral attack caused, probably, by septicæmia.

I look upon this not so much a failure of the principle of the operation, as an instance showing the danger and folly of postponing it until long passages have burrowed into distant parts, and the whole system become poisoned with septic absorption. It is obvious that the operation should be made at the earliest possible period.

Case 8.—A young woman with no evidence of Potts' disease. She had a large abscess pointing above the outer part of Poupart's ligament. On opening and exploring, I traced it upward and backward to the angle between the crest of the ilium and the spine, where I made a counter opening and instituted free drainage and injections to be thrown

through from one opening to the other. I believe the patient did well, but as she lived at a great distance I soon lost sight of the case.

Case 9.—A woman with no clear proof of Potts' disease. She was able to take the journey to the city, but was considerably exhausted from a lumbar abscess which had been discharging just above the groin for months. I opened freely both above Poupart's ligament and in the lower end of the lumbar region behind. Large drainage tubes were deeply inserted, and copious carbolized injections daily thrown through from one wound to the other. The patient began to return towards health at once. She grew daily stronger and plumper, and when last heard of some months later she was almost restored to soundness, though still wearing the tubes for safety.

The following list of opinions shows the contradictory and confused state of thought on the opening of these cavities:

The elder Gross left on record his opinion that lumbar abscesses, especially old ones, should not be opened until about ready to burst.

Prof. D. Hayes Agnew expresses views nearly similar (*Agnew's Surgery*, vol. II, p. 884).

Alex. Shaw, of England, discourages opening the cavities, but still hopes something from Listerism.

Mr. Treves, of London, at first advocated only repeated aspirations, but later has published three cases of digital exploration, with favorable results. In one of them he removed a piece of necrosed bone.

Erichsen, of London, advises antiseptic opening, and even suggests digital exploration, but does not speak of having tried it.

König, of Germany, advocates drainage in a downward direction, but omits to speak of antiseptic cleansing.

Holmes, of England, advises to allow the abscess to burst spontaneously, and on no account to open it.

Ashhurst, of Philadelphia, opposes opening.

Bryant, of Guy's Hospital, London, advises not to open early, but if the abscess progresses, to open antiseptically.

Hamilton, of New York, remarks on the contradictory state of surgical opinion, and evidently hesitates. On the whole, he advises to evacuate gradually, and never to use probes, tents, or injections, until the opening has been running several weeks.

I am led to the following conclusions by a pretty extensive experience in various methods which have been in vogue:

1. Some lumbar abscesses recover simply by a series of aspirations, with or without antiseptic washing out. This method is simple, and where the choice offers itself should be tested first.

2. If the aspiration plan fails, or is inapplicable in consequence of the abscess being already open, then free incision, exploration, and complete disinfection should be carried out at once.

3. If residual abscesses appear in the course of the treatment, they should be served in the same way as the primary one.

4. The sudden evacuation of a large cavity filled with pus, provided the sac is immediately disinfected

and kept so, has none of the dangers supposed by the old authors to beset the case.

DR. BYRD, of Quincy, Ill., in discussing the paper, spoke of the value of per-oxide of hydrogen.

DR. FENGER, of Chicago, suggested that the danger in opening psoas abscesses was to be found in the character of the abscess, the result of tubercular abscesses being much worse than a simple psoas abscess; that the value of the treatment suggested by Dr. Andrews consisted in the fact that he made his counter openings near the origin of the trouble.

DR. LEWIS, of Kansas City, inquired concerning the earlier symptoms of psoas abscess.

DR. HAMILTON, of Ohio, thought it strange that such large accumulations of pus existed without being detected by the physician.

DR. J. RANSOHOFF, of Cincinnati, believed that such abscesses should be drained after free incision if not arising from tubercular processes. Abscesses of tubercular origin he thought were unfavorably influenced by incision. The origin of the trouble was to be sought before determining the character of treatment.

DR. ANDREWS, in closing, said that the symptoms of such condition where caries was present consisted in elevation of temperature, some fulness or swelling, dullness in percussion at site of tumor, and the possible use of aspirator. That the incision should be carried to the extent of a thorough exploration of the cavity seeking for dead bone, providing for thorough drainage and antiseptic cleansing. That he had opened abscesses where spicula of bone were found in the cavity, but where the neurotic process had already been limited and the parts were healing.

A REMARKABLE CASE OF FOREIGN BODY CARRIED TEN YEARS IN THE EYE.¹

BY T. E. MURRELL, M.D.,
OF LITTLE ROCK, ARK.

A student in the Caneyhill College, Arkansas, session of 1875-76, was making some hydrogen gas with iron filings and sulphuric acid in a glass retort. Just as the gas began to escape from the retort pipe, and while still much mixed with atmospheric air, he chanced to bring a lighted match close to the escape pipe, when an explosion took place. The retort was blown to atoms and the pieces of glass driven with great force in all directions. The young man received a severe wound in his right eye. The eye was found lacerated; a transverse cut in the cornea extending from the sclera on one side into the sclera on the opposite side. The supposition was that a flying fragment of glass had done the work by an oblique stroke and had passed on.

The eye was treated antiphlogistically, and although considerable inflammation and pain followed, in a few weeks all became quiet and a transverse corneal scar marked the seat of injury. Some six

years after this Mr. F., then a lawyer, consulted me. I found right eye as follows: Extending some two lines into the sclera inwardly and outwardly and transversely through the diameter of the cornea was a somewhat flattened linear cicatrix, into which the iris was drawn with obliteration of the pupil. Above and below was clear cornea through which could be seen fairly normal fibrillated iris. The scleral conjunctiva was of normal appearance, the eye appearing perfectly quiescent. He had had no trouble with it since the recovery from the accident, and came to me for the purpose of having an artificial pupil made for optical purposes. I found, however, that he had no perception of light, and explained to him the uselessness of such procedure. Taking into consideration the extent of the wound, involving as it did the ciliary body on two opposite sides, together with the fact that the iris was also extensively incarcerated, I warned him particularly of the dangers of sympathetic trouble in the other eye eventually.

Some two years ago Mr. F. again visited me. I found the eye *in statu quo*, with no redness, pain or irritation, or weakness of his left eye. I repeated my injunctions of caution, and now, upon conservative principles, advised enucleation of the injured eye. He returned home and occasionally wrote me, stating that he was afraid, since my information imparted to him of the dangers of sympathetic trouble, to carry the eye, and would at his convenience come and have it removed.

In February last he came with his mind made up to have the operation performed. At this time the scleral conjunctiva was perfectly clear, there was no tenderness over any part of the ciliary body, no pain, and the other eye was clear, strong, and V = Sn $\frac{7}{8}$ sharp. He was a hard student, and up to this time had spent many hours daily in close application to his law books. He said, however, for a year or two, his good eye showed more disposition to tire than formerly after much work, and concluded that one of the symptoms of sympathetic irritation was upon him.

I put a drop or two of cocaine muriate solution, 4 per cent., into the conjunctival sac, and in a minute after injected 10 minims of the same into the circum-scleral tissues at four points. Five minutes later I proceeded to enucleate in the usual way, which was entirely painless, the patient and I carrying on a pleasant conversation all the while. When finished and the hæmorrhage staunch, I examined the eye in his presence. He asked me to look carefully for a piece of glass, as he could not but believe some fragment had lodged in the eye. I was disposed to make light of his opinion, and stated as my reason, the entire absence of irritation of any sort in the eye, which would hardly have been the case with so irritating a body as a piece of glass lodged in the eye. The eye was divided into halves through its equator. In the interciliary region, occupying the position of the lens, was a mass of lymph. The other structures of the uveal tract, I should say, were entirely atrophic, and the vitreous chamber filled with straw-colored water. On opening into the lymph deposit the knife came upon a hard body which, on further exposure, proved

¹ Read in the Section on Ophthalmology, Otology and Laryngology at the Thirty-Seventh Annual Meeting of the American Medical Association.

to be glass. The encystment was complete. The glass measures 15 millimetres long, 12 millimetres wide and $1\frac{1}{2}$ millimetres thick, and is a parallelogram with one corner broken off. Its position was in a vertical plane parallel with the iris, and fully as large as the whole iritic surface.

The complete encystment of so large a body, with such sharp cutting edges, exactly in the ciliary region of the eye, with such extensive involvement of the ciliary body and incarceration of the iris, with entire absence of tenderness, pain or redness of the eye at any time, taken together, serve, in my opinion, to mark this case as one unique and worthy of record.

SOME PRACTICAL SUGGESTIONS ON THE TREATMENT OF DIPHTHERIA.¹

BY WM. PORTER, M.D.,

OF ST. LOUIS, MO. PHYSICIAN TO THROAT AND CHEST DEPARTMENT OF ST. LOUIS PROTESTANT HOSPITAL, OF ST. LOUIS CITY HOSPITAL, OF THE FEMALE HOSPITAL, AND PHYSICIAN TO ST. LUKE'S.

Diphtheria is a common disease, and it is one of the most fatal. As one illustration of many, in five years there were 17,193 cases in New York alone and 7,263 deaths. It is a disease that every physician will be called to treat sooner or later, and being called must act promptly. This is not the place for a long essay upon the different theories of diphtheritic contagion and progress; rather let us enter at once upon the discussion of the practical questions involved in conducting the disease to a favorable issue.

Let me very briefly sketch the manner of invasion according to conclusions which seem most reasonable and are by many accepted:

1. Diphtheria is contagious—or rather portagious, and of parasitic origin.
2. It is most readily implanted upon a mucous membrane denuded of its epithelium.
3. It is probably always local in its incipency, sometimes becoming rapidly systemic, though in rare cases apparently systemic from the beginning.

To further explain rather than to argue these propositions, let me say that the best protection against diphtheria is a mucous membrane entirely healthy; and an ordinary acute or subacute laryngitis or pharyngitis is a condition favorable to the implanting of the diphtheritic germ. When the epithelial layer is intact the diphtheritic germ finds no foothold, but when there is an abrasion or denudation of the lining membrane the diphtheritic bacteria first attach themselves to the surface so prepared for them. This is the local period of the disease and no micrococci are found in the blood—there is no constitutional symptom. Sometimes, though there may be rapid surface involvement, and free formation of the characteristic membrane, there may still be little absorption of the diphtheritic virus.

Many of these almost purely local conditions suggest a doubt as to their specific nature. It is well to give the patient the benefit of the doubt and to treat urgently all suspicious-looking exudations upon the surface of the respiratory tract. Practically, a cer-

tain number of cases of diphtheria are constitutional from the beginning, the point of infection being in some recess of the naso-pharynx or larynx, and easily overlooked—or is beyond the range of vision. I am not sure but that infection may occur from primary invasion of the membrane of the alimentary canal. Klebs in the second Congress of the German Physicians, speaks of a diphtheritic involvement of Peyer's patches resembling the reticular appearance in the early stages of typhoid. In by far the greater number of cases the rapid multiplication of the bacteria—whether sphero-bacteria as are found in severe cases, or whether short and slender rods as in milder cases—produces an inflammation of the mucous membrane, exudation takes place, the epithelial cells die and the bacteria pass into the blood and rapidly multiply throughout the circulation. Even should we deny with Beale, that the contagium is bacteria, we still must admit that the hypothesis of local infection furnishes the most rational explanation of the sequence of symptoms.

Granting this, we have two purposes in treatment in the early stages of diphtheria:

1. To destroy or render harmless the local manifestation of the disease.
2. To increase the power of resistance in the general system to infection.

In dealing with the false membrane all measures which would tend to irritate or injure the air passages should be avoided. There should be no tearing away of the exudation, or application of caustics—nor do I think that, except in cases where there is only a small well-defined patch of membrane, the use of the galvano-cautery will prove expedient. To prevent absorption, not only should we avoid making new abrasions in the throat, but I have thought it wise as far as possible to cover up those that already exist.

First of all it is well to remove from the naso-pharynx, or pharynx, if that be the site of invasion, whatever of accumulated mucus and debris there may be. This may be readily done by means of a small syringe, and a weak solution of salt water or of Listerine. This may be used either through the nostril or directly in the pharynx. To loosen the attachments and hasten the resolution of the diphtheritic membrane many means have been advocated.

When the patch can be reached a solution of papayotin may be applied; or better still, one of trypsin. This last used in solution, as suggested by Fairchild and Foster, or still better, a few grains with one or two of bicarbonate of soda, made into a paste with water and spread upon the diphtheritic patch, is the most rapid solvent I have known. If the local disease is beyond the reach of such an application, an alkaline solution of trypsin may be sprayed into the nose or larynx.

After several applications of trypsin within the hour, a still further attack may be made upon the local disease. Having used more or less freely most of the germicides, astringents and antiseptics commended in the treatment of diphtheria, I have abandoned all else for a solution of equal parts of the tincture of the chloride of iron and glycerine. I have cause to consider this, when well applied over

¹ Read in the Section on Laryngology, at the Thirty-Seventh Annual Meeting of the American Medical Association.

the entire extent of the diseased surface, an almost complete bar to the progress and absorption of the diphtheritic virus.

1. If the potency of the disease lies in the rapid multiplication of bacteria, so strong a chlorine solution is certainly indicated.

2. If absorption takes place through the abraded surfaces and "mouths of lymphatics open," as stated by Oertel, we would from *a priori* reasoning expect some good from the local use of iron, while the glycerine may be something more than a mere vehicle, in that it may by affinity relieve to some extent the turgid capillaries of the mucous membrane. The application should be made frequently.

Let me say, in urging the efficacy of this agent, that for two years I have not seen a case of diphtheria die where the whole of the false membrane could be seen and repeatedly covered with this solution and where appropriate general treatment was given. Thrice within the last week and many times during the past year I have seen the characteristic membrane shrivel up and become detached under the influence of the iron and glycerine.

When the local attack is out of reach of the direct application by means of the brush or, better still, the cotton covered probe, the case is very different. When the invasion is in the naso-pharynx or in the larynx the result may well be dreaded. Even in such instances I believe the best procedure is to apply the iron locally by spray and where possible by the cotton covered probe.

The covering in of the diphtheritic patch with tolu varnish as recommended by Mackenzie may follow the thorough use of the iron solution, and is doubtless protective.

Not only is local treatment important, but it is important to institute it early. The physician should be called at once in every case where there is a doubt. Parents should feel that they are responsible for delay, and that delay is exceedingly dangerous. Many cases that during the first twenty-four hours are easy to treat and curable, are a little later beyond the reach of the most skilful.

A few words as to general treatment. Here too I have no sympathy with halfway measures. First of all in every case, I nearly always counsel the administration of enough of calomel and soda combined to thoroughly evacuate the alimentary tract. It empties the canal of any accumulated material, it stimulates important secretions, and with Ritter, though not to the extent to which he advocates it, I believe it has a favorable influence upon the general condition. At least it clears the decks for action. As soon as the bowels of the child have been well moved, and sometimes not waiting for that, the internal use of the iron and glycerine solution (the same as that used in the throat) may be begun; for we need not fear any chemical reaction. To show that others are falling back upon this well-known agent let me quote from an editorial in a recent issue of the *New England Medical Monthly*: "It is interesting and somewhat gratifying to note that after each excursion into the domain of experimental medicine the profession invariably returns to the older and more effective

method of treating diphtheria which consists of tonic doses of the tincture of iron and a system of extreme nourishment."

To anticipate and antagonize general invasion the general as well as the local treatment should be instituted early. Where the symptoms demand I prescribe two drops of the iron and glycerine solution for each year of the child's age, in a little water every two hours, and midway between each dose the diphtheritic patch is to be touched or sprayed with the solution. Thus there is an opportunity for the ferric solution to be brought in contact every hour with so much of the diseased membrane as is in the pharynx.

I have not discussed much of the poly-treatment of diphtheria as practised to-day—nor have I time to outline the emergencies which may arise, as I had thought of doing. My object has been to propose a plain and direct method of treatment which any one may use and which is not an experiment.

Many other remedies are often to be added. Pilocarpine, when the skin is dry and there is spasmodic laryngeal contraction; quinine, when the fever is excessive; steam from slacking lime when respiration is labored and the respiratory tract dry; and tracheotomy or intubation when the larynx is greatly obstructed.

Let me in conclusion suggest that the physician demand of the people among whom he practices, that they call him at once when suspicious symptoms are observed, and that he answer quickly, act promptly, and see that his instructions are implicitly obeyed. To treat diphtheria is to fight a battle—there should be no delays, surprises nor compromises.

DOUBLE PYONEPHROSIS;

Perineal Median Urethrotomy; Removal of large quantity of Sandy Gravel; Dilatation of Ureters; Hypertrophy of Bladder; Death.

BY EDWARD HORNIBROOK, M.D.,

OF CHEROKEE, IOWA.

N. B. Batterson, æt. 51, consulted me July 17, 1881, and gave the following history: Ancestors for several generations long-lived and healthy. He enjoyed good health till ten years ago. He then had retention of urine brought on by heavy lifting? The physician in attendance retained gum-elastic catheter for eight days. At the end of that time the patient passed large quantities of blood. He says that this was after, not before removal of catheter. He has had constant vesical irritation since. Pus and mucus passed daily for first four years. He was then free from purulent or bloody urine for eighteen months. For last two and a half years he has been passing bloody urine and pus at frequent intervals. Hæmaturia has always occurred after lifting heavy weights, which he was often required to do in his employment as a grocer's clerk. Requires to urinate every half-hour, night and day. The symptoms were not relieved by recumbent posture. He has had frequent symptoms of a calculus passing through urethra, but never saw any. After these symptoms he often passes

large lumps of hardened mucus? Has not passed catheter for last two years. Bowels constipated and passages painful. Prostate gland enlarged and tender. Catheter passes easily; but there are two slight strictures in membranous portion of urethra. Urine drawn by catheter alkaline in reaction and mixed with pus. No stone in bladder.

Under treatment, principally with the dilute mineral acids, benzoic acid and rectal suppositories, his condition was ameliorated until May 12, 1885. He then complained of the usual symptoms of vesical calculus. I readily detected stone and advised operation. Very offensive pus escaped during the examination. After repeated trials I failed to grasp the stone with the lithotrite. It was of large size and placed just above and behind the neck of the bladder, apparently lodged in a pouch from which it could not be removed. He suffered little during the attempt; there was no shock and he seemed well as usual next day. I recommended lithotomy, but the patient refused to consent to the operation.

He passed from observation until October 12, when he sent for me and urged me to undertake the operation, as his health was giving way under his constant suffering. I reluctantly consented, as the urine was then strongly alkaline, contained large quantities of pus and was horribly offensive.

On October 20, in the presence and with the assistance of several of my professional confrères, I performed the operation according to Allerton's method. After dilating the prostate I introduced the scoop to dislodge the stone from the pouch in which I thought it to be imbedded, when it crumbled into small crystals. Upon passing my finger into the bladder the whole mucous membrane seemed covered with an incrustation of this sandy gravel which I was unable to remove without removing the mucous membrane with it. I removed what I could with the scoop and irrigated the mucous membrane thoroughly with a strong stream of carbolyzed water. By these means more than two ounces of this sandy gravel were removed. Shreds of mucous membrane were also washed away.

I retained a tube in the wound with the intention of practising daily irrigation. The next day the bladder was washed out till the water came away clear. After a few minutes nearly an ounce of fetid pus followed. This convinced me that the pus was discharging from the kidneys, and added to the gravity of the prognosis.

The washing out of the bladder was continued till November 9, when he sank exhausted. He suffered less after the operation than before.

A post-mortem examination was made twelve hours after death by Drs. Sherman, Vail and Burlingame, who kindly removed the bladder, kidneys and ureters for my inspection; as I was away from home at the time. The walls of the bladder were an inch in thickness; the ureters both dilated so that they were at least three-quarters of an inch in diameter; and there was about three ounces of pus in each kidney and its ureter.

Many questions, of course, suggest themselves as to the etiology, the course of the disease and the

cause of the pathological conditions. I will not attempt to theorize but merely state the facts, leaving each reader to make his own deductions.

COLLECTIVE INVESTIGATION OF DISEASE.¹

BY H. Z. GILL, M.D., LL.D.,

OF CLEVELAND, OHIO.

In making a report under the title of "Collective Investigation of Disease" for the city and vicinity of Cleveland, O., it has been necessary to collect the meteorological conditions and then examine carefully the daily death-records of the city. This material has been made a part of this report, in order that every one may re-examine it respecting the same diseases, or may use the data for other purposes.

The first step, after the appointment of your committee, was to ascertain the daily meteorological changes for the year to be reported. This could be done more accurately at the signal office at this station than anywhere else; hence, application was made to the Bureau at Washington for the data, and also for the ozonic conditions of the atmosphere. In reply to the latter part of the request (the other items having been ordered), I received the following reply:

"CLEVELAND, O.

"I would respectfully state for your information that the Signal Office in Washington does not furnish any Station with ozone-paper and color scale for the purpose of determining the ozonic condition of the atmosphere.

(Signed)

WILLIAM LINE,

Sergt. Signal Corps U. S. A."

The state of the barometer, the thermometer, the dew-point, direction of wind, amount of precipitation and state of weather as to cloudiness, were furnished promptly. Credit is due and thanks for the same are hereby acknowledged.

This report covers a period of one year, viz., from May, 1885 to April, 1886, inclusive.

The city of Cleveland, O., is situated in N. latitude $41^{\circ} 30'$; W. longitude $81^{\circ} 27'$; and has an elevation of 690 feet. The soil is generally sandy, and through it percolation is easily effected; hence it has been found best to abandon wells in the more central portion of the city, especially so since the water-supply from the lake is pure and abundant. The city is not generally densely built, and little danger from over-crowding is feared when compared with many of the large cities of this country. Allowing the population to be as estimated, 205,000, and the mortality, as given by the Annual Report of the Health Department of the city for 1884, as 3730 (or including still-births, as 4049), the mortality would be 18.17 and 19.75, respectively, per 1000;² while that of the United States for 1880 was estimated at a fraction over 18 per 1000.

Our investigations have had reference, mainly, to those diseases which are believed to be more or less influenced by atmospheric conditions, viz.: Diph-

¹ A report made to the Ohio State Medical Society, June 2, 1886.

² For 1885 it was 17.43 and 19, respectively.

theria and croup, cholera infantum, entero-cœlitis, and other diseases of this class; typhoid fever, measles, scarlet fever, and whooping-cough.

During the calendar year 1884 there were deaths: From diphtheria and croup...196; my report, 180
 " cholera infantum.....278 " " 313
 " measles.....197 " " 6
 " scarlet fever.....18 " " 24
 " typhoid fever.....121 " " 78
 " whooping-cough.....37 " " 30

Columbus, O., had of cholera infantum for 1885 (July, August, September), 40 deaths; the maximum temperature having been 96.7° on July 20.

From the same yearly report of Cleveland, there were 1239 deaths from zymotic diseases, of which 847 were from the above-named six diseases; for 1885 there were 1016. My examination for the year (May, 1885, to April, 1886, inclusive) shows a total mortality of 4081. The first in the list—diphtheria and croup—gives a total of 180, distributed through the year as follows:

during the year. On those days respectively the atmospheric conditions were:

	Mean barom.	Mean temp.	Dew- point.	Wind.	Precipi- tation.
Nov. 28—30.	26.0	28.3	23.0	S.W.,	0
Dec. 15—30.	11.9	24.0	16.9	S.W.,	0

The number of cases and deaths reported are so distributed through the year as to show only the usual fact, that the first three and the last three months of the calendar year are those in which the disease occurs most frequently, viz., 208 cases, 113 deaths; the whole number being, 380 cases, 180 deaths—47.3 per cent.

No doubt many cases of mild form were not reported. This is in accord with a large table, in my work on Diphtheria, now in press, of 7019 cases of croup in the Hospitals of Paris, admitted from 1868 to 1880, viz.: September, 457, October, 500, June 517, all the other months having a higher number.

There are, however, conditions during this winter period of the year which may not pass unobserved;

CHART NO. I.

Cholera infantum, 154; entero-cœlitis, 13; others of this class, 39. Total deaths, 206.

May...8, (21)*...Sept., 10, (27)...Jan., 15, (22)
 June...9, (34)...Oct., 22, (45)...Feb., 6, (16)
 July...11, (33)...Nov., 24, (47)...Mar., 20, (29)
 Aug...9, (28)...Dec., 26, (44)...Apr., 20, (24)

This shows 380 cases reported, giving a mortality of 47.36 per cent., a rather high ratio considering the absence of an epidemic.

We cannot say that atmospheric conditions, as shown by these meteorological tables, had any notable influence on this death rate, not over four in one day (Nov. 28 and Dec. 15) having been recorded

these are, the lower temperature, a less amount of ventilation, and crowding; hence, concentration of the poison, prolonged activity of the contagium, etc. We had occasion to bring these conditions to the notice of the profession fifteen or more years ago, when referring to some of the contagious diseases, especially variola, in which it was pointed out that concentration of the active agent, arising from a more defective ventilation and a lower temperature, were conditions favoring the spread of smallpox, scarlet fever and diphtheria. I say conditions—this it is which we are considering more particularly. With this disease we might consider the other contagious

* Numbers in parentheses indicate the number of cases reported to the health office.

diseases; but in the order of our report *cholera infantum* and *kindred diseases* come next.

During the year reported, there were *among children, from these diseases alone*, 518 deaths, of which the alarming number of 428 occurred during July, August and September, 375 of them in the former two months. On one day, July 31, 16 are recorded; of cholera infantum alone, 13. If all were recorded in this class which I think belong to it, there would be in these three months at least 450 deaths, viz:

Cholera infantum,	296
Enterocolitis,	64
Others of this class (see table No. 1),	68
Additional cases (under head of "remarks")	22

Total, 450

A ratio of over 11 per cent. of the annual mortality of the city.

On the 17th of July the maximum temperature was over 90°. On the Thursday after this the daily mortality rose to 13, and continued high for several

Chart No. 1, on preceding page, will give at a glance the relationship of temperature, dates and deaths for July, presented in a more apparent form, perhaps, than when in a table, the light line indicating the temperature daily, in its maximum and minimum, and the heavy line the daily mortality from

CHART NO. 2.—CONTAGIOUS DISEASES.

weeks. (See Chart No. 1.) On the day of greatest mortality, July 31, the meteorological report is:

Mean barom., 29.920; mean tem., 73.6; m. rel. humid., 92.3; wind, N.; weather, clear; precip., 0.

The latter half of July had a high average temperature, 2.3° above the mean for the past three years; and a high dew-point, yet very little rain-fall. For the month of August the mean temperature was six degrees lower here than in July, and the death-rate from cholera infantum alone fell off nearly one-third, the mean temperature being 65.8°; while at Columbus it was 70°, with a higher mortality from cholera infantum than in July. Compared with corresponding months of 1884, there are some facts worth noting, if anyone could be incredulous on the relationship of temperature, etc., and diseases of this class:

cholera infantum and allied diseases in children.

This relationship shows indications for hygienic measures which we may not enter into at length at this moment.

Diphtheria and scarlet fever each has prevailed to quite a notable extent throughout the year. The latter furnished 510 cases, with a mortality of 24, a per cent. of 4.7. Deaths from measles have almost disappeared from the record, there being no death in seven of the months reported, and no case reported in three months of this time.

It is believed that the reports of cases of diphtheria, measles, and scarlet fever, made by the physicians of the city to the Board of Health, are fairly correct as to numbers; many, however, of the very mild cases, I have no doubt, are overlooked or ne-

glected. Of course calculations are always made with this in mind.

The relationship of diphtheria and scarlet fever, as shown by Chart No. 2, is, we believe, more than accidental. In this year it is rather striking. The co-existence of epidemics of scarlatina, measles and diphtheria is pointed out in Sanné's work on Diphtheria, p. 324; but as before stated, we have no epidemic to report, and no special condition of atmosphere during this period in respect of dampness or otherwise.

During the months of February, March and April the deaths from acute pulmonary diseases were unusually frequent, viz., 33, 58, and 35, respectively. The meteorological conditions were:

Month.	Mean Barometer.	Mean Relative Humidity.	Mean Temperature.	Precipitation.	Wind.	Weather (Clear days.)
Feb'y,	30.093	79.5	25.4	1.55	S.	2
Mar.	29.964	79.1	34.9	2.00	W.	6
April,	30.061	76.2	49.1	1.78	N. E.	11

as influencing the temperature of the atmosphere of the region, or the additional degrees which arise from reflection, radiation, from the heat of cooking, or from whatever source.

Hygienic measures of every possible form and kind—food, clothing, bathing, ventilation, protection from exposure to the hot sun and from accidental heat, especially with quite young children, are strongly indicated. It would be out of place to enter at this time upon the medical treatment of any of these diseases. I may say, however, that at several times I have had printed *rules for the management of children during hot weather*; and have found that parents have been greatly aided by such printed directions.

The subjects of ill-ventilation, crowding of individuals in sleeping rooms, public halls and schools, have been hinted at under the remarks on contagious diseases. Not less than twelve years since I presented this subject under the general term of *dilution*. The same thought, varied a little, is now taking on the term or expression, attenuation. It is

ANNUAL REPORT OF CLEVELAND, OHIO. METEOROLOGICAL AND MORTALITY.

Typhoid fever furnished a large total mortality, viz.: 78 (for the calendar year 1885 it is 71), distributed as follows: May to September, inclusive, 21; the other seven months gave 57, October alone, 12. We do not suppose that the number of *cases* reported is full in this item, but the total reported is 116, commencing with August. The highest report of cases is in August, viz., 35.

This collection of facts suggests many indications in the direction of general management of diseases. The first class and the most striking is

THE SUMMER DISEASES OF CHILDREN, as influenced by heat, whether it be solar heat alone

pretty well established that many poisons, when largely diluted, become harmless, but when concentrated, produce the so-called contagious diseases, each of its kind, and the same is true of most blood-poisoning.

This is a subject, even under the present investigation, that demands our careful attention; for what we cannot entirely destroy or prevent, we should render as harmless as possible. *Ventilation dilutes until it destroys; dilution attenuates until it renders innocuous.*

1216 Willson Avenue.

MEDICAL PROGRESS.

THE TREATMENT OF GRANULAR CONJUNCTIVITIS.

—In the treatment of granular conjunctivitis one of two objects is to be kept in view: either to subdue inflammation when this is already excessive; or, when it is deficient, to excite it to greater activity, so as to lead to the absorption of the morbid tissue which has been formed. For the latter purpose various chemical applications have been used, and even inoculation with gonorrhoeal pus; while attempts have also been made by scarification to lead to atrophy and absorption of the granulations.

One of the most recent methods proposed for the treatment of trachoma is that described by DR. CECCHINI SETTIMO, of Modena, in the *Gazzetta degli Ospitali*, Nos. 100–103, 1885. It consists in destroying the granulations mechanically and chemically, by scraping and cauterization. All the cases Settimo has seen involved the upper lid, which he turns up, protects the eyeball with cotton soaked in a solution of boric acid or smeared with an inert ointment, and scrapes out with a Volkmann's spoon as many of the granulations as possible. He checks the hæmorrhage with cotton dipped in cold water, and then practises a vigorous cauterization with pure nitrate of silver. Before doing this he pushes the lower lid against the reversed upper lid, and places between them a little cotton soaked in a solution of chloride of sodium, to protect the cornea. After the cauterization, the upper lid is well washed with the same solution, followed by a cold solution of boric acid. For the subsequent pain, he instils a solution of morphia and atropia, and applies light compresses dipped in iced water. In some cases he applies a leech or leeches, to the temple. The patient is ordered to keep the head elevated and the eye cool with applications of cold boiled rice, washing it out with boric acid solution.

The operation is contraindicated only when there is pronounced hyperæmia, in which case it is important to cure or diminish this before scraping. Settimo prefers not to use an anæsthetic, as the contraction of the palpebral muscles helps the scraping process, although this is quite painful.

The operation may be done at one sitting if the granulations are soft and not very vascular, and the infiltration is not very great; but, if the granulations are hard and cartilaginous, it is advisable, but not necessary, to make the scraping in two or three sittings, at intervals of not less than three days. Chemosis is to be combated by taking blood from the temple, by incision of the external angle as in the method of Gräfe, and by deep incisions in the conjunctiva.

Settimo has used this method, combining it with the administration of iodide of potassium in twenty cases, with the most brilliant results, and naturally recommends it very warmly for general adoption.

More recently, KRAMSZYK, in the *Gazeta Lekarski*, has called attention to a method of treating trachoma which was originally proposed by Wicherkiewicz, and which consists in crushing the granulations between

the thumb-nails of the operator, or by means of a pair of forceps. The operation is very painful; and, although it has succeeded in a number of cases, it does not appear to have any advantages over the method of Settimo, especially if the granulations are very numerous.

Both of these methods are so heroic, that surgeons must be strongly convinced of their utility and of the necessity for having recourse to them before they are likely to be generally employed. Meanwhile, it is interesting to note, that MINOR, in the *New York Medical Journal* for July 31, 1886, reports that he has had most excellent results with powdered boric acid dusted over the conjunctiva two or three times a day, or less frequently. The application causes pain lasting about thirty minutes, and a free serous discharge, which is soon followed by relief. The improvement in the conjunctiva and the clearing up of the cornea may not be very noticeable for a week, but after this time it will be apparent. Minor has found that boric acid ceases to be tolerated after three or four weeks, when some other drug must be substituted.—*Medical News*, October 2, 1886.

BACTERIUM TERMO TREATMENT.—DR. ROQUER Y. CASADESUS, of Barcelona, having a case of laryngeal and pulmonary phthisis of an advanced character, and wishing to test the value of Cantani's bacteriotherapeutics, asked Dr. Rodriguez Mendez, a well-known microbiologist, to assist him. The condition of the patient was carefully ascertained in consultation, cavities being found in both apices. There was a high temperature, also profuse sweats, diarrhoea, profuse expectoration, great dyspnoea—in fact every sign of acute pulmonary tuberculous degeneration. The patient was in the seventh month of pregnancy. A pure culture of bacterium termo was then prepared by Dr. Botey, and made use of both by means of inhalations twice a day and by intra-laryngeal applications. After a few days the patient's condition was improved, the temperature having fallen from 39° to 38 or 38.4° C. This improvement continued till labor came on, which was of a normal character, but shortly after delivery the woman's condition became alarming, and she died in twenty hours. Dr. Roquer concludes from this case that, whether the remission of temperature was or was not due to the treatment, the bacterium termo was perfectly innocuous, as Professor Cantani states it to be. Dr. Phillipovich, who has made several trials of the treatment of phthisis by the inhalation of cultures of bacterium termo, has published a paper describing the results obtained in the reports of the Odessa Medical Society. In one case the inhalations had to be stopped in consequence of the condition of the patient becoming worse, three cases died, and two were discharged. Dr. Phillipovich's observations agree in general with those of Dr. Görbersdorf, and are decidedly inconsistent with those of Professor Cantani. The expectoration did not diminish, but it was rather more easily secreted, and so the dyspnoea was less. This, however, was probably due to the action of the water and the better aeration of the lungs, rather than to the microbe. In one case the quantity of sputum was increased, and

it became more liquid and very offensive. At the necropsy in this case cavities were found containing tolerably pure cultures of bacterium termo. In none of the cases did the tubercle bacilli in the sputum disappear or even diminish, though the inhalations were continued for seven weeks. Again, no effect was produced on the temperature or sweats, and in all the patients there was noted a greater or less loss of weight. The author concludes that no beneficial effect can be looked for from the use of this method of treatment; indeed it would rather appear, from the post-mortem appearances above mentioned, that inhalations of bacterium termo may be positively hurtful to the human organism.—*Lancet*, Aug. 21, 1886.

SPINA BIFIDA SUCCESSFULLY TREATED.—MR. JOHN KELLOCK BARTON, in reporting this case, says: Inasmuch as the treatment of spina bifida is still unsettled, any case in which a successful operation has been performed is worthy of record. So, very briefly, I will state the particulars of the following case which has been lately under my care in the Adelaide Hospital.

On July 9, Susan H., an infant 2 weeks old, was brought to the hospital by her mother, who had been attended in her confinement by Mr. Hamilton, a pupil of the Adelaide. He had noticed at the time of birth a tumor in the lumbar region, about the size of a small walnut, of a dark purple-red color. This tumor steadily increased in size, and at the time I made my first examination was the size of a small egg, or might more accurately be likened to the half of a small orange, the convex part projecting, the flat or cut surface of the orange attached to the lumbar spine. The surface of this tumor was occupied by a greyish sloughy ulceration, while the sides were of a deep purplish-red color. Fluctuation was very obscure, but pressure certainly diminished the bulk of the tumor, which regained its original size quickly when the pressure was removed. The nature of the tumor, so far as that it was a spina bifida, was pretty clear; but to make this more certain I thrust a fine hypodermic needle into it, and drew out a few drops of a perfectly colorless serum. The question of its being a spina bifida was now established, but the further and more difficult one of whether the spinal cord formed any portion of its contents remained doubtful. The fact that no paralysis existed, either of the sphincters or lower limbs, induced me to believe that this was a meningocele, and not a myelocele; but the facts of its low position and of its purple and ulcerated surface are held by authors¹ as leading to an opposite conclusion, and the result proves that the freedom from paralysis is of more diagnostic value in deciding this important point than is either the situation or the character of the tumor.

Next day, I performed the following operation, the infant being under the influence of chloroform. I cut an elliptic piece out of the centre of the tumor, thus removing all the sloughy central portion; the wall was thick, internally smooth and white, and with numerous small nerves passing into the portion removed, which were of course cut across. Very little

time was lost in stopping all bleeding, which was insignificant, and then drawing together the thick purple flaps left on either side by a double row of sutures. Careful antiseptic precautions were observed, and the dressing consisted, first of all, of a dusting with iodoform, then a covering of corrosive gauze (1 in 400), secured well at its edges and round the body with an antiseptic gauze bandage. There was no elevation of temperature, and union was complete and firm in a week. No signs of any disturbance of the nervous system followed.

In ten days the infant was discharged cured. I questioned the mother as to any loss of power in the limbs, of which the child has free use. The situation of the tumor is now occupied by a puckered purple oblong swelling, about one-sixth the size of the tumor which I operated upon, and I have no doubt further contraction will go steadily on for some time.

P.S.—Since this report was written I have received information of the death of the child in a fit of convulsions. No doubt the union of the operation-wound was complete, but the convulsive attack came on too soon after the operation for us to dissociate the one from the other.—*Lancet*, October 2, 1886.

TREATMENT OF SYPHILIS BY INTRAMUSCULAR INJECTIONS OF MERCURY.—MR. J. ASTLEY BLOXAM states that over fifteen hundred patients have been treated by this method, at the Lock Hospital and elsewhere, during the past eighteen months, with the best results. The solution for injection contains 6 grains of the bichloride to the ounce of distilled water, and of this 20 drops constitute a dose. The sore generally begins to heal very promptly after one or two injections, the secondary symptoms are markedly modified, and after a course of treatment extending over a year, more or less, the patient is enabled to discontinue his attendance. Toward the latter end of the course of treatment the injections may be given less frequently, and, as a general rule, not more than from 8 to 12 grains of the perchloride are injected in all. It is undesirable to repeat the injections oftener than once a week, as otherwise salivation might be induced, and the quantity injected each time ($\frac{1}{3}$ of a grain) is found to be quite sufficient until the next time. There are several advantages attending this method of exhibiting mercury. In the first instance, it is only necessary to see the patient once a week, when sufficient mercury is injected to last until the following week; secondly, salivation is not produced, as was apt to happen when the patient continued to take mercury for a whole week away from the supervision of his medical attendant; thirdly, the gastric derangements which are so apt to follow the administration of mercury by the mouth are by this means avoided; lastly, the ease and certainty of the administration, which enable the surgeon to do his own dispensing with a minimum of trouble. A little quinine is generally given during the course as a tonic, but no other form of mercury is administered. The injections are made preferable deep into the muscular mass of the glutei; the pain following is slight and soon passes away, and there is no danger of an abscess. It is desirable that the

¹Dictionary of Practical Surgery, vol. ii., p. 470.

patient should not take active exercise immediately after the injection, as it has been noticed that blood may be effused at the point of injection, giving rise to the sensation of a severe bruise of the part, which lasts for a few days. The same effect has followed the puncture of a large vessel, but in any case the result is only transient, and disappears after the lapse of a few days.—*Medical Record*, October 9, 1886.

LOCAL ANÆSTHESIA FOR ELECTROLYSIS.—DR. FRANKLIN H. MARTIN, of Chicago, says: "Where it is necessary to use a very strong current of electricity for purposes of electrolysis, or any other purpose, and a reliable means of measuring the current, other than by the sensations of the patient, is at hand, it is very desirable, oftentimes, to have some means of producing anæsthesia. Especially is this the case with women who have been brought to an anæmic and nervous condition from menorrhagia coincident with a fibroid growth of the uterus. In these cases where electro-puncture is used as a means of removing the growth, or even where the somewhat milder electrolytic current is employed for the purpose of causing absorption of inflammatory exudates, there is a very disagreeable burning sensation experienced at the positive sponge electrode. By utilizing the properties of the galvanic current, discovered by Haertner, viz., the direct transference by the galvanic-current of particles in solution through permeable bodies, in a direction from the positive to the negative pole of the battery (the *cataphoric* action of Du Bois-Raymond), a very satisfactory condition of local anæsthesia can be accomplished. The method adopted is as follows: Before applying the positive sponge electrode to the surface moisten the sponge with a $\frac{1}{4}$ of 1 per cent. solution of muriate of cocaine. As the current is turned on, it will be found that the absorption of sufficient amount of the cocaine is immediately promoted to produce a complete state of anæsthesia of the surface beneath the electrode. This, of course, does not affect the point of application of the negative pole—the point of introduction of the needle. Cocaine can still further be utilized here by injecting hypodermatically a small quantity of the aqueous solution at the point of introduction of the needle through the skin, or by applying a solution of the oleate upon the mucous membrane of the vagina or uterus, if the needle is introduced in this location. By bearing these simple facts in mind, electrolysis for fibroid tumor can be made familiar without the necessity of administering a general anæsthetic."—*Medical Record*, October 9, 1886.

SALOL, A NEW ANTI-RHEUMATIC AND ANTISEPTIC.—DR. SABLİ has discovered a new compound in which salicylic acid combines with phenol, to which he has given the name of salol. It is a white powder, tasteless, with a slight aromatic smell, insoluble in water, but soluble in alcohol. The author made several experiments on animals with the drug, and found that the total quantity given with the food could be detected in the urine. Decomposition takes place within the body, through the influence of the pancreatic juice, when the drug passes through the stom-

ach unchanged, which may account for the absence of nausea and vomiting. Sabli did not encounter any unpleasant symptoms with 4 grammes (3j) daily, and he himself took as much as eight grammes (3ij) in one day, without experiencing any noises in the ears. It did cause noises in the ears, however, in some patients, but not to the same degree as salicylate of sodium. Under the administration of salol the urine becomes dark, as it does when carbolic acid is given.

The author has given salol in all rheumatic affections, and has attained, at least, the same results as he would have with salicylate of sodium; if anything, the fever seemed to subside more rapidly under the former. A case of chronic urticaria which had resisted all other treatment was rapidly cured with salol, as were also several cases of orbital neuralgia. Salol, in 2-gramme (gr. xxx) doses, three to four times daily, is a powerful antiseptic. In phthisis it is better to begin with small doses (gr. vijss). The author recommends it in diabetes, and, on account of its antiseptic qualities in diarrhoea, typhoid fever, cholera, and cystitis, and as a surgical dressing instead of iodoform. He has had a good result with it in one case of ozæna. It can be used locally in gonorrhoea. To the alcoholic solution some water may be added and an emulsion is thus formed.—*New York Medical Journal*, Sept. 11, 1886.

EXPOSURE TO THE SUN IN CHRONIC HYDROCEPHALUS IN CHILDREN.—This means of treatment has been rarely tried, or even mentioned by writers on pediatrics. Locatelli, of Milan, reports one case which was thus cured, and Nicita of the same city reports three cases. Several of the ancient and early writers expressed the opinion that heat applied to the head would effect a cure. Somma has treated five cases with the following results:

1. *Hydrocephalus Externus*.—Treated with solution of phosphate of lime, vesicants upon the scalp, exposure to the sun for periods of fifteen or twenty minutes. Cured.

2. *Hydrocephalus Internus*.—Iodide of potash, solution of phosphate of lime, exposure to the sun. Cured.

3. *Hydrocephalus Internus*; also paresis of the lower extremities and pulmonary catarrh. Exposure to the sun, with improvement for five months, finally death from broncho-pneumonia.

4. *Hydrocephalus Externus*.—Exposure to the sun. Cure after three months.

5. *Hydrocephalus Externus of Syphilitic Origin*.—Iodide of potash and calomel, acid calcium phosphate and exposure to the sun. Cured.

The following method of exposure to the sun was followed:

An attendant held the child with uncovered head, the occiput being turned toward the solar rays, the position being unchanged for half an hour or less. After four or five days the duration of exposure was increased to forty or fifty minutes. Of course this method did not apply during the cold of winter or the excessive heat of summer.—*Archives of Pediatrics*, April, 1886.

FEEDING INFANTS—AN IMPORTANT ERROR.

At the recent meeting of the British Medical Association in Brighton, DR. R. P. B. TAAFFE, President of the Section on Public Medicine, in his opening Address to his Section discussed several topics of much interest. After mentioning the efforts that had been made to destroy or abate the coal-smoke and to purify gas, he showed from the vital statistics furnished by the Registrar-General that the annual death-rate in England and Wales during the decennial period ending 1880 was 21.27, instead of 22.4, which it had been for the three preceding decades. He showed further that for the last half decade ending with 1885 this mean death-rate had fallen to 19.3 per 1,000. The details indicated that the greater part of the improvement had resulted from the diminished mortality in childhood caused by improvements in the sanitary conditions affecting the poorer classes.

Following the discussion of general vital statistics, Dr. Taaffe presented some important facts concerning the mortality from infantile diarrhoea. Of 582 deaths from diarrhoea at all ages recorded by himself in seven years, 526 occurred among children under five years of age, and of the latter 433 were children under one year. Of 441 children who died under five years, concerning whose feeding special inquiries were made, 49 only were nursed wholly by their mothers, while 392 had been "fed more or less artificially." Of these, 269 were fed on milk from the bottle; 40 were nursed by the mothers and fed also upon artificial foods; 64 were fed partly on milk and partly on artificial foods; and the remaining 21 were fed on artificial foods, such as oatmeal, arrowroot,

corn flour, baked flour, Ridge's and Mifflin's foods, tea-cakes, tops and bottoms, bread-sop, and beef-tea. Dr. Taaffe, after condemning the practice of either feeding or nursing infants too frequently, gives the following directions: "No infant at the breast, or who is being brought up by hand, should be fed more than once in *three* hours during the day and twice in the night; after five months old every *four* hours in the day and twice in the night. If brought up by hand, the food should consist only of milk and water, to be sucked from a bottle. For the first day or two (after birth) the proportions should be—milk one-fourth, water three-fourths. After the first day or two, and up to two months old, milk one-third, water two-thirds; from two to four months old, milk and water in equal parts; from four to seven months old, milk two-thirds and water one-third. A dessert-spoonful of sugar of milk may be added to each bottle."

We have copied these directions from the otherwise excellent address of Dr. Taaffe, not because they are new, for they are substantially the same as have been given by many writers, and which mothers and nurses have endeavored to execute in their care of infants for half a century at least, but because careful clinical observation over a wide field of practice long since taught us that they contained an error of very great practical importance—namely, the excessive *dilution* of the food of infants. Our attention was attracted to this subject at an early period, and more than thirty years since, in addition to careful clinical observation, we prosecuted investigations, chemical and microscopical, concerning the mother's milk in healthy uncomplicated lactation and also when complicated with menstruation and pregnancy.¹ In the same connection we prosecuted inquiries concerning the effects of various degrees of condensation and of dilution of pure milk of the cow as food for infants. The analyses of the milk of three healthy mothers with healthy nursing children, one in the third month of lactation, one in the fourth and one in the seventh, gave a mean composition in 1,000 parts: Water, 878.07; casein, 49.78; butter or oil, 35.53; sugar and extractives, 32.15; and salts or inorganic matter 4.31. In other words, the proportion of assimilative or nutritive matter to the water, was little more than 1 to 7. According to the analyses of Payen,² good cow's milk contains in 1,000 parts: Water, 864.0; casein and lacto-protein, 43.0; butter or oils, 37.0; sugar or lactine, 52.0; and salts or inorganic matter 4.0; being in the proportion of 1 part of assimilative material to 6.3 parts of water. It is thus seen that

¹ See Transactions of the American Medical Association, vol. ix, p. 427, 1856.

² See Flint's Physiology of Man, Volume on Alimentation, etc., p. 78.

the excess of assimilative or nutritive material in the cow's milk is less than four-tenths of one part, which is less than the differences often found between different specimens of healthy human milk.

Suppose, in applying the rule given by Dr. Taaffe, we commence the day feeding of a child under two months old at 6 A.M. and end it 9 P.M., and add two feedings for the night, it would allow eight feedings every twenty-four hours. If we allow four ounces for each feeding, which is a large allowance for an infant of less than two months, it would get thirty-two ounces per day of twenty-four hours; four ounces of which would be nutritive matter and twenty-eight ounces water if it were good mother's milk, and a fraction more if it were good cow's milk. If we may suppose the infant able to appropriate the whole four ounces in the twenty-four hours and lose in the same time by eliminations or waste two ounces, it would grow, or gain in weight, two ounces per day, or at the rate of nearly four pounds per month. But if we comply with the rule and make the milk two parts water to one of milk and still allow the infant four ounces each feeding, or thirty-two ounces per day, instead of four ounces of nutritive material and twenty-eight of water, it would have received only $1\frac{1}{3}$ ounce, of nutritive matter to $30\frac{2}{3}$ ounces of water; and if, as in the former supposition, the infant lost by elimination or waste two ounces per day, instead of gaining an aggregate of near four pounds per month it would actually have lost one pound and a quarter during that time. And such has been the actual tendency of every attempt we have seen made to literally adhere to the rules given in the Address mentioned, although many such have come under our observation during the preceding thirty years. The suggestion of Dr. Taaffe that a dessertspoonful of sugar of milk might be added to each bottle of the diluted milk would only tend to restore the natural proportion of this ingredient, while the proportion of caseine, butter and salts would be largely deficient, and the water in proportionate excess. An infant thus fed with milk containing only one-half or one third of the proportion of solid or nutritive constituents belonging in the natural mother's milk, soon begins to be restless and in less than an hour after feeding is fretting and crying for more. If the mother or nurse yields to its demands its stomach is kept almost constantly filled with the attenuated fluid, which either soon encourages the rejection of much of it by vomiting or diarrhoea, or if absorbed renders the watery element of the blood greatly in excess, and two or three months suffices to bring the child to a state of complete emaciation, the mother and

nurse worn out with the fruitless effort to pacify the child's almost incessant worrying; or with less patience they have obtained rest for an hour or two at a time by adding either the anæsthetic effect of a few drops of brandy or whiskey to the child's milk, or ample doses of opiates in the form of cordials and soothing syrups.

We have seen scores of these little sufferers soon restored to the condition of quiet, cheerful, thriving babies by simply insisting on their being fed with milk containing the full natural proportion of solid elements, and sometimes slightly increasing these by either boiling enough to evaporate some of the water, or by adding a very little wheat flour and a few grains of salt while the milk was boiling. The child thus getting enough nutritious material to supply the demands of its tissues in a less bulk of water, yet easy of absorption and assimilation, avoiding over-distension of the stomach, takes long quiet sleeps, and grows fat and happy.

HYSTERICAL SOMNOLENCE AND TRANCE.

The *London News* contains the history of a very curious case in the Salpêtrière Hospital of Paris. The patient, Eudoxie Hedouin, a woman of 51 years of age, has recently had two periods of morbid somnolence, one of fifty days, the second of eighteen days. This, however, seems to be nothing new for her. As a child she was hysterical; and at the age of 22 she entered La Salpêtrière to be treated for paralysis, doubtless of hysterical origin, and it is said that she has not yet recovered from this. In May, 1875, she fell into a state of trance which lasted only two days. On May 12, however, she went into another trance from which she did not awaken until May 27. On the next day she took a full meal; laughed violently, and then became delirious, which scarcely leaves a doubt that her trouble was purely hysterical in origin.

In the last state of trance, lasting eighteen days, Dr. Voisin ascertained that she was not unconscious to her surroundings, and that she could be made to obey a command. He placed a paper containing a drug on the skin of the patient without saying anything; no effect followed. This being removed, a piece of folded paper, empty, was placed on the skin, and the remark made that she would surely vomit. Ten minutes afterwards she vomited. In some respects this case resembles one of hypnotism. She was given a glass which she was told was filled with champagne, though it contained nothing; she eagerly drank the supposed wine. A piece of aloes was given her in place of sugar, and she scarcely seemed to detect the difference.

Trance has been defined as a condition of the nervous system characterized by general muscular immobility, complete mental inertia, and insensibility to surroundings. This definition cannot be accepted, however, as there is often some degree of muscular mobility, the mind is not always completely inert, and the statements of the patients show that they are not by any means always insensible to surroundings. Thus, in the case of the hystero-cataleptic girl in Nebraska, (reported in Pepper's System of Medicine, Vol. V, page 344) she said that she was conscious during the whole time of her trance of seventy days, but that she could not move a muscle, although she exerted her will to the utmost to show that she was conscious. The fact is, it is very difficult in all cases to draw a hard and fast line between trance and a prolonged somnolence, since the same patient may be affected in slightly different ways at different times. Two years ago Dr. Charles L. Dana reported fifty cases of prolonged morbid somnolence. Briquet very properly draws a distinction between prolonged hysteria (or somnolence) and lethargy, as the patient may have periods of sleep within the lethargy. A most interesting case is reported in the *British Medical Journal*, of December 12, 1885, by P. J. Cremen, under the name morbid somnolence. The patient seemed to be in a deep sleep from which he could not be aroused, or as one under the influence of an anæsthetic; and he could not be awakened. At first he was analgesic all over the body, but sensibility returned, as he was able to eat when bread was put into his hand, and he was seen to eat in the somnolent state with the eyes closed. A strong magneto-electric current would arouse him. When told to do so he could walk, but only in a straight line, and he took no pains to avoid obstacles. This somnolent state could be induced at will by pressing on the closed eyes for about two minutes. A very interesting case is recorded in the Transactions of the Royal Society of Edinburgh (Vol. VIII). She remained in a somnolent state from July 1 to August 8. She was bled, blistered and bathed in order to awaken her, but all to no purpose. After having slept for seven days she showed signs of wanting food. She was deaf while in this state until four days before she recovered. When she awakened fully she said that she had no knowledge of what had occurred, even of the blistering and bleeding. In this case also there was some degree of paralysis, which was probably hysterical.

According to Rosenthal, lethargy is never fatal when complicated with hysteria, but uncomplicated with this affection it is rapidly fatal. He records a

case in which a young woman remained in this state for thirty hours, and afterwards enjoyed good health. The attack was induced by violent emotional excitement. This case will not fall at all within those cases of morbid somnolence of which we have spoken, but it shows to what conditions an excitable, nervous system may subject a person.

THE INTERNATIONAL MEDICAL CONGRESS.

The Executive Committee of this body, to whom has been entrusted the work of organizing and developing the interest of the profession in making this Congress fully equal to any previously held, have lately shown their interest in the work by sacrificing private engagements, and at their own expense travelling from distant points to meet in general session in Pittsburgh. The meeting was fully attended, and the various reports of the sub-committees and the extensive correspondence of its chairman all showed the advance made in the perfect organization of the Congress. All the Sections of the Congress reported highly satisfactory progress in the appointment of Sectional officers, and the promise of original papers of a high class. The various officers of the Sections, including members of the Council, now exceed three hundred and seventy-five well-known members of the medical profession in the United States. Numerous appointments to Sections have also been accepted by prominent members of the profession in Great Britain, France, Belgium, Holland, Germany, Brazil, and other countries; so that there can now be no doubt as to the international character of the Congress.

Among those recently accepting office as Vice-Presidents of the Congress we note Sir B. Walter Foster, President of the Council of the British Medical Association; Mr. Ernest Hart, Editor of the Journal of the British Medical Association; Sir Thomas Longmore, Surgeon-General (retired) of the British Army; Sir Joseph Fayrer, Surgeon-General of India; Mr. John Eric Erichsen, Sir Dyce Duckworth, and Mr. Jonathan Hutchinson, of England; Professor Dujardin-Beaumetz, M. Bouchut, M. Cadet de Gassicourt, and M. Grancher, of France; Professor Moncorvo, of Rio de Janeiro; M. Servais, of Belgium; Alfred Vogel, of Germany, with many others equally well-known.

As the Executive Committee will continue to quietly prosecute its work, with the sole object of maintaining the honor of the profession in the United States, and making good the invitation given and accepted in 1884 at Copenhagen, and in 1886 at Brighton, we anticipate a result in every way creditable to

our countrymen, and a proper compliment to our guests. Arrangements are under consideration for reduced fares on steamships and railways, and in hotels; and we feel assured that not only will our visitors find all arrangements thoroughly perfected for their pleasure and comfort, but an opportunity to visit this new and extensive country at greatly reduced rates of travel, and under the most favorable circumstances.

SOCIETY PROCEEDINGS.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Regular Meeting, September 17, 1886.

THE PRESIDENT, DANIEL T. NELSON, M.D., IN THE CHAIR.

W. W. JAGGARD, M.D., EDITOR.

DR. JAMES H. ETHERIDGE read a paper entitled

REPORT OF A CASE OF SUPRA-VAGINAL AMPUTATION OF THE PREGNANT UTERUS, COMPLICATING A MULTILOCULAR FIBROID TUMOR.

Mrs. A. B., aged 34 years, married several years, no children, first experienced uterine symptoms some four years ago, which Dr. Knox, her medical attendant, recognized as due to a uterine retroversion, and treated with a pessary for six months. On March 10, 1884, he was again called to her, and found the uterus again retroverted. "This time, however," he writes, "it was apparently fixed in the pelvis; the *os tinca* was caught firmly behind the pubes, and in Douglas's *cul-de-sac* was a firm sensitive mass that seemed to be more than the *fundus uteri*. There was also considerable abdominal tenderness, fever, and nausea. It was difficult to diagnose between cellulitis and simple retroversion with impaction. Careful manipulation, however, in Sims's position, corrected the displacement with complete relief of the distressing symptoms. Hot fomentations and vaginal douches aborted the threatening cellulitis. Two days thereafter, on careful examination, I detected a sub-peritoneal myoma on the left posterior aspect of the fundus. It was about half the size of an unimpregnated uterus. This accounted for the tight impaction of the retroverted organ.

"A pessary was again introduced, and 20 minim doses fluid extract of ergot, three times a day, ordered. The drug was faithfully taken for about twelve months. During that time a second fibroid appeared upon the right lower and anterior surface of the womb. These tumors steadily enlarged until the uterus was lifted entirely out of the pelvis. Excepting the results of mechanical pressure, the patient's health was excellent, and menstruation was undisturbed.

"April, 1885, the ergot was discontinued. Owing to the sub-peritoneal character of the fibromata their growth was uninfluenced by the drug."

The growth of the tumor in the last two years has

been slow but progressive. In the last six months it caused no special symptoms beyond vague supra-pubic pains at times.

In May, 1886, thirteen months after the stopping of the use of ergot, Dr. Knox was again summoned to attend her for a distressing nausea. At the same time the menses, which had never been excessive, ceased. Mammary changes supervened.

In the ensuing three months the tumor grew rapidly. To Dr. Knox must be ascribed diagnostic skill of the highest order in determining the presence of pregnancy in such a mystifying condition of things. He decided that she must be pregnant, and awaited the expiration of the first three months to produce an abortion, hoping thereby to induce involution to such an extent as, at least, to arrest the rapid increase in the growth of the tumor. Accordingly, on Aug. 1, 1886, when the three months had expired, he introduced a sound into the uterus four inches. Its withdrawal was followed by a small amount of blood, the nausea and vomiting ceased, and the mammary symptoms disappeared. Nothing further ever followed indicating the previous existence of pregnancy or an abortion, and the conclusion was reached that conception had not occurred.

The rapid encroachment on the abdominal organs was progressively killing her. Her strength had greatly diminished. For six months she gradually emaciated. Her sufferings from the pressure of the tumor were great, and eventually led to her giving up and remaining in bed nearly all the time because she thus experienced the most comfort. In addition she was easily put out of breath by exertion.

Forty hours before the operation she had a free purge, and twenty hours later she went to the Presbyterian Hospital to remain overnight, to receive a bichloride of mercury bath and to have her pubes shaved.

At the time of the operation she presented the following measurements:

1. Girth at the umbilicus, 31 inches.
2. From ensiform cartilage to umbilicus, 7 inches.
3. From umbilicus to symphysis pubis, 6.5 inches.
4. From either ant. sup. spin. proc. to umbilicus, 7 inches.

From external examination it was found that the tumor extended from the right iliac fossa across the abdominal cavity in a straight line to the spleen. Its length was, apparently, double or treble its width. It was freely movable, free from adhesions, and solid. It presented great tenderness in the right iliac fossa.

Per vaginam the *cervix uteri* was found very high up in the left iliac fossa and the *fundus uteri* was apparently thrust into the right iliac region. The whole tumor moved with the uterus. A very small resiliency offered to conjoined manipulation led me to think that I had to do with a *fibro-cystic tumor of the uterus*. The sound entered the uterus four inches and seemed to pass towards the umbilicus.

Just before commencing the operation a sound introduced into the bladder showed that this viscus was not enlarged by being drawn up out of the pelvis by the growth of the tumor.

At the same time, the sound was introduced into

the uterine cavity and entered only four inches. It had to be bent at an obtuse angle to make it engage in the cervical canal. Its introduction was attended with a small hæmorrhage, which subsequently was the innocent cause of severe but brief alarm.

The instruments used in the operation were dipped in a five per centum solution of carbolic acid, and subsequently kept in a two per centum solution of the same agent when not in actual use. No spray was used. The sponges were antisepticised with carbolic acid. The details of the operation were simplicity itself. The incision began one inch above the umbilicus and extended down to within an inch and a half above the pubes. It was carried to the left of the umbilicus and measured six inches. Upon exposing the tumor it was found wholly free from adhesions. It extended to, and pressed upwards, the spleen. It was oblong, its length being about treble its width. It was situated obliquely across the whole abdominal cavity. Its upper end was easily turned out of the abdomen, and the whole mass was lifted out of its bed. Its smooth, red surface nowhere indicated the outline of the uterus. Its lower end seemed to be one solid mass of pedicle extending completely across the whole inlet of the pelvis from side to side. The laminae of the right broad ligament were separated in the most conspicuous manner that I ever beheld. The two ovaries were attached to the mass on a level with the umbilicus, having been lifted completely up into the abdominal cavity.

After buttonholing the capsule of the tumor as low down as was practicable, it was peeled off as far as the finger could reach right and left, and ligatured in small masses in two places an inch or more apart and then divided between the ligatures. In this way all of the capsule that could be secured in ligatures and cut was soon treated, and the hæmorrhage from the operation was barely worth mentioning. The right uterine artery, which was much enlarged, was torn across and quickly secured. All of the spermatic and uterine arteries were secured with double ligatures of No. 14 silk. Thus the apparently large pedicle was much reduced in size and was found to be about equal to the normal *corpus uteri*.

Around this mass was placed a Kœberlé's *serre-nœud*, which was properly tightened, and the tumor excised. Small vessels were then secured. The clamp was then slowly loosened and the vessels of the stump were tied.

The cervical canal was conspicuously visible in the centre of the stump. It was drawn up by a vulsellum as tautly as possible and excised for the length of at least one inch. The piece removed was cone-shaped, with its base upwards. Six stitches were then used, from side to side, placed so that when tightened the peritoneum was accurately brought together over the top of the stump. They were tied as tightly as they could be drawn. All further bleeding was attended to *secundam artem*, and the abdomen closed with nineteen stitches. The initial incision was made at 10:30 A.M., the stitches were begun at 11:42 A.M., and the operation was completed at 12:01 P.M.

She rallied from the operation in a few hours. For a period of four days afterwards she had a most intractable vomiting. After feeding by the rectum and permitting absolutely nothing to pass her lips, this troublesome symptom slowly diminished and gradually disappeared, but not until she had acquired a slightly pinched condition of the *ala nasi*, which brandy caused to disappear. On the third day an offensive odor proceeded from the vagina. A carbolic solution permanently corrected it. It must have arisen from decomposition of the small amount of blood provoked by the introduction of the uterine sound.

Thereafter naught especially eventful occurred to direct attention to, excepting the following points:

1st. The patient never had an alvine defecation after the operation. Flatus passed only after the colonic distension permitted it, through a rectal tube. Repeated efforts were made to secure defecation, without result.

2d. At no time after the operation did she have a chill or sweats. The days were very hot and her greatest comfort was in being gently fanned and in dabbling her hands in a bowl of water placed at her side.

The following record of pulse, temperature and respiration was kept till the death of the patient, which occurred eleven days and nineteen hours post operation.

August 19.—1 A.M., T. 102°. Death at 6:45 A.M.

The autopsy was made thirty-two hours after death, and revealed a pelvis filled with fluid consisting of blood and pus. The small intestines were agglutina-

ted over the pelvic inlet, almost hermetically. The surfaces of the small intestines turned towards the cavity of the pelvis presented a condition of sphacelus approaching demarcation. The pelvic cellular tissue was completely honeycombed with pus cavities. The stump presented a shrunken appearance, as though all of the stitches had been loosened, yet no pelvic fluid had found its way into the vagina through the cervical canal. The patient had succumbed to septicæmia. I regret that I did not drain.

Examination of the tumor revealed the fact that it was a multilocular fibroma, and that it grew from the anterior wall of the *corpus uteri*. The cavity of the uterus was found on a level with the umbilicus and contained a three months foetus in unruptured membranes, evidently alive up to the time of operation. The cervical canal was $5\frac{1}{2}$ inches long, which fact explains the immunity of the membranes from puncture by the introduction of a sound only four inches. The canal resembled the letter U, with its legs pulled apart, starting from the extreme left iliac fossa at the *os uteri* it passed towards the umbilicus two inches, and was then deflected at an obtuse angle towards the spleen. *

Upon laying open the uterine cavity it was found to be in appearance a cavernous hollowing out of the posterior surface of the tumor. In front of it was nearly the whole width of the tumor. Its posterior boundary was a wall of uterine tissue thinner than the normal, unimpregnated posterior uterine wall. It was situated in the middle of the tumor.

The membranes presented a leaden grayish appearance, and were filled with fluid, its smooth undulating surface, in contrast with its nodular surroundings, looking not unlike the surface of "The Devil's Punch Bowl" on the top of Mt. Mangerton.

The foetus was a male. Its cord was seven inches long and was normally attached.

Microscopic examination of the tumor by Dr. Ochsner shows its character to be purely *fibromatous*. Its weight was about ten pounds.

Remarks.—The removal of fibroid tumors which are slowly but surely killing patients has now passed into the category of recognized and justifiable operations. The astonishing successes of Keith in removing them are sufficient guaranty of justification for removing such growths under proper conditions.

But the complication of large fibrous tumors of the uterus with pregnancy presents the gravest possible condition for the surgeon's consideration. Conception seemed to give an impulse to the rapidity of the growth of the tumor under consideration that was very surprising. The arrest of its growth or its removal were the two horns of the dilemma. Against the production of abortion there are serious objections. It is followed by disproportionately great dangers and cannot possibly lessen the size of the growth materially. The possibility of uncontrollable hæmorrhage from the seat of the placenta on a non-contractile mass of tumor must be faced in producing an abortion. In addition the dangers of septicæmia from puerperal disintegration of the tumor are not to be forgotten. While running the two risks of hæmorrhage and septicæmia from producing an abortion

there is the very great possibility of avoiding a future extirpation of the whole mass by inducing a cessation of growth of the tumor, or even possibly by inducing a greater or lesser involution of the growth. The examination of the tumor shows conclusively that the uterus could never have extruded the foetus and its adnexa through the elongated cervical canal because of the inutility of the uterine muscular fibre through fibromatous degeneration. Consequently abortion would in all probability have proven fatal through septicæmia. I am thoroughly convinced that the patient could not have lived many weeks longer without the death of the foetus, when the overwhelming disaster of fatal sepsis would have speedily ensued without any compensatory explanation short of an autopsy, since the idea of pregnancy was about abandoned because abortion failed to occur; and the non-appearance of the foetus *per vias naturales* would afford no satisfactory evidence of what had occurred, but quite to the contrary would have rendered a mysterious case much more mysterious. In such an event, *sine autopsy*, the pathological reasoning would have been that spontaneous necrosis of the fibroma had occurred and septicæmia followed.

References.—Hegar and Kaltenbach report six cases in the third edition of their "*Operative Gynecology*," 1886, as follows:

Author.	Date.	Time of pregnancy.	Character of Tumor.	Result.
Kaltenbach	Mch. 2, 1880	Fifth month	Myoma	Recovery
Wasseige	Mch. 18, 1880	Fifth month	Myoma	Death 6th day
Nieberding	May 10, 1882	Fourth month	Myoma	Death 40 hours P. O.
Schroeder	June 21, 1884	Third month	Myoma	Recovery
Schroeder	June 10, 1884	Third month	Myoma	Recovery
Walter	1883	Fourth month	Colloid	Death 9th day

Case 7.—Dr. H. R. Storer amputated the pregnant uterus, in a primipara, æt. 37 years, after three days of labor had passed, for a fibro-cystic tumor. The pedicle was constricted by a double metallic ligature and kept outside. The patient died in seventy hours of septicæmia. (*Journal of Gynecological Society of Boston*, Oct., 1869, p. 223.)

Case 8.—Prof. S. Tarnier, Neuilly, France, on February 24, 1879, removed the uterus from a primipara æt. 33 years for a fibrous tumor of the uterus, after the patient had been in labor seven days. Condition of patient at the time of operation, very unfavorable. The foetus was putrid, gas in the uterus having been found. Pedicle was kept out with a metallic pin and metallic ligature. Patient died of septicæmia on third day. (*Annales de Gynécologie*, Aug., 1879, p. 81.)

Case 9.—Dr. Zweifel, of Erlangen, Germany, on July 31, 1880, removed, from a primipara æt. 37 years, the uterus, several hours after labor began, because of a fibroid tumor in the cervix. Patient died on the sixth day of septicæmia. The pedicle was tied with double silk ligature. (*Archiv für Gynäkologie*, B. 17, H. 3.)

Case 10.—Prof. Cataliatti, of Palermo, Italy, on October 28, 1880, removed the pregnant uterus from a primipara æt. 41 years for an interstitial fibroid of the posterior uterine wall soon after the inception of labor. The pedicle was kept outside with wire ligature and transfixed with metallic pin. Recovery fol-

lowed. (*Bulletin dell. Accademia di Medicina di Palermo*, 1880.)

Case 11.—Dr. L. Prochownick, of Hamburg, Germany, performed hysterectomy, April 21, 1881, on a primipara æt. 40 years, at seventh month, about twenty-four hours after the discharge of the liquor amnii, for a fibromyoma of the uterus impacted in the pelvis. The pedicle was held out of the abdomen with Péan's constrictor, two long pins and stitched to the lower angle of the wound. The patient died in sixty hours p. o. from septicæmia. (*Deutsche Medicinische Wochenschrift*, No. 40, 1882.)

Case 12.—Dr. Fochier, Lyons, France, on November 23, 1882, amputated the uterus at term, after the patient had been in labor three days, for a fibroid in the uterine cervix. Recovery followed. It was her fourteenth pregnancy. The pedicle was kept out in the lower angle of the wound. (*Lyon Med.*, May 20, 1883.)

Case 13.—Dr. M. Hanfield Jones reported in *Transactions of the Obstetrical Society of London*, vol. xvii, 1886, the case of a woman at term in whom delivery was impossible because of a subperitoneal fibroid in the true pelvis. The entire uterus and its appendages with the tumor was removed and the cervix clamped. The patient died of peritonitis on the third day.

Case 14.—Amputation of the pregnant uterus at term, by Dr. M. Hofmeier, for fibroid tumor in the pelvic cavity. Reported by Dr. P. F. Mundé in the *American Journal of Obstetrics*, Sept., 1886, vol. xix, p. 905. Mother and child both saved.

Case 15.—Large pediculated subperitoneal fibroid. Pregnancy, two months. Removal of tumor, uterus and ovaries. Result not stated. Operator, Meredith. Reported in the *American Journal of Obstetrics*, Sept., 1886, p. 923.

DR. J. S. KNOX said: I want to call attention, in the case reported by Dr. Etheridge, to the rapid development of myomata after the establishment of pregnancy. I have two other cases of uterine fibroid that came under my care about the same time as the patient reported by Dr. Etheridge and who were treated similarly, and in whom also menstruation was not disturbed. They are still in perfect health, and the probabilities are that when they die it will be of some other disease; one being a widow, the other an unmarried woman. The growth of this myoma before us was slow but persistent, in spite of the use of ergot, and until the time the menses ceased and pregnancy commenced, the woman enjoyed perfect health, all unfavorable symptoms appearing within three months preceding operation. Another fact I would like to call attention to is the danger of abortion in such cases. With the consent of Dr. Etheridge, I delayed any operative procedures until the woman had reached the full three months of pregnancy, that I might produce an abortion; I introduced the sound with great difficulty, and passed it up full four inches; it produced considerable hæmorrhage, which continued for about three days. The nausea ceased immediately and the patient noticed a diminution of the size of the breasts and lost the sense of fullness

of the abdomen. Her appetite returned and she took a great deal of nourishment, which improved her physical condition very much. A strange result, seeing the abortion was not accomplished. In opening the tumor after its removal, I was satisfied that if I had produced the abortion the woman would probably have died of sepsis or hæmorrhage. There was no possible outlet for the contents of the uterus, and I think it was a fortunate thing that we did not succeed in accomplishing the abortion. Under similar circumstances I would prefer hysterectomy with its risks to abortion with its risks.

DR. E. C. DUDLEY said: Notwithstanding the general principle established by ovariectomy that the extra-peritoneal method is in itself dangerous, and that it should consequently be avoided whenever perfect intra-peritoneal hemostasis can be secured, and notwithstanding the fact that this general principle should stand for all operations involving the removal of abdominal tumors, yet the best statistics of the intra-peritoneal method in hysterectomy show a mortality of 30 or 40 per cent., while Keith and Bantock, with the clamp or *serre-nœud*, have a mortality of only 10 or 15 per cent. Now if it be true that certain dangers are inseparable from the extra-peritoneal method, it follows that part of this 10 or 15 per cent. of mortality must be in consequence of it, and that the statistics might still further be improved if by some means an intra-peritoneal ligature could be applied which would give the same security against hæmorrhage and permit operators to dispense with the clamp. But the dangers of the silk ligature are greater than those of the clamp because, however thoroughly applied, and however carefully the stump be stitched together, shrinkage of the stump from the escape of serum almost always occurs within a few hours, with consequent loosening of the ligatures and hæmorrhage which may be fatal at once from great loss of blood, or later from septicæmia. The indication clearly is for an elastic ligature capable of following up the shrinking stump and of securing thereby permanent hemostasis. India-rubber fulfils this indication; and if properly applied is capable of becoming readily and safely encysted. The experiments of Löwenhardt and Hallswachs, together with the numerous operations of Olshausen and others, give good evidence that the India-rubber tube when dropped into the abdomen is free from danger. It is true that certain cases have been reported in which sloughing of the pedicle has followed the application of the elastic ligature with resulting abscess, but this occurs in consequence of using a ligature of any material, so large that it cannot imbed itself in the stump, and thereby permit the surface to close over it so as to secure the prompt establishment of collateral circulation to the distal portion of the stump.

Not very long ago the question was raised whether in supra-vaginal amputation it is necessary to remove the ovaries at the same time—a question to which experience has given an affirmative answer. Péan has observed a case of catamenial hæmatocele, Hegar a case of extra-uterine pregnancy and Kalténbach a case of distressing molimen recurring monthly in consequence of leaving the ovaries after hyste-

rectomy; therefore, unless the patient has passed the menopause, they should if possible be removed on principle.

DR. H. T. BYFORD said: I would like to ask whether such ligatures as Dr. Dudley speaks of could be prepared beforehand? (Dr. Dudley: You might prepare 300 of different lengths and select the one you want.) With such a quantity of fresh ones on hand one could undoubtedly find one to use. Schroeder's later percentages are, I believe, a little more favorable than Dr. Dudley seems to think, and enable him to claim with some degree of reason, that his intra-peritoneal method is the best.

THE PRESIDENT said: One word in relation to the remarks of Dr. Dudley concerning ligature: The shoemaker's stitch, using the silk ligature, was introduced in 1881 by Dr. Marcy, of Boston. I am not informed how many times it has been used. It comes nearer obviating the difficulties of the silk ligature, I think, than any other plan in use. His method is sewing the cervix with the shoemaker's stitch. One end of the silk ligature is carried through by a strong needle threaded at the point and mounted in a handle. This is then unthreaded and the other end threaded, bringing this through as the needle is withdrawn. In this way both ends of the suture lie in the same opening in the tissues, though running in opposite directions. Other stitches, as many as may be needed and as near together as is deemed necessary, are inserted in the same way.

This is a continuous suture, and consequently more elastic than the ordinary suture, and there is but one knot, at the termination of the suture, and if there seems to be danger from hæmorrhage a second row of sutures may be put in at right angles to the first. In the cases I have known with this suture there has been no difficulty from hæmorrhage or sepsis. The tumors were not large, and perhaps that explains the success of the method. I have never had an opportunity of trying it. It seems to me very desirable to use silk if we can stop the hæmorrhage or oozing from the vessels. I don't exactly know Schroeder's plan of using the double row of stitches, whether it is substantially this method or not. One thing further which Dr. Merriman has touched upon and which we should all profit by, viz.: that when there is evidence of sepsis slight or considerable we should open the abdominal wound. In all the autopsies I have made after these operations where sepsis has been the cause of death, I believe they could have been saved if the wound had been opened and properly treated three or four days before the death of the patient.

DR. H. P. MERRIMAN said: I was so fortunate as to be present at Dr. Etheridge's operation. One point that he did not mention is that after the removal of the tumor and after the use of the ligatures, which he applied to each artery by itself, and not in one mass around the pedicle, the pelvis was entirely dry, so much so that when the question of a drainage-tube came up, I believe every one present said they could see no reason for its use. There was no exudation. The sponge came out hardly colored after it was placed in contact with the sur-

face that had been denuded, and there was apparently no need of drainage, yet afterward we had oozing from this surface and the formation of bloody serum in the cavity, with septicæmia as a result. I was present at the autopsy, and am convinced that had a drainage-tube been used this patient would have recovered. I don't know but that if after eight or nine days, when the symptoms began to show septicæmia, there had been an opening of the cavity, the septic material might have been removed and the case have had a fortunate termination. The danger seems to me to come from septicæmia rather than from any direct loss of blood there may be from hæmorrhage, although I can see that there might be, even with the drainage-tube, sufficient exudation of the parts to exhaust the patient and produce a fatal termination. There was one thing that struck me with considerable interest, and I don't know what bearing it may have. She had taken ergot uninterruptedly for a year with a general improvement of her health; after this use of the ergot she became pregnant for the first time in her eight years of married life. Was it a coincidence or was there some relation between the use of ergot and pregnancy?

DR. C. T. PARKES said: I am very much interested in this discussion, as it has brought up the question of how to treat the pedicle. Out of five hysterectomies that I have done, four by the intra-peritoneal and one by the extra-peritoneal method, the one that was treated by the elastic ligature died quicker than any of the rest. I am not favorably impressed with it, and think it is an unsafe ligature to use because it never ceases acting; it succeeds in stopping bleeding, but is apt to stop all circulation, and in quite a number of these cases the portion beyond the ligature sloughs and you have a sloughing wound, and may have the slough lodging in the peritoneal cavity. In the case just referred to the stump of the uterus sloughed and was a stinking, decomposing mass on post-mortem examination. Another objection I have to this ligature is that it can be applied only to the uterus, the stump itself. There are many cases, where from one circumstance or another you are led to operate, and in which the tumor does not always have a pedicle that can be embraced by any ligature. The plan that I have used for a number of years in employing the elastic ligature for other purposes, is to draw it taut and tie the ends together with silk. By fastening the ligature while tightly drawn, you can cut the ends fairly short and have no knot at all. The plan I adopted in the operation reported to-night, was a combination of the silk ligature and the cautery. I believe it to be the best method. I was very much impressed on reading Dr. Keith's recent work on uterine tumors, by an expression in reference to the treatment of the pedicle. He now treats it almost entirely by the extra-peritoneal method, but thinks the intra-peritoneal will be the coming method, the pedicle being secured by some application of the cautery to the divided surfaces. This is the best method for controlling hæmorrhages. Often there will be certain spots where arteries of some size come up through the tissue, and perhaps an isolated ligature will have to be

applied to them. I don't believe that any wound in the peritoneal cavity that is at all extensive in character, should be left without drainage. I have been satisfied, in the cases that have come under my observation, that one of the main causes of death has been from the neglect of this precaution. When I have divided a large surface, whether I have a dry cavity or not, if that surface is free in the peritoneal cavity, I shall use drainage. I do not think that it is possible to make any comparison between laparotomies for uterine tumors and ovarian tumors. There never will be the same conditions and the proportion of recoveries will never be the same. Dr. Keith does not pretend to say that one out of fifty of the cases that come to him are subjected to operation. I believe the proper method of controlling hæmorrhage and treating the stump in uterine tumors is by the combination of the silk ligature and searing the stump. The heat of the cautery I use is always a dark red. I have always adopted the plan of putting on to the stump that is to be seared the compress forceps or clamp, leaving a quarter of an inch of the tissue above it, and burning that down close to the forceps until it is perfectly smooth. I have always drained through the external wound, normally the abdominal cavity is closed and abhors any abnormal effusion; the elasticity of the walls and viscera presses it out if an opening be present.

Dr. Bartlet asked with reference to a case of double ovariectomy: At the time of the operation it was noticed that notwithstanding active purgatives had been used previously, the descending colon was full of hardened fæces: she subsequently developed obstruction of the bowel and it was impossible to get any motion at all. I examined the rectum high up, found a tight stricture, and got the bowels emptied after this was forcibly dilated.

DR. CHARLES T. PARKES read a paper, entitled,
SUCCESSFUL REMOVAL OF THE UTERUS FOR
FIBROIDS.

Mrs. L., an American lady, 37 years old, was first examined by me March 11, 1886. She had been married about nine years, but had never been pregnant. The consultation was held for the purpose of getting relief from an abdominal tumor, which first began to show evidence of its existence some three years ago. The first symptoms noticed was a burning pain in the right side, which continued with greater or less severity for about six months, when a small painless tumor was recognized deep in the right groin. This growth continued to enlarge steadily until she saw me, without any exacerbation of rapidity, until during the last six months when it has grown more rapidly and its volume has increased to a greater extent than during the entire previous period of its history. Lately also the patient has lost rapidly in strength and flesh. There has been no interference with menstruation, that function being performed normally the entire time.

The tumor has seemed to diminish in size during menstruation, at least the feeling of fullness was lessened at those periods. The mammæ have not shown evidence of change of any nature. The right leg has

swollen slightly for short periods of time and been the site of considerable neuralgic pain. On inspection the abdomen was evenly distended by a symmetrical tumor, occupying a central position and reaching close to the *appendix ensiformis*; the respiratory acts make no impression upon it. Palpation determined the presence of considerable free fluid in the peritoneal cavity and an indistinct, uncertain kind of fluctuation in the tumor itself. There was well-marked resonance surmounting the upper half of the tumor. The mass itself was quite tender to the touch. Vaginal examination revealed the os high in the pelvis, centrally located, with a small mass behind it, seemingly continuous with it, which was supposed to be the retroverted uterus. The free abdominal fluid rendered this examination unsatisfactory. No sound was passed. No positive diagnosis was made, but the supposition favored an ovarian growth. The patient desired an early operation.

She was advised to remain quietly in bed and to take such medicines as would probably lead to removal of the ascites. These instructions were carried out, and the second and final examination was made April 11, 1886. The patient was very much reduced in flesh and very anæmic, all the mucous surfaces exceedingly bloodless. Examination showed the peritoneal fluid entirely removed—the tumor standing out freely and prominently for inspection on all sides. It still seemed to give rise to fluctuation; palpated by several medical gentlemen, and the testimony of all was that it contained fluid. To pressure the sensation was that of elasticity. Vaginal examination now showed plainly that the uterus was incorporated with the tumor, the sound went directly into it for five inches. On the posterior surface two small tumors were now plainly felt, the largest of them was supposed to be the retroverted uterus at the first examination. The diagnosis now was a uterine tumor.

The operation for removal was done at the Presbyterian Hospital, April 13, 1886, in the presence of Drs. Gunn, Etheridge, Graham, Adolphus, Mitchell, Ochsner and others. An incision was made in the *linea alba* from the umbilicus to the pubes and the tumor exposed. It showed a white, glistening surface, very much like a cyst, and seemed to contain fluid—the introduction of the trocar was not followed by any flow of fluid, and during the manipulations the tumor changed to a darkish-red color. This change of color upon manipulation I have seen occur on other occasions, and its occurrence is a very sure indication of a uterine tumor. The incision was prolonged several inches above the umbilicus and the mass turned out of the cavity. After ligating and compressing the broad ligaments with forceps they were divided and the uterus cut through three-fourths of an inch above the cervico-vaginal junction. Paquelin's cautery was used to disinfect and destroy the cervical canal and to sear the uterine stump. It was also applied freely to the edges of the divided broad ligament on both sides. This controlled perfectly all hæmorrhage except from two spurting arteries on the opposite lateral edges of the uterine stump; these were isolated and tied separately. All ligatures were of carbolized silk. A large rubber

drainage tube was carried to the bottom of Douglas's *cul-de-sac* and the extensive abdominal wound closed by eighteen sutures.

The patient was put to bed considerably collapsed, but rallied well, and as the record shows until she left for her home, May 30, never had a temperature of 100°. There still remains a small sinus at the site of the drainage tube, discharging about 1 dram of sero-pus in twenty-four hours. One of the silk ligatures has been discharged through it. The lady has gained flesh and strength rapidly, and is free from a trouble which was rapidly robbing her of all comfort in life and hastening her death.

The drainage tube did excellent service in this case, allowing the exit of large quantities of bloody serum for many days after operation. In my practice its use has always served a good purpose when large raw surfaces were left in the abdominal cavity from whatever cause.

In spite of the absence of rise of temperature I have never managed an abdominal section in which the external wound did so badly. The main portions of the skin united by first intention but a large abscess formed in the sheath of the rectus muscle, the pus from which extended from one end to the other of the wound; the nozzle of the irrigator introduced at one extremity of the wound and the carbolized water turned on, caused the pus to flow out freely from the opening at the lower end; the peritoneal edges united firmly at once and so saved trouble from this source.

It was slow in healing, several weeks, but finally united very soundly. The patient's very feeble vitality may account for the bad course taken by the wound. The wound was dressed, as I have been in the habit of doing for years, absolutely dry, with absorbent cotton and iodoform. My experience with these cases rather confirms a supposition that the frailest and weakest patients are the ones most likely to recover.

At the time of removal the tumor weighed fourteen pounds. Even after removal many gentlemen present were convinced from its consistence that it contained a cavity holding fluid, so very deceptive was its elasticity.

ception, and the pleasure which it gave him to be in America and appear before the Academy, he stated that it was thirty-six years since he had first met Dr. Jacobi. This was when they were both attending lectures at the University of Bonn, on the Rhine, and he paid a graceful tribute to the talents and industry of the latter as a student.

The subject which he selected for his address was "Some Phases of Cerebral Syphilis," and the special topics to which he directed his attention were syphilitic coma and syphilitic hemiplegia. While the latter was one with which our specialists have for a considerable time been more or less familiar, the subject of syphilitic coma was almost wholly a new one, and Dr. Althaus presented a graphic clinical picture of the affection which was in every way masterly and which fairly enchained the attention of his audience. Altogether he had met with eight cases of syphilitic coma, and they were all in males between the ages of 20 and 40. In one case the coma came on only eight months after the contraction of the primary sore; in six the period after infection varied from three to five years; and in one it was developed after an interval of no less than seventeen years.

The exciting causes which he mentioned were overwork, mental anxiety or excitement, sexual excess and alcoholic excess; but in two of the cases referred to no appreciable exciting cause could be made out. Among the premonitory symptoms he spoke of headache, confusion of ideas and drowsiness, defective vision with black spots before the eyes, numbness in the limbs, and more or less loss of muscular power.

He then proceeded to describe the symptoms of the initial stage. Habitually the coma comes on during sleep, and the patient is usually discovered in the morning lying quietly on his face. He evidently suffers no pain, and there is no restlessness or tossing of the body. The countenance is utterly devoid of expression, and is generally pale. Sometimes the patient can be partially aroused. If so, he will complain that he cannot see, and on opening the lids, the eyeballs will be found to be deeply contracted within the orbits. There is also divergent strabismus, the degree of which will vary according to the intensity of the coma. The pupils are contracted, and the reflex sensibility of the conjunctiva abolished. There is marked relaxation of the muscles, the tone of which is completely lost, and the limbs on both sides are affected alike. There is more or less anæsthesia and the tendon reflexes are either diminished or entirely abolished. There is also incontinence of the excretions from paralysis of the sphincters. The urine dribbles away, but, as a rule, the bowels are constipated. If they are opened by purgative medicine, however, their contents are passed involuntarily. The pulse is generally slow—40, 50 or 60. In one case it was as slow as 36, but in another it was 86. Its quality is variable. The respiration is slow and shallow; the average frequency being 8 to 10 a minute. The temperature is below normal (96 to 97), and in one case was as low as 95. As a rule, the skin is dry and parched, and the tongue is dry also; while deglutition is performed with great difficulty.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Dr. Julius Althaus's Address before the Academy—Some Phases of Cerebral Syphilis—The Cautery in Paraplegia from Potts' Disease.

The opening attraction at the Academy of Medicine, at its first meeting after the long vacation, was the distinguished London neurologist, Dr Julius Althaus, who has for some time past been a corresponding Fellow of the Academy. He was greeted with a very large audience, and received with much applause when introduced by the President, Dr. Jacobi. After expressing his appreciation of this cordial re-

Here, said Dr. Althaus, there are unmistakable signs of paralysis; but there are also signs of irritation. Such a coincidence, however, is by no means so singular as might at first appear. The brain is an exceedingly complex organ, and the gray cortex requires a larger supply of oxygenated blood than any other part. In poisoning by carbonic acid there is first a stage of irritation, and then this is followed by coma. In syphilitic coma there is also probably a short stage of irritation. The initial stage lasts from two to five days, when recovery begins, or else the patient sinks into the final stage. In ten days or a fortnight he may apparently be well, and may be able to resume his accustomed occupations. In other instances, however, the improvement is more gradual; but it is to be noted that recovery, whether rapid or slow, takes place, as a rule, as the result of active specific treatment, and the medical attendant, if such is the result, has great reason to congratulate himself.

If, on the other hand, the progress of the coma is towards a fatal termination, at the end of the initial stage there is an intensification of the symptoms of loss of voluntary muscular power and reflex sensibility. The lower jaw drops, and the mouth lies wide open. The breath is fetid, and the power of swallowing becomes totally lost. The surface of the body is bathed in a clammy sweat, and the pulse is small, feeble and very quick. Finally it cannot be counted, and the sphygmographic tracing produced by it is that of a person in collapse. The respiration grows more and more rapid, and it may be of the Cheyne-Stokes character. Hypostatic pneumonia is also likely to result. This stage lasts from twenty-four to thirty-six hours.

Of the eight cases seen by Dr. Althaus, six ended in recovery, and two in death, in the first attack. In three of the six which recovered from the first attack there was a relapse. One of the patients recently died, after having had no less than five different attacks of syphilitic coma within three years.

The pathological explanation which Dr. Althaus gave of the affection was that it was due to occlusion of the basilar artery, which, as he pointed out, supplies some of the most important vital parts of the brain. He could produce no post-mortem evidences to support this hypothesis, however, as no autopsies were permitted in the cases which proved fatal; the opinion being based by analogy, on a number of non-syphilitic cases recorded by Vulpian, Bastian, and other authorities, in which sudden occlusion of the basilar artery caused death by profound coma. In the discussion which followed the reading of the paper, while it was admitted by a number of the speakers that occlusion of this artery might be in part the cause of the coma, it would not, in their opinion, entirely account for the condition. Thus, Dr. Amiden said that he thought a weak heart was an important factor in the production of syphilitic coma. Dr. Althaus had mentioned as the exciting causes over-exertion, anxiety, and alcoholic and sexual excess; and all these conditions were well recognized as conducing to weak heart. Taken in connection with a weak heart, he thought the arterial

occlusion would satisfactorily account for all the phenomena so graphically described in the paper. Dr. Landon Carter Gray, of Brooklyn, expressed the opinion that the textural changes which take place in the brain in these cases were out of all proportion to the arterial changes, and he based this view upon two autopsies which he had had the opportunity of making, in cases where the coma was the predominant symptom before death; the paralysis present being secondary. The mere theory of some occlusion of the basilar artery, he thought, was not sufficient to account for the coma; and if the coma were very profound, it might be impossible to say whether any paralysis was present or not.

But to return to the paper itself. The diagnosis of syphilitic coma, said Dr. Althaus, may be easy or difficult according to the circumstances of the case. Apoplexy usually occurs in the aged, while this affection is rare in the prime of life, and apoplexy is attended with hemiplegia, which is lacking in syphilitic coma. The variety of apoplexy which the latter most closely resembles is that in which the hæmorrhage takes place into the pons. It may be mistaken for opium poisoning; but in syphilitic coma the pupils are not so extremely contracted as in either opium poisoning or hæmorrhage into the pons. If itching of the skin and retention of urine are present, it will indicate opium poisoning. The fits in epilepsy, hystero-epilepsy, etc., are of much shorter duration than an attack of syphilitic coma, and are also apt to be accompanied by biting of the tongue, frothing at the mouth, and perhaps petechiæ of the face.

In suspected alcoholic coma the odor of the breath is not a reliable sign, as alcoholic stimulants may have been administered at the onset of an attack of coma due to some other cause; but if the urine is found to contain alcohol, the diagnosis will be plain, since this agent, if taken in large quantities, is eliminated unchanged in the urine. The temperature is usually lowered in alcoholic coma, but not to so marked an extent as in syphilitic coma. Having spoken of the differential diagnosis of uræmic coma, Dr. Althaus went on to say that in diabetic coma, which terminates so large a proportion of the cases of diabetes mellitus, the peculiar dyspnœa and the presence of acetone and its allies in the breath and urine are principally to be relied upon in the diagnosis of this form of coma.

The prognosis of syphilitic coma is always grave, although not so hopeless as in the case of either uræmic or diabetic coma. It is serious, however, because the presence of this condition shows that the syphilitic disease has invaded the cerebral centres. Even if the patient recovers from the attack present, there is always danger of a return of the trouble. The prognosis of the immediate attack is usually favorable; but active treatment is required, and the future prognosis also depends to a large extent on this. Death or progressive paralysis of the insane is the fate of any patient who is unwilling to submit himself to persevering and prolonged medication.

In speaking of the treatment Dr. Althaus highly recommended the hypodermic injection of ether; the usual dose being 20 minims three or four times a

day. Blistering was sometimes of service, but ammonia was of little value; while the cold douche, applications of ice, etc., he thought did more harm than good. The great reliance must be on specific treatment, and the best method of employing it was in the form of mercurial inunctions. There was perhaps nothing so good for this purpose as the old time ointment; though the oleate of mercury, made with the yellow oxide, was excellent too. Lanolin could also be used with good results as a vehicle for the mercury. For hypodermic use the bichloride was the best preparation, and care should be taken to make the injections deep in the gluteal muscles, so as to avoid as far as possible the risk of abscesses.

In treating of syphilitic hemiplegia he referred to a variety of different types, scarcely any two cases being precisely alike; but remarked that they all had certain points in common. In the first place, syphilitic hemiplegia almost invariably occurred in males (95 per cent. of all cases being males); secondly, it occurred in the young (between the ages of 18 and 40); and third, it was characterized by the peculiar behavior of the deep reflex phenomena. The diagnosis of this affection by the test of treatment was often fallacious, for many cases were not materially benefited by specific treatment. There was, however, one truly pathognomonic sign, viz.: an excessive exaggeration of the deep tendon reflexes, both of the upper and lower extremities; and it is upon this symptom that Dr. Althaus depends in making the diagnosis of syphilitic hemiplegia. It can only be depended upon, of course, in cases in which the reflexes on one side are normal. The treatment, he said, is not always satisfactory, and therefore in such instances the prognosis is not good; and some cases unfortunately terminate in general paresis. It is the secondary consequences of the syphilitic process which often prove unamenable to treatment; for the removal of a syphilitic gumma will not restore the nerve cells and fibres which have already been destroyed. The lesson to be derived from these cases, therefore, is, that active treatment must be commenced as soon as there is the slightest evidence of cerebral trouble. The secondary ordinary lesions which result from syphilitic lesions of the brain are not, unfortunately, affected by anti-syphilitic treatment.

In discussing this division of the paper Dr. Robert W. Taylor, the well-known syphilographer, spoke of the labors of Drs. Van Buren and Keyes, of this city, in connection with syphilitic hemiplegia, and called attention to the fact that in a paper read here a number of years ago, which embodied these researches, and which had now been incorporated in several text-books, Dr. Keyes had described all the prominent symptoms to which Dr. Althaus had referred this evening.

As regards the treatment of cerebral syphilis, Dr. Gray remarked that he was somewhat surprised at the views expressed by Dr. Althaus. He depended, it seemed, entirely on mercurials, and had little or nothing to say in regard to iodide of potassium. For his part, he had some time since given up the use of mercury altogether in these cases, as he had never

seen any beneficial results from it. He had had indisputable evidence in his experience of the superior value of the iodide, and he believed that this was the experience also of the great majority of neurologists in this country.

Dr. Putzel, on the other hand, stated that he agreed entirely with the author of the paper in regard to the marked efficiency of mercury. It was now about six years since he had become convinced that syphilis did not yield, or at least very slowly, to iodide of potassium. Formerly he employed the bichloride of mercury; but more recently he had found much better results from the use of inunction. It was his practice to employ this until the teeth began to be touched, and then to discontinue it. In connection with this, small doses of iodide of potassium sometimes seemed of service.

On the following evening Dr. Althaus read before the Neurological Section of the Academy of Medicine a paper on "The Pathology and Treatment of Paraplegia resulting from Potts' Disease," the object of which was to advocate the use of the actual cautery, and this at as early a period as possible; since if the sensibility was already affected, it would be of no service. It was the opinion of most of those present, however, that while in occasional instances the actual cautery might be beneficial, there were other methods of treatment at our command which were, as a general rule, much preferable and much more efficient.

MR. TAIT ON "OTOMIES."

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Having been much interested in the discussion on the letter of Mr. Lawson Tait to Dr. Nelson, read before the Chicago Gynecological Society on May 28, I hope you will permit me to add a few words to what was said on that occasion.

I think that Mr. Tait is wrong in "protesting against those stupid Greek words ending in *otomy*," for by so doing he ignores a necessity, long recognized by scientists, of borrowing, from some classical language, their technical terms. If they were all of one nation and spoke the same tongue, there would be no such necessity; but in order that the different nations might profit by each other's work, it is necessary that they adopt conventional terms that would be understood everywhere.

The term "abdominal section," preferred by Mr. Tait, would do very well for all of us English-speaking people, but it would convey to a German no more meaning than his "Bauchschnitt" does to us. Without these conventional terms the work of any one nation would be a dead letter to all others, and each would be obliged to prosecute their scientific studies independently; so that to communicate and compare their work, these conventional terms become a necessity.

The Latin and Greek languages, which occupy so important a position in the curricula of the colleges, are understood by educated men the world over, and have therefore been adopted as the medium of intercommunication. The Greek being the more fertile,

has supplied us with most of our technical terms, without which the study of the sciences would have dragged heavily, and could hardly by this time have reached their present status.

Though Mr. Tait is evidently a better surgeon than linguist, it is somewhat surprising that the term "oncotomy" should be new to him. He must have met with it, and it is strange that, by its very ugliness, it was not impressed on his mind. It is a very old word, being contained in Dunglison's dictionary at least forty years ago. Professor Fenger was evidently right in designating mere opening of an abscess or tumor by this name, its derivation being from the Greek *ογκος*, a tumor or abscess.

Mr. Lawson Tait objects to the word "laparotomy" "because the signification of its *derivatives* (italics mine) in the use of the people who spoke the language is such that it could not by any human ingenuity be applied to any modern surgical proceeding;" but he must be reminded that it is *we* who make the "derivatives" from the *roots* supplied by "the people who spoke the language" to describe "our modern surgical proceedings." A greater objection to this term, in my opinion, is, that it might justify an inference that the operation (abdominal section) was limited to the lumbar region, it being derived from *λαπαδα*, the loins. On this account "gastrotomy," which seems to be the favorite term with the French, is much less objectionable. But perhaps the term least liable to objection is the one proposed by Dr. Fenger, viz., "peritonotomy," notwithstanding it has the termination so abhorrent to the distinguished English surgeon.

We all must acknowledge, however, that Mr. Lawson Tait's wonderful success in this particular branch of surgery, which has justly given him a world-wide reputation, should entitle him to the privilege of selecting its name, whether from the English or any language he prefers. S. K. JACKSON, M.D.

Norfolk, Va., August 20, 1886.

TOXIC URINE AND SURGICAL OPERATIONS. TO THE EDITOR OF THE JOURNAL:

Dear Sir:—I am pleased with the editorial, "Toxic Urine and Surgical Operations," in THE JOURNAL of October 2d, and hope that Mr. Reginald Harrison is entitled to all the attention your article bestows upon him, but an American, Prof. Hal C. Wyman, of Detroit, published, some years ago, ideas so very similar to those you attribute to Mr. Harrison in his article in the *Liverpool Medico-Chirurgical Journal*, that I cannot refrain from using this occasion to say that Dr. Wyman not only described all the toxic effects mentioned by Mr. Harrison, but devised an operation for relief of hypertrophied prostate, the main feature of which was that no urine could come in contact with the wound to poison it.

The principles involved in your editorial are very important. I feel that it is only right that our countrymen should have full credit for any good work they have done. Under the title of "Tenotomy of the Levator Prostatæ," Prof. Wyman published an article in the *Medical Age*, of January, 1883, in which

he advised special surgical measures to avoid the toxic effects of urine. At the time the article was often quoted by other medical journals, and must be still fresh in the minds of many American surgeons.

DAYTON PARKER, M.D.

Bluefield, Mich., Oct. 5, 1886.

NECROLOGY.

JAMES IRVIN KELLER, M.D.

Died at his home, Hot Springs, Arkansas, on September 29, of typhoid fever, DR. JAMES IRVIN KELLER, aged 31 years, 5 months and 18 days. By request we clip the following from the *Memphis Appeal*:

The *Appeal* has already announced the death of this brilliant young man; but at the request of those nearly allied with the deceased we give additional particulars as to his death and our further estimate of his character. The deceased was young, handsome and accomplished. God gave him a massive intellect, and beneath his ample brow lay a capacious brain comprehensive in grasp and which did much mighty thinking. His language was ornate, his style terse and beautiful, and in conversation he was voluble and interesting. He was one of those extraordinary creations who leap into manhood without the probation of youth, for he was eminent in his profession by the time he reached his majority. No wonder his father, Dr. James M. Keller, and his mother, Mrs. Sallie Phillips Keller, made him the idol of their lives, and worshipped him as a bright particular star whose radiance was destined to grow in splendor long after they had crumbled into dust. But "whom the Gods love die young," and the sun of Dr. Irvin Keller went down ere it reached its noon, but is sunk amid the prophetic splendors of an eternal dawn. Never was there a death seen more pathetic than his. No man ever had greater inducements to live; but young as he was, he was a philosopher, and he met the fate which his knowledge as a physician told him was inexorable with the courage of a hero. He summoned the family and his friends to his bedside, and said to Dr. Rector: "I am about to pay that debt which we all must pay sooner or later, but I shall do so like a man;" and death in all his triumphs never mocked at a scene so pathetic and heart-rending. Farewell, noble Irvin. We knew you in infancy, in childhood, in boyhood and manhood. Your life was a poem, a perfect star, and the loyal hearts that loved you are bleeding, but they will ever be harps tuned to the sweet melody of remembrance. You have left unfinished the beautiful pyramid you were building to your fate, but like the lightning which leaves more picturesque the shattered shaft, death has not destroyed the symmetry and brightness of your life. Heaven gave you everything but time to accomplish a great mission. You "flashed, the meteor of an hour," and the darkness your death has created tells of the brilliance of the light that has forever gone out. While dropping tears over your grave, the sympathies of your loving friends will be lavished upon

the father and mother you loved more than all the world beside. With cautious and reverent hands your friends will lift the veil of that stricken sanctuary. The whole South sympathizes with the father and wife whose girlish love lighted up with joy his early home, and is the mother of one of the most talented sons that ever lived so beautifully and died so sadly.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Duglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

PROFESSOR E. WILLIAMS, OF CINCINNATI.—It is with deep regret we learn that the health of this eminent ophthalmologist is so seriously impaired that he feels compelled to relinquish all professional engagements, including the Presidency of the Section of Ophthalmology, the duties of which he had been prosecuting with zeal and success, and to seek the restorative influences of rest and a more favorable climate.

NEW IMPROVED COMBINED TROCAR AND CANULA.—This instrument, an account of which was given in THE JOURNAL for September 25, Dr. H. L. Getz wishes us to state may be procured of George Tiemann & Co., New York, the well-known surgical instrument makers.

AMERICAN PHARMACEUTICAL ASSOCIATION.—At the last meeting of this Association the following resolution was adopted:

Resolved, That this Association solicit the aid and coöperation of the American Medical Association, in promoting the prescribing by physicians of official medicines only, or such preparations as have published formulas, in preference to others; and that the several State Pharmaceutical Associations make similar requests of their respective State Associations.—*Medical News*, Oct. 16, 1886.

SUCCI'S FAST.—The *Sanitary News* says: The somewhat phenomenal fast of Signor Succi, at Rome, which was recently brought to a conclusion after thirty days' continuation was undertaken to convince

people of the efficacy of his herb liquor as a life sustainer. The experiment can be called a fast only because the gentleman consumed nothing but his herb liquor in given amounts, and draughts of mineral waters. In point of continuance the fast of the notorious Tanner lasted ten days longer than his Italian imitator. But while Tanner came out from his fast greatly emaciated and weakened, Succi lost none of his strength and vitality. The first three days of the recent fast were passed in bed, but after that Succi rode on horseback and took violent exercise nearly every day. His abstention from food is declared positive by those who watched him constantly. The success of his herb liquor in sustaining life is but a forerunner of what chemists may do for us in future years, when it may be that a closer study of the requirements of the human frame will reveal foods in forms we know not of, and when the refreshing meal may come from the apothecary's rather than from the shambles.

OFFICERS OF THE WASHINGTON OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY FOR THE ENSUING YEAR.—President, A. F. A. King, M.D.; Vice-Presidents, S. C. Bussey, M.D., and W. W. Johnston, M.D.; Rec. Secretary, H. M. Cutts, M.D.; Cor. Secretary, S. S. Adams, M.D.; Treasurer, George Byrd Harrison, M.D.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 9, 1886, TO OCTOBER 15, 1886.

First Lieut. Edward Everts, Asst. Surgeon, ordered to proceed to Ft. Grant, A. T., and there take station. (S. O. 94, Dept. Arizona, Oct. 1, 1886.)

First Lieut. W. W. R. Fisher, Asst. Surgeon, ordered, on the expiration of his leave of absence, to report to the commanding officer, Ft. Bidwell, Cal., for duty as Post Surgeon. (S. O. 93, Dept. Cal., Oct. 4, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING OCTOBER 16, 1886.

Woolverton, Theoron, Surgeon U. S. N., detached from the U. S. S. "Shenandoah," proceed home and wait orders.

Means, V. C. B., Asst. Surgeon U. S. N., detached from the U. S. S. "Shenandoah" and ordered to receiving ship "Independence."

Parker, J. B., Surgeon U. S. N., detached from the U. S. S. "Swatara," proceed home and wait orders.

Shafer, Joseph, Asst. Surgeon U. S. N., detached from the U. S. S. "Swatara," proceed home and await orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE WEEK ENDED OCTOBER 9, 1886.

Peckham, C. T., P. A. Surgeon, granted leave of absence for thirty days, to take effect when relieved. Oct. 5, 1886.

Kalloch, P. C., P. A. Surgeon, granted leave of absence for twenty-one days, to take effect when relieved. Oct. 5, 1886.

Pettus, W. J., Asst. Surgeon, to proceed to Evansville, Ind., for temporary duty. Oct. 8, 1886.

Kinyoun, J. J., Asst. Surgeon, appointed an Asst. Surgeon, Oct. 4, 1886. Assigned to temporary duty at New York, N. Y., Oct. 5, 1886.

HEALTH INSURANCE, OR OUR FINANCIAL RELATION TO THE PUBLIC.¹

BY WOODS HUTCHINSON, A.M., M.D.,

LECTURER ON HYGIENE, IOWA COLLEGE OF PHYSICIANS AND SURGEONS,
DES MOINES, IOWA.

If I were to put the question to this august representative assembly, "What is the most annoying and unpleasant feature of our professional work, from what source spring our most harassing, though comparatively petty cares and our most provoking disappointments?" I think I should have no difficulty in determining even if all spoke at once, that what we may call the financial question in medicine, enjoyed that "bad eminence" more generally than any other which could be suggested. No doubt much of this difficulty and unpleasantness is inherent in the very nature of the process; for this is the point of metamorphosis at which our talent and industry must be coined into their equivalent of hard cash, where our lofty ambitions, noble aims or Utopian schemes for benefiting the race, come into merciless contact with the hard, cold realities of life and the struggle for existence, always at best a mortifying experience. Friction at this point is inevitable, a reduction to a minimum is all we can hope to effect. Whether the financial relations which we sustain to the laity are the best possible which could be assumed to effect this reduction, is the question to which I wish briefly to call your attention to-day. I stand here simply as an animated interrogation point.

No doubt the question has suggested itself to many of you that the treatment of this subject would have been much more appropriately undertaken by one of wider experience and longer standing in the profession, but it is the peculiar privilege of youth and inexperience to ask the *raison d'être*, even of truths which we have come to regard as axiomatic and customs which have grown hoary with centuries of observance. Is the system of remuneration only for services rendered, in fact of making a physician's income from a family or community depend solely upon the amount of sickness occurring in it, the best that can be devised for the mutual interests of both parties concerned? Such practically is our system. Its philosophy might be condensed in the motto "Millions for Cure, but not one cent for Prevention."

¹Read in the Section on Public Health at the Thirty-Seventh Annual Meeting of the American Medical Association.

The astute Chinese who were discussing civil service reform when our ancestors were building the reed hut and hurling the flint-tipped javelin, are said to pay their medical attendants regularly as long as they enjoy good health, but to promptly discontinue their remittances on the first appearance of sickness, to resume only on recovery; which no doubt has arisen from their absurdly attempting to live up to a foolish old proverb of ours about "an ounce of prevention."

It seems to me that the weakness of our system lies in this one fact, that it gives us such an exceedingly limited opportunity for what has been well called the practice of preventive medicine. No one thinks of consulting us until they at least "feel unwell," and in many instances not until days, or even weeks of precious time have been wasted or worse, in trying to "wear the trouble off," or in blindly applying every crude remedy which household experience, patent quackery or superstition can suggest; all because they are "not sick enough to call a doctor," in other words don't feel uncomfortable enough to be willing to pay more than the price of a bottle of patent medicine for relief. To such an extent has this habit of delaying been carried, that we often find patients hesitating to call us in just because they are unwilling to admit even to themselves that they are "so seriously ill" as to need our services. In fact the abominable phrase "sick enough to need a doctor" has become almost the popular synonym for, at best, a serious indisposition and often a well developed stage of a possibly fatal disease. The phrase and the feeling that it represents ought to be obliterated from the speech and thought of every civilized community. Through its influence, we are brought face to face with the legitimate result of months or even years of violation of the laws of our being aggravated by days of neglect or maltreatment, and confidently expected to avert the vengeance of outraged nature and undo the work of years, in days or weeks. "If I had only been called sooner" is a sadly familiar phrase in our professional vocabulary. To thus stem or even reverse the current of nature, we are driven to use the most powerful agents, many of them deadly poisons, to call "halt!" in tones which will compel the attention of the most obstinate morbid process and every few decades, a not wholly unnatural wave of popular indignation sweeps over the community, not against itself for living so as to render such drugs indispensable, but against physicians, forsooth, for prescribing them. It was on the crest of such ever recurring waves that the Hahnemanian, Thompsonian, Botan-

ical, Hydropathic and Faith-cure manias successively came into popular favor. Thus the mutual confidence and sympathy which should exist between the profession, and the public is seriously impaired and the interests of both suffer in consequence. Would not a system of constant medical attendance, remunerated alike in sickness and in health, enabling us to give advice or treatment just when we see it is needed, even if unasked, and rendering professional counsel, not only in disease but in health, the first thought, the easiest and most natural thing, the rule instead of the exception; would not such a scheme as this, if practicable, most happily modify the condition of affairs and prove a long step toward securing the health and happiness of the race?

But supposing ourselves installed in full charge of a case, are we even then freed from the perplexities of our financial system? Scarcely even then. How often are we annoyed in the very midst of a serious case, when every shadow of change must be instantly noted and promptly met, by the remark of the family, friends, or even of the patient, that they "can't afford to have us come so often." This fortunately is not a very common experience, but all of us can testify that when it does occur it is, to say the least, exceedingly disheartening. When, however, we reach the period of convalescence, another head of the hydra springs up to confront us: "Really, doctor, I feel so much better this morning that I don't think you need call again until I send for you," is the remark of our wan-lipped and languid patient, blissfully ignorant of the hundred and one pitfalls which yet lie between him and health, and we can but submit to his decision or run the risk of being thought anxious to make all we can out of the case and possibly of having our bill for subsequent services protested. How often are we called in hot haste only to find our patient beyond help, or if we escape this, how frequently does the convalescent, dissatisfied with the slow and uncertain progress he is making, conclude with charming consistency that it is the fault of our treatment, "too much strong medicine" perhaps, and resort to some rival physician, quack or vender of patent medicines, to whom he ascribes all the credit of the cure. These results are patent to the most unskilled eye, but what a prophecy of evil to come, can be read in living letters by the eye of the trained observer in the history of many of these half cured cases even when their course and termination may have been perfectly satisfactory to the unsuspecting patient and his friends. How many of our most serious and most obstinate chronic troubles spring directly from the half removed result of some acute attack? How often are the germs of evils which will curse generations yet unborn, left lurking in the system, simply because the subject thinks himself cured and doesn't want to make his bill any larger? Of course much of this too early cessation of treatment is due to a simple aversion to taking any kind of trouble unless spurred on by pain or fear, but would not this tendency be greatly checked by a knowledge on the patient's part that his bill at the end of the year would be just the same whether he took further treatment or not, while other advice or

new remedies would be an additional expense; as would be the case under a system of constant attendance.

What influence does our present system of attendance give us over the sanitary surroundings, diet or habits of life of our patients? Almost none. It is true we have the priceless privilege of giving any amount of excellent advice on these subjects, which they may perhaps remember for a week, though usually they regard it simply as customary and harmless prelude to the prescription which they regard as the "value received" for their fee. Such an effect has the proportioning of our remuneration to the number of distinct definite services rendered had upon the ideas of the laity, that many of them have no idea of paying for anything, except some such tangible benefit as a prescription or an operation. In some instances we are actually obliged to give a prescription in order to secure the right (in their minds) to claim a fee. They will pay a dollar for a prescription and get the advice thrown in for nothing, and as the immortal "Josh Billings" has sagely remarked, "what people gets for nothing they are mighty apt to value at about what they gave for it." Over the home life of our patients, we have almost no control or even supervision until after the mischief (which often might have been averted by a few timely precautions) has been done, and even that ceases almost as soon as we began to exercise it. What sort of success would we expect from a nurseryman who was not permitted to prune his trees until they were already misshapen, to destroy their infesting parasites until the foliage was withered, who was not allowed to water them till they began to droop or manure them till they were almost exhausted? And yet this is the relation to the bodies of our patients in which we are practically placed by our present system. The words "cobbler and tinker" are terms of reproach, and yet cobbling and tinkering is about all we are permitted to do to the vital mechanisms of most of our patrons.

When we consider this fact in the light of the deliberate statement of Mr. Chadwick, the distinguished English sanitarian, that he can build a city which shall have any required death-rate from 3 per 1000 up. When we remember that "the white plague of the North," as Holmes aptly calls consumption which is responsible for the lion's share of our death-rate, is more than analogous to the familiar spindling of plants deprived of air and sunlight; that as much as fifty years ago, even a layman like Lord Palmerston declared that "for every death from typhoid somebody ought to hang;" that an unfailing specific for malaria, diphtheria and cholera, is contained in a six inch drain tile, in short that nearly one-half of our existing diseases are absolutely preventable, does not a readjustment of our relation to the public appear urgently necessary? How would a system of constant attendance at a fixed sum per year or month, including an annual or semi-annual sanitary inspection of the residence and surroundings, and review of the diet and habits of life of the family, if practicable, modify the conditions under which we are now attempting to promote the health of the public? I

am well aware that this system at present is generally stigmatized by us as a "quack method" if not a form of quackery itself, but I think even the bad hands into which it has to some extent fallen, should not prevent our candidly recognizing, and, if worthy, appropriating any feature of value which it may possess. Besides, we must remember that the system in part at least, is in practical operation in the different lodges and benefit associations, in manufacturing establishments and mines all over the country, with generally eminently satisfactory results regarded from an economic standpoint. Of course the principle upon which all these plans are adopted is a purely economical one, to get the greatest amount of service for the least possible cost, and they could only be expected to be a success in this direction.

The plan which I would respectfully submit is much wider in its scope, and is briefly as follows: That at the beginning of the calendar year, each individual or family should engage his or their medical attendant for the next twelve months, agreeing to pay him a specified annual salary in advance, either in full or in quarterly or monthly installments. The physician on his part should agree to render any and all professional services required, except operations or manipulations requiring the skill and training of a specialist, for the annual consideration specified, which might readily be fixed according to some rate *per capita* or *per familiam* laid down in the fee bill. The physician should further agree in consideration of the sum specified, to make an annual or semi-annual inspection of the sanitary condition of the house and premises of his client, and to offer such suggestions as he saw fit in regard to the diet or habits of life of himself or his family, in short to act as general adviser on all matters of hygiene or therapeutics. The system might briefly, and perhaps not inaptly, be described as a scheme of "health insurance." What are the advantages which seem to be presented by this plan? In the first place, our patients would have no inducement whatever to delay consulting us, in fact moved by a not unnatural desire to get their money's worth out of us, would probably hasten to do so at the earliest appearance of discomfort or danger, and thus give us full control of the case at that period in which a "stitch" properly taken often saves not "nine," but "ninety and nine." We should have every opportunity to abate or favorably modify the attack, and it needs no word from me to point out to you the well-nigh inestimable value of this vantage ground. Later during the progress of the case there would be not the slightest danger of any objection to the frequency of our visits, on the contrary the difficulty would lie in exactly the opposite direction, and would constitute the principal drawback of the system. In convalescence, we need fear no interruption to those finishing touches which may exercise such a powerful influence upon the future comfort or safety of our patient, and in the giving of which the master hand finds scope for the finest and most highly appreciated subtleties of its skill.

Above all it would give us a fair opportunity for the practice of the grand branch of preventive medicine, a privilege which under the present system is

practically denied to us. How is it that until within the last few years in scarce even one of our many and justly famous professional schools and colleges, was there to be found a full Professor of hygiene or a chair of preventive medicine? Why is it that one could almost count upon his five fingers all the really valuable and exhaustive treatises upon this subject by American authors? Where are the Grosses, the Bartholows, the Flints, the Emmets of Hygiene or the Agnews, the Hammonds, the Knapps and the Roosas of Preventive Medicine? The profession of the United States has yet to produce the man who has won a national reputation solely by his work or writings in this department. One reason at least for this state of affairs is not far to seek; the field for work in this direction has been either so exceedingly limited or so barren and difficult of cultivation as to almost deprive us of any inducement to develop it. Skill and proficiency in any other branch of our art are highly appreciated and well remunerated, but in this one they are regarded with the utmost indifference. As medical students we are required to practically acquaint ourselves with, say seven branches in a comparatively short space of time, knowing that the public are quite willing to pay us for proficiency in six branches out of the seven, but will hardly even accept our advice gratis in the seventh, and the result is well-nigh inevitable. How can we expect it to be otherwise when the student has absolutely no prospect of a fair remuneration for the time and labor expended in obtaining a thorough knowledge of this branch, unless he chooses to enter the uncertain arena of politics as a candidate for the often poorly paid and unpopular position of a health officer? In spite of this utter lack of pecuniary or even honorary inducement, in the face of sneers at his "pretended" zeal, to his everlasting credit be it spoken, the American physician is today the truest promoter of the health of the people, the most earnest, and I had almost said, the only persistent advocate of sanitary measures; but would not the "health insurance" system if generally adopted give a new dignity to his labors and immensely increase the scope of his energies?

Would not this system also do much to break up that unfortunate mental habit impressed upon us from earliest infancy which involuntarily connects the doctor with discomfort and bitter medicine, if not with the undertaker and the sexton? A habit whose influence upon the popularity of the profession, though slight, is sometimes unpleasantly appreciable. It would also tend to lessen the present unfortunately too common tendency to select professional advisers on the spur of the moment or dismiss them from some momentary impulse of dissatisfaction, a course highly prejudicial to the interests of both parties. Most men give less careful, deliberate consideration to the choice or dismissal of their family physician than they would to the consummation of a horse-trade. The financial advantages of the scheme in rendering our incomes, not only more definite, but also more certain, are obvious, and the few figures bearing upon the subject which I have been able to collect, which I dare hardly dignify by the name of statistics, render it at least highly probable, that a rate *per annum* can

be fixed, which would be both satisfactory to the public and remunerative to us. The agreement would simply be an ordinary common sense business arrangement, legally binding, so that there could be no possible objection on the part of our clients to being reminded of their delinquencies by a collector or any dissatisfaction with the size of the bill. Each "policy holder" would know in advance the exact amount of his "premium" and the date at which it would be due, and could prepare to meet it promptly like any other business obligation, instead of, as now, neither knowing the amount nor the date till after it is due and regarding the obligation as a part of an inscrutable dispensation of Providence, which he will try to meet when he can conveniently spare the money.

Now just a word on the drawbacks of the scheme, though it is probably a subject which might safely be left to those who are to follow me. No doubt the objection which is already uppermost in the minds of most of you is the enormous and unreasonable demands on our time, which would be made by some of our patients under this system. In addition to the insane craving of some persons for constant medical attendance, there will be added the not wholly unnatural desire to "get their money's worth" out of us, but would we not be in some respects, in a better position to meet these demands than at present? In the first place, when entering upon the agreement, we should give our patients to clearly understand that they were engaging us, not to be simply medicine-carriers or visit-makers, but to advise them to the very best of our judgment, and that the question of the necessity of the visit must be left largely to our discretion. Then the tenure of our professional position being so much more secure, we shall be able to treat these unreasonable cases on a much more rational basis. We could safely reason with them, if necessary reprove or scold them, or even occasionally afford to tell them the truth. We might occasionally find ourselves in a position to make use of Abernethy's celebrated prescription given to a gentleman who somewhat pompously introduced himself as "James Peet, of Rock Villa, Clonmel, Waterford, Ireland." It was not committed to writing, but was delivered verbally somewhat as follows: "James Peet, of Rock Villa, Clonmel, Waterford, Ireland, go back to Rock Villa, Clonmel, Waterford, Ireland, and fancy you are well and you will be well." If these means should fail us, there are a hundred and one rusty weapons in our armamentarium such as blisters, nauseous draughts, venesections, or hypodermatic injections of *aqua destillata*, which could be used with deadly effect.

But perhaps the most practical objection would be based on the probable unwillingness of the laity to pay any sum in advance for services which they are not even sure that they are going to need; but even this objection loses some of its force, when we consider the almost innumerable number of lodges, guilds and benefit associations into which not only the educated, but even the most unintelligent classes are forming themselves for just this kind of mutual protection. When we further consider that scarcely

fifty years ago, life insurance was regarded as not only absurd and impracticable, but even impious, while now men of every condition are willingly paying from \$10 to \$1000 a year solely for life insurance, it would scarcely seem improbable that their education up to the point of paying the comparatively trifling sum necessary for "health insurance" would simply be a matter of months or years.

Of course the annual fee would necessarily have an important effect on the weight of this objection. This can only be determined by past experience. Simply as a rough estimate of the probable amount of this fee, I would refer to a few fragmentary statistics which I have been able to collect. These statistics have been taken from four different ledgers, one of which was kept in a country village of about 1200 inhabitants, another in a town of about 6000 inhabitants, and the other two a city of 35,000 population, thus embracing nearly all classes of practice. The results even from so small a number of data are comparatively uniform. The village series comprises only twenty-seven families, or about 130 persons, who spent the exceedingly low sum of \$7 per annum for medical attendance. The town statistics, covering nearly 400 families, show an average of about \$13.50 per annum, while the city series, embracing 150 families, or nearly 700 persons, show an average expense of over \$19.00.¹ From these it would appear to be probable that the average expense per annum, making the necessary allowances for healthfulness of location and habits of life, would approximate very closely to \$13 per annum, or a little over \$1.00 per month, the actual average from the enclosed figures being \$13.60. When we consider the really appreciable preventative influence which we might exercise, I think we would almost be justified in concluding that we could afford to render the proposed services for the present average expense, or perhaps even for less, especially when we remember the greatly increased certainty of our being paid; and when we can represent to our clients that all these invaluable hygienic advantages may be secured in addition to regular attendance, at the cost of the latter, surely a reasonable man need have no hesitation about adopting the system. Surely we could afford to perform the same services under more favorable circumstances for the same sum. The sum proposed very closely approximates to that contributed by miners for similar purposes, the assessments ranging from seventy-five cents a month for a single man, to \$1.25 to \$1.50 a month for a married man, according to the size of his family. Probably a fair average under our system would be for adults \$5.00 and children \$1.25 per capita per annum, which would impose almost exactly the average expense per annum on an average family of five members. Taking these scattered figures as an indication, it would hardly appear probable that any serious objection will be raised by the laity on account of expense.

Without doubt the objections to the plan are neither few nor groundless; but are not the advantages proposed to be secured both real and valuable? In fact, it seems to me that the time has already come

¹ These statistics cover an average of about three years.

when an effort must be made to secure them. The crying need of the age is for sound hygienic teaching, and if the profession fail to give it, who can fill their place? I care not what means be adopted to reach the end, but it must be reached, and to provoke a discussion of ways and means is the sole object of these informal suggestions.

Discussion of the paper was opened by DR. ALBERT L. GIBON, U. S. N., who stated that while in Nagasaki, Japan, the system suggested was substantially that pursued in his own private practice, and was found satisfactory both to patient and practitioner. It is indeed the only independent and dignified way in which to practice medicine.

He was followed by Drs. Horatio R. Storer, of Newport, R. I., W. L. Schenck, of Osage City, Kan., Geo. H. Rohé, of Baltimore, Md., Foster, of Portland, Me., Wyman, U. S. Marine Hospital, St. Louis, Hazelwood, of Grand Rapids, Mich., and Tupper, of Michigan, all of whom approved of the plan presented in the main, theoretically, at least; though most of them doubted its practicability at present.

A CASE OF AORTIC ANEURISM TREATED BY THE INSERTION OF WIRE.¹

BY JOSEPH RANSOHOFF, M.D., F.R.C.S.,

PROFESSOR OF DESCRIPTIVE ANATOMY AND CLINICAL SURGERY, MEDICAL COLLEGE OF OHIO.

The subject of aneurism never fails to arouse the interest of the surgeon. Happily the progress of our art has been such, that he who is thus afflicted needs, as a rule, no longer to consider himself an object of scientific interest solely, but can with at least a fair prospect of successful issue rely upon one or other of the methods recognized as radical in the treatment of his disease. There are cases, however, and notably those of the aorta, which are not amenable to ligation or compression, and in which despite medicinal treatment and the observance of absolute rest a rapidly fatal result must be predicted. Such cases ought not to be forsaken without an effort to save. As our science stands to-day, we are restricted to a choice between distal ligation, galvano-puncture and the introduction of foreign material into the sac of the aneurisms. It is to this latter method only that I beg to direct the attention of my colleagues of the Surgical Section. The cases of aortic aneurism in which it has been adopted are so few that the report of the following case may prove interesting if not instructive:

Case.—Alfred P., æt. 35, colored, presented himself at the Dispensary of the Medical College of Ohio, and was admitted to the Good Samaritan Hospital in May, 1885. Has been a moderate drinker, but has always enjoyed good health. Had a chancre several years ago, but never had syphilis. In August, 1884, while pulling an oar, he made a very sudden and strenuous effort which was followed by a sharp, stinging pain in the right side of the chest.

Pain has been constantly present since. Difficult breathing, more or less severe cough and inability to do hard work have gradually supervened. Slight exertions are often followed by paroxysms of dyspnoea that threaten to terminate life. From February 24 to April 27 the patient was an inmate of the Cincinnati Hospital, where, according to the records, he was kept at rest and upon the iodide of potassium, but without marked benefit.

Status præsens.—Man well-nourished and of good muscular development. Breathing labored, short, and frequently interrupted by spells of coughing whereby a thick tenacious mucus is expelled. A marked oedema of the root of the neck and extending to the right side of the face and the shoulder is observed. Inspection of the chest reveals a conical prominence on the right side of the sternum and extending over the second and third intercostal spaces. The projection is as large as a fist, pulsates perceptibly, but presents no discoloration of the integument. On palpation a pronounced expansile pulsation is felt from below the clavicle to the fourth rib and from the right margin of the sternum to half an inch beyond the mammary line. The tumor is very soft, fluctuating and exceedingly sensitive to pressure. Percussion elicits a dull sound. No thrill can be felt. Auscultation over the tumor reveals no adventitious sounds produced within it. The cardiac sounds are transmitted with more than ordinary clearness, and particularly is the accentuation of the aortic sound noticeable. The position of the apex beat is normal. While the patient is at rest his pulse is 100. According to the sphygmographic tracings taken by the late Dr. Keyt, the pulsation in the radials is synchronous and the pulse-waves agree sufficiently in form. Auscultation over the right lung reveals a harsh inspiratory noise below the lower angle of the scapula. Coarse mucous râles are audible over both lungs.

Diagnosis.—Sacculated aneurism of the ascending aorta, with perforation of the chest wall, unattended by atheroma or cardiac hypertrophy.

Treatment.—When the patient was admitted to the Samaritan Hospital he was placed in bed and kept as much at rest as the cough and dyspnoea would permit. His diet was greatly restricted and 20 grains of the iodide of potassium given three times a day. For a week this treatment, with the administration of an hypodermic injection of morphia at night, was continued with apparent benefit. The pain and dyspnoea were somewhat diminished and the pulse rate reduced to 90 per minute. No perceptible change in the aneurism occurred. The improvement in the condition of the patient was dissipated two weeks after his admission after a severe spell of vomiting which was followed by an increase of pain and dyspnoea, and protracted epistaxis. When the irritability of the stomach had been allayed, the administration of the iodide was resumed, but without marked benefit. During the third and fourth weeks of the patient's stay in the hospital, six subcutaneous injections of ergotine were made in the vicinity of the tumor, with but faint hopes of benefiting him. While no direct detriment to the diseased vessel resulted from

¹Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

them, they were followed by so much pain that they were discontinued.

It was at this time that Loreta, of Bologna, reported his favorable case of aneurism of the abdominal aorta in which he had given a new and striking impetus to Moore's method of treating aneurisms which from their position are not remediable by ordinary surgical procedures. Recognizing the otherwise hopeless condition of the patient, and after consultation with my colleagues Drs. Whittaker and Nickles, it was determined to insert a coil of wire into the sac in the hope of causing its obliteration by the formation of a firm, organizable clot. The material used was flexible silver wire which had frequently been coiled by passing it into a box of the apparent dimensions of the aneurism.

Operation June 13. A straight hollow needle with thumbscrew attachment was pushed into the aneurism from the right side. The needle was directed parallel to the chest wall, to avoid as far as possible the entrance of a coil into the lumen of the main vessel. Ninety-six inches of the wire were thus introduced into the aneurismal sac without any technical difficulty. The pain experienced was very slight and during the introduction of the first four feet of wire the pulse continued unchanged. It suddenly became almost imperceptible and very rapid. The patient complained of great faintness and it appeared that death was imminent. After the administration of several injections of whiskey, the pulse gained in strength and the remainder of the wire was introduced without further interruption. The end of the coil was pushed into the sac by a secured piece of wire which was withdrawn with the canula. No hæmorrhage attended or followed the operation. An icebag was applied over the aneurism and an opiate administered.

On the day following the operation an amelioration of all the symptoms was noticeable. The œdema of the neck had materially subsided, the pain had diminished and the tumor was decidedly firmer in its outer portion and the pulsation was very much less marked than before the operation. From day to day, for a period of two weeks, the condition of the patient gradually improved. The pulse rarely exceeded 80; was regular and of fair volume. The temperature except on the second day was practically normal. The dyspnoea and cough were no longer distressing and it seemed certain that the organization of a firm clot was in progress. The outer portion of the tumor had become quite firm and fluctuation in it was no longer appreciable. In the last days of June, a change for the worse supervened; a change which coincided with increased pulsations and greater prominence of the internal segment of the tumor. The œdema of the neck, right side of the face and right arm became greater than at any previous period. The right eye was completely closed. The patient now could sleep only on this side. In the hope of consolidating this part of the sac a second operation was performed on the 5th of July, whereby ninety-eight inches of wire were inserted into the sternal portion. Considerable pain, but no distress attended this operation, but the symptoms remained

unchanged. The region of the tumor had become quite sensitive within three days after the operation. A distinct induration of the tissues over the tumor was perceptible, and the pulsation appeared less marked. Hopes were still entertained of material improvement when the patient was found dead in bed on the morning of the 12th of July.

Autopsy.—The autopsy was made by Dr. F. Kebler, Pathologist of the Samaritan Hospital. The body is that of a negro, well-nourished and about 35 years of age. Post-mortem rigidity well-marked. The right side of the face, neck, right arm, right side of the trunk and the right lower extremity are markedly œdematous. On the right side of the chest from the clavicle to the nipple is a swelling conical in form, having a base four inches in diameter. To obtain the specimen in its entirety, the right half of the anterior chest wall was removed together with the heart, aorta and trachea. When the necessary incisions were made, the right pleural cavity was found filled with blood, the right lung being compressed.

From the anterior surface of the arch of the aorta springs an aneurismal tumor which has a long diameter of seven and a transverse diameter of four inches. The mouth of the tumor is an inch wide, and circular. Its lower margin is one inch removed from the commencement of the vessel. In the posterior and outer part of the aneurism where it is covered by the mediastinal layer of the pleura is an opening a little larger than a silver dime, where the aneurism had ruptured. When the tumor was opened from behind, there was found in the upper and outer third of the sac a firm laminated clot of considerable thickness and adherent to the sac wall. The walls of the remaining portions of the aneurism were covered with a thin layer of fibrin, the interior being filled with soft coagula of recent formation. Throughout the sac of the aneurism, imbedded in firm and recent clots, are numerous coils of silver wire. One of these rests just above and in close relation to one of the leaflets of the aortic valve. Near the seat of rupture no wire is found. When the clots were removed from the sac, it was found that the second and third ribs were perforated and that the anterior wall of the external cavity was largely made up of the pectoral muscle, which contained about two feet of closely coiled wire. Subsequent dissection of the specimen showed that the aneurism pressed severely upon the right bronchus and right innominate vein. Indeed, the latter could not be completely exposed without endangering the sac wall. The orifices of the large arterial trunks springing from the transverse arch were found pervious, and evidently the circulation in them during life was uninfluenced by the dilatation of the ascending part.

In a case like the one presented, comment should be directed towards the solution of four questions: 1. Was the operation justifiable? 2. To what extent did it imperil the life of the patient? 3. Did it offer any prospects of a radical cure of the aneurism? 4. Do the cases hitherto reported in which this plan has been tried warrant its repetition?

1. It can hardly be questioned, but that in the case before us, medicinal and postural treatment

were fairly tested and found inefficient. The choice remained between galvano-puncture, the introduction of wire and distal deligation. Were the favorable reports of Ciniselli corroborated by others, his method should certainly have been resorted to. According to most recent and weighty authorities, electrolysis fails, as a rule, to be of more than temporary benefit. Of eight cases referred to by Poore, all terminated fatally. Indeed, it is justly questioned whether the method accomplishes more than acupuncture, and in a recent supposed successful case of aneurism of the root of the neck treated by galvano-puncture, it was found that the current was almost *nil*. In the absence of atheromatous changes in the arteries my choice would have been distal deligation. I was deterred from following it because the dyspnoea was so intense and the œdema of the neck so pronounced that there was every probability of death during the operation. The introduction of wire was therefore practised as a last resort.

2. That the life of the patient was imperiled by the operation is certain. The specimen shows that notwithstanding the caution observed in introducing the wire, a loop passed beyond the neck of the sac, entered the aorta and was probably deflected by the semilunar valves. When this occurred, syncope which was all but fatal supervened. I was the less prepared for this mishap, since it had not occurred in the few cases previously recorded; furthermore, according to Bacelli, the absence of cardiac hypertrophy made the existence of a large aperture of communication exceedingly improbable.

Even with a loop of wire in the aorta, embolism, the danger most dreaded, did not occur. In only one of the reported cases, that of Moore, did death result from embolism which possibly originated in an inflammatory state in the heart itself and not in the aneurism.

The supposition that a severe hæmorrhage might ensue upon the prolonged retention of a canula in the sac wall is purely theoretical. Neither in this case nor in those already published was there any bleeding during the operation or immediately after the withdrawal of the needle. In Loreta's case of abdominal aneurism, in that of Levis of the root of the neck, and in my own, death resulted from rupture of the sac. In the case of Levis the rupture occurred on the fourth day. In Loreta's the tumor had consolidated to such an extent as to weaken the main trunk, which gave away at the neck of the sac. In the case presented, this explanation will not suffice, since neither coagula nor loops of wire were found near the seat of rupture. This took place despite the operation, and not in consequence of it.

3. To the extent that physical signs can be construed to indicate the condition of the contents of an aneurism, those of the case presented precluded the existence of organizable coagula before surgical interference was undertaken. The tumor was soft, even fluctuating, pulsating forcibly and rapidly increasing in size. The physical signs after the operation indicated the beginning of an attempt at a radical cure. The induration of the tumor, its decreased pulsation and the simultaneous improvement in the

symptoms, justified a belief in the formation of an "active" clot. Post-mortem evidences confirm the belief. The walls of the sac are lined with firm, the interior with firm and loose coagula imbedded within which are the coils of wire. Similar conditions were found in the cases of Moore, Donville, Bryant, Bacelli, Schrötter, Loreta and Cayley. In almost all of them, however, all parts of the aneurism were not alike affected by the treatment, and it is therefore certain that very decided improvements in the technique of the operation, and particularly in the material introduced, must be devised before more than a partial or temporary coagulation shall result. It is not improbable that a less rigid and hence less dangerous material than wire or watch-springs will be determined upon. The firmness of the wire loops prevents unlimited diminution in the size of the sac during the process of contraction and, as was probable in Loreta's case, may lead to rupture near the attachment of the sac to the main vessel. Watch-springs are readily changed chemically by their immersion, and, as happened in Bacelli's cases, are subject to breakage. To overcome these objections, Levis, Bryant and Stimson have inserted horsehair, Murray catgut, and Schrötter, Florence silk. In Murray's case, as was to be expected, the gut was found softened and without coagula about it. Whatever faith we can have of permanently relieving these cases should be centred in horsehair rendered aseptic. It is easily passed through a canula, and in large quantity; it coils readily and is as easily compressed. The report of Loreta's case influenced me in the choice of the material used.

4. To determine the propriety of repeating the operation, at least a brief *resumé* of the literature of the subject is essential. This method of treating aneurisms may be said to have originated with Phillips,¹ who advised the retention of a seton for half an hour. Later, Sir E. Herne² introduced heated needles into an iliac aneurism and thereby achieved coagulation. Velpeau, Agnew, Heath, Murray, Buck and many others have since resorted to acupuncture, but without notable success. The last-named author, from his experience in two cases of aortic aneurism, considers the procedure inadmissible. In one of his cases threads of silk, in another suture pins were allowed to remain in the sac for twenty-four hours or more. Laminated clots were not developed.³ Richet⁴ mentions five cases in which acupuncture was tried without good results. The most successful cases in which acupuncture has been resorted to are those of MacEwen⁵ of popliteal and ileo-femoral aneurisms respectively. Fine needles were introduced into the tumors and retained for an hour, but were moved from place to place every ten minutes. Here, as in Rizzoli's⁶ case of femoral aneurism, compression was used at the same time, and probably played the more important rôle in the production of a thrombus. In both instances digital compression was resorted to

after the withdrawal of the needles. Murray,⁷ in a case of subclavian aneurism, by repeated trials of complete transfixion with long needles achieved partial consolidation.

The first case of the permanent introduction of a foreign body into an aneurism was that reported by Mr. Moore,⁸ of the Middlesex Hospital, in 1864. The case selected was one of large thoracic aneurism which was on the point of bursting both into the pericardium and through the skin. Twenty-six yards of fine iron wire were inserted through a fine canula, the point of which was moved about during the operation. Rapid coagulation and temporary arrest of pulsation followed. The pulse-rate was reduced from 116 to 78. The improvement was transitory. Severe inflammation of the sac and contiguous tissues supervened and the patient died on the fifth day. Pericarditis was presumably the immediate cause of death. Abscesses were found in the kidneys, but it is doubtful whether they were of recent origin.

On May 14, 1872, Wm. Murray,¹⁰ of Newcastle, reported a case to the Medico-Chirurgical Society in which a man lived for three weeks with twenty-one feet of wire introduced into an aortic aneurism.

On March 23, 1871, Dr. Domville⁹ inserted fourteen inches of fine iron wire into an aortic aneurism that had perforated the chest wall. The tumor became firmer, but continued to increase. On the 9th of April, nine needles, each two and one half inches long, were introduced. Fatal hæmorrhage supervened two weeks later. The foreign substances were found imbedded in a firm clot.

The next cases operated upon were those of Levis, of Philadelphia, Bryant, of London, Bacelli, of Rome, and Stimson, of New York. The case of Levis¹¹ was one of right subclavian aneurism into which twenty-four feet of horsehair were inserted. The patient succumbed on the fourth day from rupture of the sac.

Mr Bryant's¹² case was one of popliteal aneurism in a man with ulcerative endocarditis and "chronic heart disease." Daily attempts were made with compression which was continued for hours at a time. Epistaxis supervened and the patient was evidently sinking. Twenty feet of horsehair were then introduced into the sac and produced rapid coagulation. Death four days after the operation. The horsehair was found entangled in huge laminated clots.

The cases of Bacelli¹³ were all of the aorta, and watch-springs were used. The first patient was operated upon on March 27, 1873. By April 4 the cough was less severe, the pulsations less marked and the tumor had decreased in size. The patient died on May 26. The autopsy revealed an aneurism of the ascending aorta which contained laminated clots surrounding six fragments of the watch-spring. The internal surfaces of the aneurismal wall were covered with dense fibrinous layers. Bacelli's second case

occurred in 1877. On April 23 he introduced three watch-springs of a total length of five feet. The tumor decreased in size and pulsations almost ceased. The patient did well until examined by a considerable number of medical men, when she commenced to fail. She died on May 3. At the autopsy the sac was found filled with clots containing parts of the spiral spring, but the coagula were not adherent to the sac wall. This separation Barcelli attributes to the examination alluded to. This author operated on a third case in the presence of the delegates to the Sanitary Conference at Rome. Through an exploring needle he introduced seven watch-springs, each twenty inches long. Death resulted on the third day, apparently from exhaustion.¹⁴

Dr. L. A. Stimson¹⁵ introduced fifteen pieces of horsehair each six inches long into an ileo-femoral aneurism with entirely indifferent result. Coagulation did not ensue. A favorable result was subsequently obtained from ligation of the iliac.

On November 9, 1885, Prof. Schrötter,¹⁶ of Vienna, inserted twenty inches of Florence silk into the outer segment of an aortic aneurism that had perforated the chest wall. On the 13th, thirty inches of the same material were pushed into the lower segment of the tumor. The aneurism became firmer and pulsation less marked. It subsequently increased in all its dimensions, while intense œdema developed in its immediate vicinity. The temperature rose rapidly, probably from inflammation of the sac, and death resulted from *œdema pulmonum* on November 28. The extra-thoracic part of the sac was filled with a laminated clot in which was found the Florence silk deposited in spiral coils.

In December, 1885, Loreta,¹⁷ of Bologna, after a careful study of other operative procedures in similar cases, resorted to laparotomy in a case of sacculated abdominal aneurism. The tumor was situated in the epigastrium and left hypochondrium. There was a loud bruit. The pulse was hardly perceptible in the femoral arteries and ceased altogether when the tumor was compressed. Loreta determined if possible to separate the sac from its connections and to close its opening out of the artery by suture or ligature. If this should prove impracticable it was determined to stuff the cavity with wire. At the operation by which an incision was made from the xyphoid cartilage to the umbilicus, the sac was found united to the stomach, omentum, transverse colon and liver. It was impossible to sever these adhesions and therefore to trace the aneurism to its mouth. A little more than two yards of silvered copper wire were then inserted into the tumor through a canula, and the point of puncture was lightly touched with pure carbolic acid. There was no bleeding. The abdominal wound was closed and healed by first intention. By the seventieth day after the operation, the tumor, which had been as large as the head of a new-born child, was reduced to the size of a walnut and was firmly consolidated. The patient left the

hospital cured. On the ninety-second day, however, he died of rupture of the aorta below the sac. This was filled with consolidated fibrinous clots. Loreta attributes the rupture to an ischæmia of the aortic tunics due to compression and to changes going on in the interior of the sac.

The last case published is that of W. Cayley,¹⁸ reported to the Royal Medical and Chirurgical Society, February 23, 1886. The patient was a man aged 48, with a pulsating tumor, rising about three inches into the neck behind the right sterno-clavicular articulation. The patient was unsuccessfully treated according to Tufnell's method, and given large doses of iodide of potassium. The tumor increased in size and it was evident that it must either soon burst externally or extravasate among the tissues of the neck. On June 24, Mr. Hulke introduced forty feet of steel wire. This caused no constitutional disturbance or local pain, and this portion of the aneurism became completely consolidated. Towards the middle of August, signs of the extension of the intra-thoracic portion of the tumor became more marked and there was an increase of pulsation behind the sternum and towards the left sterno-clavicular articulation. To anticipate fatal pressure on the trachea, Mr. Gould, in the absence of Mr. Hulke, introduced a canula just above the left sterno-clavicular joint, directing the instrument obliquely towards the middle line, and inserted thirty-four feet nine inches of wire. No constitutional disturbance followed, but no relief was given to the symptoms. The patient died in a paroxysm of dyspnoea on September 19. On post-mortem examination, a large aneurism was found springing from the ascending aorta and communicating with the vessel by a very large orifice; the whole of the upper portion was completely filled by a clot, imbedded in which was the wire. The lower portion of the sac caused compression and flattening of the trachea, just above its bifurcation. The first operation produced the desired result in preventing the imminent rupture of the aneurism. The size and connections of the sac rendered the second operation ineffectual.

In the discussion of this case Dr. J. Liston Paul¹⁹ reported a case of innominate aneurism under his care in 1874 which had been treated according to this method. The tumor bulged forward on the left side of the sternum. Into this fifteen feet of cleansed white horsehair were introduced. Slight pain and prickling over the tumor followed. In three days the tumor had grown larger and gave greater distress; on the fourth day the patient died in a convulsion. No search for emboli was made.

It is not remarkable that with such a record of failures the method under consideration has been pronounced "utterly useless" by so competent an authority as the late Dr. Gross, and that Agnew condemns it as "a rash if not criminal trifling with human life." The fourteen cases in which it has been tried terminated fatally, with the exception of Stimson's case in which the result was entirely negative. Still, analysis of the record tends to show that the criti-

cisms just quoted are undeservedly severe and that there are ample reasons for repeating the operation in suitable cases. In the first place, death has in no instance ensued during the operation, although after examining the specimen before us, the possibility of such an occurrence must be conceded. Again, considering the gravity of the disease, the insertion of foreign material into an internal aneurism is not particularly hazardous. In the third case of Bacelli, and in those of Moore, Levis and J. Liston Paul, death followed on or before the fifth day after the operation, so that in only 30 per cent. of the cases can death be attributed to the operation itself, while in the remainder it in no way depended upon the procedure.

In conclusion, the post-mortem reports that are available show that coagulation almost invariably took place in the sac, and when sufficient time elapsed before death, the clot was found laminated and often adherent to the sac wall. In some of these cases at least, progress was made towards a cure. The aneurismal wall was strengthened, the tumor as a rule decreased in size, life was made comfortable and even prolonged. This, I think, was accomplished in the first case of Bacelli, in those of Loreta and of Cayley and probably in the one above reported. In all these cases death was imminent from compression of vital structures or from threatened rupture of the sac. Life was sustained for periods varying from three weeks to three months from the date of the operation. In view of these facts and notwithstanding the failure of the method in effecting a cure, it appears to me that the practice is worthy of further trial. Of course, it should rarely if ever be resorted to in aneurisms of peripheral vessels, when so many safer methods are at our command. Nor is it admissible in intra-thoracic and abdominal aneurisms until all ordinary therapeutic measures have been fairly tried. Practised as a last resort in such cases, it has undoubtedly lengthened life, and it is far from improbable that, if often adopted, a permanent recovery will occasionally be obtained in cases that are hopeless without it.

DR. HERRICK, of Cleveland, asked the cause of aneurisms and whether we were justified in treating such cases on purely empirical grounds?

DR. RANSOHOFF, in answer, stated that the aneurism was traumatic in origin, that atheromatous degeneration would preclude such treatment, and that it was used only as a *dernier ressort*; but that the treatment was rational and not simply empirical.

AN OBSCURE CASE OF EXOPHTHALMOS.¹

BY J. H. THOMPSON, M.D.,

OF KANSAS CITY, MO.

In presenting this report of a case to the Section, I beg to apologize for its apparent insignificance, but inasmuch as I am at a loss to account for an extremely interesting condition, I am prompted to ac-

¹ Read in the Section of Ophthalmology, Otology and Laryngology, at the Thirty-seventh Annual Meeting of the American Medical Association.

¹⁸ Brit. Med. Jour., Feb. 27, 1886.

¹⁹ Ibid.

quaint you with it, that I may secure information which will aid me in the future.

A little boy 5 years old received a slight cut across the face from a whip in the hands of a playmate. The eye was not injured. The only manifest result was a slight scratch on the bridge of the nose. From all accounts he was not sufficiently hurt to cry, and did not complain afterwards. I may here state that there was mumps in the neighborhood, but at this time the child was in perfect health, and as far as I could learn, had never suffered from any serious complaint. Some two weeks after the receipt of the injury, and after all traces of the blow were off the face, he began to complain, at night, of pain in his head. It was paroxysmal, for he would start up from a sound sleep, cry a moment, say that the side of his head and eye hurt him, and as quickly fall asleep again. This would happen three or four times during the night. At other times there were no indications of trouble. These attacks came on during several nights, when the family physician was consulted.

At first, after a careful examination he could find no cause for the pain, but afterwards he thought he could see that the right eye protruded, and he called me in consultation. When I saw the child he had a well-marked exophthalmos of the right side. That was all I could discern. The eye projected about one-half inch forwards, but not so far that the lids could not be closed. It was forced outwards in the axis of the orbit; was slightly movable in all directions, but could not be pushed back into the socket by moderate pressure. There was no swelling of the lids, nor any congestion or œdema of the conjunctiva. In fine, the external eye and its surroundings were normal. I searched carefully for evidences of periostitis and cellulitis, but found none. The internal eye, other than a slight clouding of the disc, perhaps some swelling, and an enlargement of the veins, was normal. Vision was good.

Inasmuch as I could not find a cause for the exophthalmos I called in consultation one of the leading surgeons of Kansas City. Again we examined carefully for retro-bulbar trouble, but in vain. Under an anæsthetic the orbit was explored both with the finger and the hypodermic needle. A small drop of serum was the result; certainly not more or different in kind than could be drawn from any tissue similar to that behind the eye. Under ether we attempted to replace the eye, but could not. It seemed as if the orbit was filled with some hard substance.

We could not make a diagnosis, nor could either of us suggest a line of treatment. However, the patient was placed upon tartar emetic and saline cathartics, with the hope that if there was a serous effusion absorption might take place. After three days' trial, the medicine did no good, but made the patient utterly miserable. The eye remained the same, if not a little worse as far as the displacement was concerned. On my own responsibility I withdrew all internal medication, prescribed a simple belladonna and white precipitate ointment for the forehead, tied a silk handkerchief over the deformed parts, and turned the child out to play with his com-

panions. In one week he was well, the eye returned to its normal position. I afterwards examined it with an ophthalmoscope, but could not find that it had been damaged in the least. During all the time there was no quickening of the pulse, and no elevation of temperature.

THE BEST SUBSTITUTE FOR MOTHER'S MILK.¹

BY SELDEN B. SPERRY, M.D.,

OF DELAFIELD, WISCONSIN.

If it were not for the immense importance of this subject I should feel like apologizing to this learned body for presenting a paper upon a subject so thoroughly written upon by learned practitioners and specialists of this and other countries. Yet on the other hand, we have but to glance at the innumerable preparations as recommended by physicians, and the overwhelming number of proprietary articles, to realize that the substitute for mother's milk has not been found. It then becomes the duty of the general practitioner to add his experience to that of the specialist, that his position may be strengthened. This I say because this paper presents nothing original, yet having given the subject some attention, I would add my experience to the general stock, as I feel it very desirable that we reach some conclusions on the all-important subject.

Having found, as I think, a substitute which is all that can be desired in the way of an artificial food, I purpose in this paper, in a very brief manner, to discuss its preparation and some of the reasons of failure in its use. I take it for granted that all present, like myself, believe that as a basis for an infant food cow's milk is the proper and by all means the best substitute for the mother's. It seems hardly necessary to present any arguments in favor of this statement. At the same time, you all know that cow's milk presents some differences in composition to that of human milk, and for that reason has been rejected after a short trial when found to disagree, without properly inquiring into the means of overcoming these obstacles.

What are these differences? Cow's milk contains more caseine and less sugar than human milk, and is slightly *acid*, while human milk is slightly *alkaline*. If these points of difference can be bridged it is very evident that we will find the substitute for mother's milk. And I think it can be done. But how?

First of all, to insure the coöperation of both mother and nurse in our efforts, it will be all-important that we exert the utmost patience in telling the "whys" and "wherefores" of what is done. It is also necessary that the process of preparing the food be as simple as is possible; that the mother and nurse be carefully instructed in the physiology of infant digestion and things pertaining to it; and of the importance of *cleanliness* and *precision* in the preparation and care of infant food.

In the March, 1883, number of the *American Journal of Obstetrics*, I gave a formula for preparing

¹ Read in the Section on Diseases of Women and Children, at the Thirty-Seventh Annual Meeting of the American Medical Association.

milk for infants, which is as follows: On a tablespoonful or more of granulated pearl barley is poured a pint of boiling water, and allowed to boil for five minutes. For infants under three months one-third of a pint of fresh cow's milk and two-thirds of a pint of this barley water are mixed and sweetened with a *tablespoonful of milk sugar*. In this you have a mixture closely resembling mother's milk, and on which infants thrive.

Barley has been found the best substance for diluting the caseine, but in diseased conditions oatmeal water or rice water can be used with advantage. In preparing the barley water the nurse will often use too much barley, or not strain it, and this will be a source of failure, and a common one, too. It will be necessary, when this mixture has failed, to question the nurse closely as to how it was prepared. When the food is prepared for the baby the barley water, *hot*, should be added to milk. This will then obviate the mistake of boiling the milk, which is too often done.

In selecting milk that from ordinary cows is to be preferred to that from blooded stock. As there is a great difference in the richness of cow's milk, and in the difference between country and city milk, it may be in given cases that a dilution of two-thirds may be too great.

When infants grow rapidly and do nicely cream may be added, or the amount of milk increased. Sugar of milk is the proper substance to sweeten the mixture with, for it is not apt to cause fermentation; it is slightly laxative, and when lime-water is used with the mixture to make it alkaline, the sugar of milk makes the lime more soluble, and therefore the more readily goes to form bone tissue.

A good way is to add the sugar of milk to the barley water when made, and put it into a clean bottle. It is best to make only enough for the day. When the barley water and milk have been mixed it remains to see if the mixture is alkaline; if not, to use lime water or soda bicarbonate until it is.

Phosphate of soda has been recommended, but I have never used it. It will be necessary to provide the nurse with litmus paper.

After four years use of this food in a country practice, where I have had every chance to know when it agreed or when disagreed, and how, enables me to urge you to give it a thorough and impartial trial. I have never found it to fail. Sometimes failures result in not correcting dyspepsia when existing, or the results of improper feeding or improper food.

In the majority of cases in which the subject of the infant's food comes to our notice, we are called in to treat the child for some sickness. When an infant has been for a long time fed improperly, and the mucous membrane of bowels and stomach is out of order, the condition needs to be corrected, else the food will fail. It will not be enough to give the proper food and say the child is not sick. Bromides, with soda and chloral, or hyoscyamus, are needed just as much as proper food. Unless this is attended to the nurse will surely give it soothing syrups, and you will fail, and very likely lay it to the mixture. It is necessary to mention this source of failure for the benefit of the younger practitioners.

In conclusion, I will say that my experience with this mixture has been that it is perfect. It can be used when the mother does not furnish sufficient food herself, and the infant does just as well as if it was all her own. It only remains to say that after the age of three months it should be diluted about half for six months, for eight months one-third, and when it is ten or twelve months old it can be given clear milk.

Delafield, April 29, 1886.

A CASE OF VAGINAL HYSTERECTOMY FOR CANCER OF THE UTERUS.

BY ROBERT FUNKHOUSER, A.M., M.D., LL.B.,

OF ST. LOUIS, MO.

PROFESSOR OF TOPOGRAPHICAL ANATOMY AND CLINICAL SURGERY
IN BEAUMONT HOSPITAL MEDICAL COLLEGE.

At the present day one of the most difficult operations is the removal of the uterus through the vagina. At first the hope was strong that the dread disease had at last found a cure. As results were heard from, from time to time, the utility of the operation began to be debated. Though it has found much favor with some, it is opposed by others equally as able. The outcome of the controversy, however, will be productive of great good and serve to point out more specifically and definitely the suitable cases for operation. An abundance has been written relative to the local or constitutional origin of cancer. Few doubt the local origin of the epithelial type of this disease. Whatever the causes may be, I am convinced that irritation of the organ, causing inflammation, especially of a chronic character, is a fruitful source; though Tilt says that in the course of thirty years' practice he has only once witnessed the passage of the womb from inflammation to cancer.

I have now a case under treatment which clinically presents every symptom of the commencement of the disease, but microscopically fails to furnish pathological changes characteristic of the disease itself, but so confident am I that malignancy in time will appear, that I would not hesitate to advise some radical treatment, as for instance, amputation of the neck. As A. Reeves Jackson says, when cancer is limited to the cervical mucous lining, it is rarely detected, perhaps never (*THE JOURNAL*, August 15, 1885). The disease is not discovered until it has passed deeper. We might say of cancer, generally, that applies to that of the cervical mucous lining, that it is not recognized in many cases until it ceases to be a local disease, and has advanced too deep in the tissues for a permanent cure to be effected. There can be no doubt that the microscope fails to indicate the disease in its inception in very many instances. Must we wait, then, until the disease has advanced to such an extent that the microscope can demonstrate the specificness, when the chances of rendering durable aid are greatly lessened? Will not the time come, and that soon, when we shall be able to reach with certainty a diagnosis at an earlier period of this dread disease than the microscope at present offers? Is there not some forerunner before the present pathological change is seen?

The bacillus is offered as the *fons et origo* of disease. A specific microbe is present in a specific disease. In the past year, great advancement has been made in the study of morbid changes, especially in regard to the ptomaines, which, as the result of the action of bacteria of decomposition upon organic matter, bear a close relation with each other. Lately the bacillus has been associated with the giant cell. (THE JOURNAL, May 15, 1886, Whittaker.) May not future investigation demonstrate that the bacillus precedes and is nature's warning of impending evil?

Cancer cells *per se* do not exist, but are designated such when compared with the normal cells of the tissue in which they are found. As the tendency of opinion is toward the local origin of this disease particularly of the epithelial variety, the sooner an operation is performed the greater the likelihood of saving the patient from so terrible a disease. All of the diseased tissue and some of the healthy must be removed. When, indeed, is it certain this has been accomplished? Even though the organ has been removed, immunity does not always crown our efforts. Is not the effort worth making, even though up to the present time the statistics are not as favorable as at first indicated? If Sir J. Y. Simpson removed a cancer by amputation of the neck and the patient was well eighteen years after, why should not a patient who survives the removal of the entire organ for the same disease, do as well? The operation is but comparatively new, and we must not forget the many failures in other operations for the removal of this and other diseases. Is it just and fair to question the accuracy of the diagnosis in cases that have been reported favorably, or to judge the operation by a standard far too critical, even for an old and well tried operation? Before reading Dr. Jackson's paper, referred to above, I was quite enthusiastic about this operation, but since then my ardor has become moderated. No doubt in the cauliflower type, as its extension is circumferential, some of the less radical operations would serve as well.

The history of the case is as follows: Mrs. R. R., mulatto, 29 years of age, married, servant. Her mother, 47 years of age, has uterine hæmorrhages, the cause of which at present unknown, as no examination has been made. Patient menstruated at 13 years of age, when she suffered much pain. As a rule has been regular. Has had leucorrhœa more or less since the first menstruation. Mother of two children. Character of labors, normal. About four months ago had metrorrhagia. For the last ten months the discharge has been offensive, which increased in quantity and offensiveness several weeks before the operation. The examination per speculum revealed a cauliflower excrescence, the extension being circumferential, but more prominent anteriorly. Owing to the excessive growth, which occluded the os, it was impossible to insert a sound. The patient and family were explicitly informed of the character of the disease, particularly the prognosis and treatment. Different operations were explained and statistics given. Without advising this operation or promising any favorable result, the patient was anxious to have it performed.

Assisted by Drs. King, Cole, Laidley, Gehrung, Mulhall, Shaw, and Mr. Buchanan (student of medicine), I removed the uterus July 1st, 1886. Much difficulty was experienced in bringing the patient under the influence of the anæsthetic, Squibb's ether, more than an hour being consumed in its accomplishment. The vagina having been thoroughly syringed out with carbolized hot water, the patient was placed in position. The uterus was dragged down and freed from the vagina all around. A male sound was then introduced into the bladder to indicate the relation of that viscus with the uterus, and thus facilitate the separation of the two from each other, which was done by both the scissors and fingers. The hæmorrhage, though not great, was controlled by the hot douche. The pouch of Douglas was next opened into posteriorly, and upon the fingers of the left hand passed into the wound; the peritoneum anteriorly was opened into by means of a probe, the opening being enlarged by tearing. After clearing the uterus before and behind, I attempted to retroflex it on itself, but was unable to do so on account of its enlargement and firm consistency. Besides, the vagina was not capacious. I succeeded with much difficulty, by aid of the volsella, in pulling down the uterus, when I proceeded to apply two ligatures to each broad ligament. The broad ligament of the right side was transfixed and tied in two portions, with silk ligatures. An additional silver wire was placed around the ligament nearer the uterus. The left broad ligament was tied *en masse* with a silk ligature and further up with a silver wire. The organ was then cut away with serrated scissors, and the bleeding stopped by the hot douche. After the oozing had ceased, the edges of the cut surfaces of the vagina were brought together. I was unable to bring down the stumps of the broad ligaments into the wound. Nor was the peritoneum closed. A glass drainage-tube was inserted and made firm by packing it around with absorbent cotton. The parts were insufflated with iodoform. The uterus measured $5\frac{1}{4}$ inches long, 3 inches transversely, $2\frac{1}{8}$ inches anteroposteriorly, and the excrescence about 3 inches in diameter. Over fifteen hypodermic injections of brandy were administered during the operation, which consumed a little over an hour. The patient was consequently under the anæsthetic over two hours. Throughout the operation it was unnecessary to apply a ligature, with the exception of the ligatures to the broad ligaments, the means adopted to control hæmorrhage being the hot douche. Considerable difficulty was experienced in tying the broad ligaments, as the tissues gave very little in the attempt to draw down the organ. In ligating the left broad ligament I found a cystic condition of the Fallopian tubes, a large hydro-salpinx with a clot of blood situated in the uterine extremity, due to atresia or occlusion of the tube. Very likely the closure of the os externum by the growth had much to do with this condition.

Upon opening the womb, the mucous membrane appeared congested, and a considerable quantity of thick mucous lined the surface. The shock was very profound. Everything was done to bring about a reaction, which was slow in occurring, and was not

fully secured till the morning of the third day. The temperature after the operation was below normal, and gradually rose till the middle of the second day, when it was $99\frac{1}{2}^{\circ}$, and on the third day reached 100° , remaining so for four days, after which it lowered to the normal. The pulse was very rapid and feeble, for three days varying from 125 to 135. On the sixth day it lowered to 90, and from that time till the thirteenth day gradually fell to 80. At the end of three weeks, as the ligatures had not come away, I attempted to remove them. In doing so, the ligature of the right stump parted near the loop, but subsequently in a few days passed out. Several days after the other wire ligature was taken away. The silk ligatures likewise were removed, as I was afraid should they remain longer they might cause irritation.

I am not favorably impressed with the silver wire ligatures, and in future in operations of a similar character shall use the silk, as they are less likely to produce trouble should they remain behind from some unavoidable accident. At this writing, August 25, the wound has not entirely closed. There is some discharge, but no foetus. I am afraid of the return of the disease. Should it return, it will very likely make its appearance behind the posterior wall of the bladder, as the tendency of the growth was in that direction. Especial care was taken to remove as much of the tissue as was possible without opening the bladder. On the 22d of July blood was discharged from the small opening and continued for several days. It corresponded to the usual time of menstruation. It occurred again on the 21st of August, a month later. I consider it a vicarious menstruation. Though there was no uterus, the ovaries remained. In the intervals no blood appeared. Since the removal she has been free from pain in the pelvis, though at times suffering considerably from pain in other parts of the body, of a neuralgic character, which I attributed in great measure to cold.

The growth was examined microscopically by Dr. A. Alt, who pronounced it an exquisite sample of cancer of the cauliflower type. He discovered no trace of the disease in the cornua of the organ. Before and since the operation I have prescribed Donovan's and Fowler's solutions.

Frequently in this day of surgical procedure, the medical treatment is too apt to be neglected. It is well recognized that whatever tends to depreciate the vital powers, favors the appearance and progress of this disease. The general condition of the patient should be watched and appropriate medication administered. Not that any specific cure has ever been discovered, but certain remedies in this, as in disease generally, are beneficial, and have a tendency to build up the system as well as counteract the malignant effects of the disease, and assist or increase the power of the tissues for resisting morbid development. Such are arsenic, mercury, iodide of potash, and tonics in general. The progress of the case will be watched and reported.

2650 Olive St., St. Louis, Aug. 26, 1886.

MEDICAL PROGRESS.

FRACTURE OF THE ULNA IN ITS UPPER THIRD COMBINED WITH DISLOCATION OF THE HEAD OF THE RADIUS.—DR. HANS DOERFLER of Nuremberg, in discussing the mechanism of this injury, concludes from the study of nineteen cases, that direct violence alone less frequently occasions it, than combined violence, as exercised by a fall, the proportion being five to eleven. The greater number of cases occurred between the ages of 3 and 15, all others after the 35th year.

The question in what causative relation the two injuries stand to each other, is next considered. Grénier's assertion that the two injuries could not be simultaneously produced by means of any applied violence, is disproved by the author, who experimented upon ten cadavers. After chiseling partly through the ulna, he could easily fracture it, and by continuing the pressure, could occasion luxation of the radius. He therefore believes that both injuries occur simultaneously, but that the fracture is primary and the dislocation of the radius secondary. Further experiments were performed to prove this. Luxation of the radius proved very difficult to effect, but when present, application of further violence entirely failed to fracture the ulna, but produced typical fracture of the radius in its lower third. After partial incision of the ulna, however, direct violence easily effected the desired injury, luxating the capitulum radii forward and outward, if applied from behind and laterally. The post mortem condition of the parts is accurately described in these cases of artificial production of the injury. The fragment of the ulna is not instrumental in causing the dislocation, in the author's opinion, but the radius-head may be displaced either by the continuation of the same direct violence which caused the fracture, or, by indirect violence, as by pressure upon the extended hand. The first of these modes is illustrated when the patient has been kicked, run over, hit by a stick, shot, or has fallen against some hard object; the latter, when he has first fallen against some hard body and subsequently fallen on his extended hand—as when falling down stairs. Luxation of the radius cannot occur if the ulna be fractured below its upper third. These conclusions are drawn from further experiments on the cadaver.

The *symptoms* of the injury are given as follows: Inspection reveals an angle outlined by the contour of the soft parts of the dorsal aspect of the forearm. The elbow-joint shows a well-marked bulging either towards the front, or laterally and anteriorly or posteriorly combined. This prominence, caused by the capitulum radii, moves when pronation and supination are performed. The circumference of the injured joint is increased from $2\frac{1}{2}$ to 4 cm. On the posterior aspect three points can be made out, with the help of which a triangle may be constructed, having as its apex, the point of fracture of the ulna, and, as its base, a line drawn from the olecranon to the capitulum radii. This line passes directly over the external condyle of the humerus in its middle. The injured arm appears shortened to the extent of $1\frac{1}{2}$

cm. The dislocation of the fragments depends upon the direction of the violence; the lower fragment remaining parallel to the radius in all cases, the upper one varying in position. The fore-arm is generally found half flexed, and half pronated. The elbow is frequently much swollen. Crepitation is always present at the point of fracture. Flexion is interfered with, but extension is possible; supination is somewhat impeded. The ulna alone is shortened about 3 cm.

Complications of the injury are some times present and consist in subluxation of the styloid process of the ulna, paralysis of the musculo spiralis nerve—a frequent source of danger—compound fracture, or injury to the soft tissue, and fractures of the epicondyles or condyles of the humerus, the latter being of very rare occurrence.

The prognosis is quite favorable if the treatment is begun at once, or even within the first six weeks. After the first two months there is less hope of success on account of the capsular degeneration; a new capsule is soon formed wherever the head of the radius remains, so that function may, in a measure, return, if the fragments of the ulna unite. If the latter does not occur, the use of the hand is entirely lost. Arthritis deformans may occur in later years as a result of the injury. The prognosis of paralysis is unfavorable.

As regards treatment, it is of great importance to bear in mind the possibility of an existence of a luxation of the radius in all cases of ulnar fracture. After replacing the capitulum of the radius with the help of extension and direct pressure from below, the arm is to be fixed in a half-supinated position and flexed at an acute angle at the elbow (so as to eliminate the action of the biceps) by means of a water-glass or starch bandage, to be left on for four or six weeks. The position of half-supination is maintained in order to prevent the new-forming callus from again occasioning a displacement.

In old cases where replacement is impossible, resection of the capitulum radii is indicated. Osteoparalysis of the ulna may become necessary in some cases. Compound fractures are to be antiseptically treated.—*Deut. Zeitschr. f. Chirurg.* Bd. 23. H. 3 and 4.—*Annals of Surgery*, September, 1886.

HOW TO INCREASE THE BODILY WEIGHT.—In a little pamphlet entitled "Brief Practical Directions for Exercising and Using the Developing Apparatus in the Pratt Gymnasium, Amherst College," we find the following:

"Exercise all the muscles moderately for a short time daily. Do not become greatly fatigued. Take a short spray bath, with moderately cool water, two or three times a week. Avoid excessive mental exercise, study, or worry. Do things quietly and moderately, and not with a rush. Lie down and rest, or sleep for half an hour after dinner and supper if possible. Do not study soon after eating. Practice deep breathing and holding the breath, to exercise the diaphragm and stomach. Retire early at night and sleep as long as possible. If sleepless from brain work, eat a few graham crackers before retiring, to draw the excess of blood from

the brain to the stomach. Then bathe the head and back of neck with cold water, and if necessary the feet also, and rub them briskly till red and dry. Eat slowly and freely, thoroughly chewing the food. Choose especially the following varieties of food. If any of them causes indigestion take less of that one. Sugars, syrups, and all sweet things. Fats, fat meats and soups. Sweet vegetables of all kinds. Corn-starch, tapioca, and all puddings, cakes, candies, and nuts, tea, coffee, chocolate, and cocoa diluted with much milk and well sweetened. Cream and new milk. Butter, eggs and condiments. All other foods may be indulged in to the extent of the inclination. Chewing gum daily before eating and between meals increases the flow of saliva, and so aids the digestion of fat-making foods. It also indirectly stimulates the secretion of the digestive juices of the stomach."—*N. Y. Medical Journal*, Oct. 16, 1886.

GASEOUS MEDICATION PER RECTUM.—BERGERON says that this therapeutic method is based on the physiological principle established by C. Bernard that the introduction by the rectum of substances, even of toxic nature, is not dangerous so long as elimination by the respiratory passages is not hindered. It has been also observed that a current of carbonic acid gas may be introduced in indefinite quantity into the rectum without giving rise to any ill effects, provided certain precautions be adopted. After having tried the effect of a number of balsamic parasitocides and antiseptics, the author has concluded by giving preference to sulphurous mineral waters. A current of four or five litres of carbonic acid gas traversing from 250 to 500 grammes of sulphurous mineral water (Eaux-Bonnes, Allevard, Saint Honoré, Challes) is introduced by the rectum twice every twenty four hours. After the employment of these measures for a few days, it has been observed that the cough has been greatly relieved, the expectoration has been profoundly altered in quality and its quantity reduced to a very low ebb, the perspirations have been stopped, the general state has been correspondingly improved, and this not only in incipient phthisis, but also in the confirmed stages of the disease.—*Lancet*, Oct. 2, 1886.

RUPTURE OF THE BLADDER.—The result of suturing the rent in cases of rupture of bladder has not hitherto been successful, but the opinion held by surgeons, that it is the right treatment to pursue in such cases, receives strong confirmation from a case now under the care of SIR WILLIAM MACCORMAC in St. Thomas's Hospital. The patient, a strong, florid, healthy man, aged 33, injured his abdomen by running up against a post, about fifteen hours before he applied for admission. Interrupted silk sutures were used for the bladder, the rent in which was about three inches long, a catheter was tied in, and the abdomen drained by a glass tube. There was a large amount of urine in the peritoneal cavity, which was washed out with a solution of boracic acid. The operation was performed on the 22nd ult. The patient passed urine the following day, when the catheter was removed. The drainage tube was taken out on the 24th, and there has been no fever or other symptom since the operation.—*Lancet*, Oct. 2, 1886.

SOME POINTS IN BRAIN SURGERY.

At the recent annual meeting of the British Medical Association Mr. VICTOR HORSLEY read a very interesting and practical paper on "Brain Surgery," in which he handled the subject by describing in detail the treatment of an imaginary case, and illustrated his remarks by photographs and specimens from patients exhibited, and from lower animals which had been made the subjects of experiments. Even in the best courses on operative surgery little or nothing is done in the way of making the student familiar with operations on the brain, and it will therefore be of interest to follow closely, in this place, the matter of Mr. Horsley's paper.

On the day before the operation the head of the patient is shaved, and washed with soft soap, and then ether; after which the position of the lesion is ascertained by careful measurement, and the place marked on the scalp. After this the head is covered with lint, soaked in a 1 to 20 solution of carbolic acid, oil-silk and cotton-wool; by which it is thoroughly carbolized for at least twelve hours before the operation. The usual purgative is then administered, on the evening previous to, and an enema on the morning of, the operation. In anæsthetizing the patient Mr. Horsley advises the use of a quarter of a grain of morphia, hypodermatically, and then chloroform. (It should be remembered that chloroform is more used in England than in this country.) The morphia allows a prolonged operation with a smaller quantity of the anæsthetic; and, as ascertained by Prof. Schäfer and Mr. Horsley, it causes well-marked contraction of the arterioles of the central nervous system; so that an incision into the brain is accompanied

by comparatively little oozing if the patient be under its influence. The author remarks that he has not used ether because he feared cerebral excitement from its use, while chloroform causes cerebral depression; but he states that in case of heart complications ether would be used. He thinks that in case of considerable heart trouble cocaine might be used as the anæsthetic; and if so, a very strong solution should be used when the dura mater is reached, as this membrane is very sensitive. As sepsis is the one cardinal point on which success of brain surgery depends, any solution applied to the dura must of course be thoroughly aseptic. Mr. Horsley thinks that in treating the wound the strictest Listerian precautions should be used: the spray, 1 to 20 carbolic solution, and for the first few days at least dressings of carbolic gauze. Sublimate gauze, the skin being protected by carbolic gauze, may be more serviceable; but good carbolic gauze is elastic enough.

He condemns the usually advised cruciform incision as inconvenient, for it is necessary to hold back four flaps; a semilunar flap simply has to be thrown back, and is not again in the way. It is important: 1. To carry the incision vertically to the bone and to raise with the flaps all parts superficial to the periosteum. 2. To make a shallow curve, so as to avoid cutting collateral vessels. 3. The incision must be so drawn as not to divide the main arterial trunks supplying that portion of the scalp (which can be easily done so as not to interfere with the first twenty-four hours' drainage of the wound, even if the flap be turned downwards; since, as the patient lies in the supine position, the discharge can always escape from the posterior border). The periosteum should be reflected by a crucial incision from an area corresponding to the first trephine hole, and subsequently as more bone is cut away. In removing the bone "one of the safest and most rapid plans is to make a couple of trephine holes at the opposite extremities of the area to be removed, then to cut half the sides of such an area with a Hey's saw, and finally to complete the division with a powerful bone-forceps. Assuming that the dura mater has been, by means of the trephine-holes, separated as far as possible from the under surface of the bone to be removed, I should have premised that, as no doubt will usually be the case where exploration has to be made, the opening of the skull will have been commenced by the removal of a large disc with the trephine." He prefers a trephine of two inches in diameter. When it is possible to preserve the dura mater intact the removed portions of bone should be kept in aseptic sponges, and placed between

the skin and dura mater at the end of the operation, they having been previously divided into small fragments in the manner indicated by McEwen. "The dura mater should be incised round four-fifths of the circumference of the area exposed at $\frac{1}{8}$ inch distance from the edge of the bone, so as to render it possible to stitch the edges together afterwards. The dura mater is best opened first by incision with the scalpel, and then by blunt-pointed curved scissors, great care being taken not to wound the meninges beneath. The main branches of the middle meningeal artery are best secured by a ligature passed through the dura mater just outside its cut edge, and knotted before the vessel is divided.

We now come to the treatment of the brain. The first practical point to notice after division of the dura, says Mr. Horsley, is whether the brain immediately bulges into the trephine hole or not. "I am inclined to believe that the fact of the brain bulging very prominently into the wound indicates pathological intra-cranial tension—a piece of evidence which, if true, is obviously of the highest importance, since, other things being equal, it will indicate the existence of a tumor. I have never, in experiments on healthy animals, observed such immediate bulging, and, conversely, it has never been absent in the three cases of tumor. Should no abnormality be found in the membranes, the color of the brain should be carefully noted. Of course in order to judge as to the color one should have experience, and this may be gained by experiments on the lower animals." "The existence of a slight yellowish tinge, or, possibly, the opposite condition, namely lividity, will indicate the existence of a tumor beneath the cortex in the corona radiata. The condition of the vessels and the perivascular lymphatics must next be investigated, and particular notice taken of any yellowish white patches in the walls of the latter, indicating old mischief. An accurate knowledge of the arterial and venous supply of the brain is highly necessary, since, not only for this purpose, but also for the more difficult one of removing portions of the brain, is it of great service to see at once what portions of the brain are actually, or likely to be, deprived of their blood-supply. Alterations in the density of the brain must next be observed; but it must be remembered that cerebral tumors situated beneath the cortex are scarcely to be detected, save by exploratory incision." Now comes the consideration of the removal of a tumor or a portion of brain substance.

Probably the greatest dread of interfering surgically with the brain is the fear of hæmorrhage, which, says Mr. Horsley, is as unreasonable as the taking of

aseptic precautions is indispensable. As in the kidney, the arterioles of the brain are directed perpendicularly to surface; and we know that a slight incision of the kidney is followed by free hæmorrhage, which often causes no little alarm, but which ceases if the wound be plugged for a few minutes with a piece of sponge. "We ought to treat the brain in the same way, and thus while being conservative as far as possible, we should obtain in addition a cleanly cut surface most favorable to rapid union." It will be remembered that much of this hæmorrhage may be avoided by the use of morphine. It seems scarcely necessary to say that every main vessel should be left intact, in view of the terminal character of the cerebral vessels. Owing to the fact that the vessels run in the pia mater they can be raised from the brain, and especially from the sulci while a portion of the subjacent brain is removed, and without serious damage to the vessel-wall. In incising the cortex the cut must be made exactly vertical to the surface, and directed into the corona radiata, when necessary, in such a manner as to avoid damage to fibres coming from the portions of the cortex, and surrounding the seat of the operation; which is easily done by remembering the paths taken from the cortex to the internal capsule. With a knowledge of cerebral localization it will be possible to operate without destroying all portions of any particular centre, unless total paralysis of a part be preferable to leaving diseased tissue which would keep up the symptoms for which the operation is made. After the removal of a portion of brain the floor of the wound bulges almost to a level with the surrounding cortex, and there is a tendency to hernia cerebri. Hence the value of the large semilunar flap becomes more apparent, as it more readily unites by first intention, and it is strong enough to resist the upward push of the brain; which is not the case with the cruciform incision.

In regard to closure of the wound Mr. Horsley says: "I suppose that at the present time I shall be accused of insanity if I propose to lay down the dictum that, as a rule, wound cavities produced by removal of portions of the brain are not to be drained for more than twenty-four hours; but it is, nevertheless, my intention to make such a proposition. Let us consider for a moment the conditions of the problem. We wish to obtain union by first intention—that is, firm union in four or five days. We also wish to secure pressure on the brain, which, as just mentioned, is tending to extrude; and, finally, we wish to arrange matters so that, when the wound is finally healed, the flap of skin may be separated

from the brain beneath by a cushion of soft normal (that is, non-inflammatory) connective tissue. All these latter conditions are to be obtained by allowing a certain amount of tension of wound-exudation within the cavity. During the first twenty-four hours, there is a steady oozing of blood and serous fluid from the cut surfaces. This is best removed; and therefore I put in a drainage-tube at the most dependent point of incision (that is, as the patient lies in bed). This tube is to be taken out the next day, and the wound carefully dressed, firm but gentle pressure being made over the centre of the flap. If the wound-exudation that subsequently collects in the cavity accumulates to any appreciable extent, on the third day the patient may complain of some pain and throbbing in the wound, which, when exposed, will be found to be distended in the centre, the periphery being firmly united. Now comes a most difficult point in the treatment—namely, the question whether this tension is to be allowed to proceed, or whether it should be released. By adopting the latter measure, the advantages of the pressure will be lost; so that the point in question is one requiring special attention. The practical feature upon which it is to be decided is the very simple one whether the primary union is in danger of being broken down by the pressure or not. If the former is the case, the pressure can easily be diminished by gently opening up the track of the drainage-tube with a probe, and liberating some of the exudation. The value of the tension in reducing the tendency to hernial protrusion is obvious; but I wish to draw attention to the fact that, until it is finally absorbed, the heightened pressure serves two purposes. In the first place, it compels the lymphatics of the brain meninges to absorb the fluid, just as the peritoneal vessels do after ovariectomy, so admitting of rapid union of the whole skin-wound; and, in the second place, it acts as a kind of scaffold for the building up of normal connective tissue in the part. This latter point is very obvious in the lower animals, in which, if we reopen the wound at the end of a few days, the cavity is always found filled with a delicate, spongy, pink connective tissue, the meshes of which contain the above mentioned wound-exudation. It is this connective tissue which is to form an elastic barrier between the scalp and the brain. As a general rule, it will never be necessary to do more than relieve the tension in the wound once. At the end of a week or five days, the wound may be lightly covered with a little powdered boracic acid, cotton-wool, and collodion; and the stitches may be removed at any time after the first week. It will always be found that the scalp

tends to fall in a little at the seat of operation; but, if the foregoing directions have been faithfully followed out, the hollowing will be slight. It may be considered as a point of practical importance whether a patient will not run considerable risk in pursuing his avocations with a large gap or gaps in the skull. As a matter of fact, this is of little account, as evidenced by experience."

In case a second operation be necessary it will be found that the cicatricial tissues referred to above will be more vascular than the normal tissues, and the dura mater will be slightly adherent to the surface of the brain close to the cut margin on the dura mater. Old cicatrices in the substance of the cortex, above all those which have healed by suppuration, filling up cavities caused by loss of substance, frequently displace large vessels and give passage to large veins.

Mr. Horsley reported three cases of operation on the brain for epilepsy, in which the patients recovered. In one case a tumor was removed, and as the brain substance all around it appeared dusky and rather livid he removed all the part apparently diseased. Microscopic examination showed that the tumor was of tuberculous origin. Since Mr. Horsley's paper was read he has operated on another case of tumor of the brain. The patient was a man who had been absolutely hemiplegic for a month, and had passed into a semi-comatose condition; and before the development of these symptoms he had suffered from fits and a terrible pain in the head. Mr. Horsley trephined over the motor region of the right hemisphere, and removed a tumor weighing four ounces and a half. On the day after the operation the patient was perfectly rational, and free from pain. On the fourth day the wound was entirely healed. The successful outcome of these four operations gives all the more value to his admirable paper, which may be found, with an able discussion, in the *British Medical Journal*, of October 9, 1886.

SHOULD PHYSICIANS PRESCRIBE OFFICIAL MEDICINES ONLY?

The following resolution adopted by the American Pharmaceutical Association at its last annual meeting is worthy of more than a passing notice:

"*Resolved*, That this Association solicit the aid and coöperation of the American Medical Association, in promoting the prescribing by physicians of official medicines only, or such preparations as have published formulæ, in preference to others; and that the sev-

eral State Pharmaceutical Associations make similar requests of their respective State Associations."

To what extent members of the profession are in the habit of prescribing unofficial medicines and preparations, accurate formulæ for the preparation of which are not published in any manner accessible to pharmacutists generally, we have no mean of knowing. That it prevails to a considerable extent must be inferred from the fact that it has attracted the attention of the American Pharmaceutical Association and is by its members deemed of sufficient importance to require a protest from them. So far as the practice does prevail it is injurious in all its tendencies. If the physician prescribes a medicine of any particular drug-manufacturer's preparation instead of the standard article as given in the Pharmacopœia, he lessens the value of his clinical results for comparison with those obtained by others; and if he prescribes the compounds of this drug-house and that, as "Nichol's Calasaya Iron and Strychnia," or Battle's "Iodia," or the prescription of some eminent physician, as Gross's or Brown-Séquard's anti-neuralgic pills, etc., he not only renders his results valueless for therapeutic comparison, but he fosters the injurious habit of prescribing compounds without carefully adjusting the relative proportion of each ingredient to the condition of the individual patient, and greatly neglects the study of the therapeutic action and value of every drug he uses. Such prescribing is also unjust to the honest pharmacist or prescription druggist, who is compelled to keep a large assortment of unofficial and proprietary medicines for the purpose of filling such prescriptions instead of using articles of known strength and purity, perhaps prepared by himself in accordance with the standard of the Pharmacopœia; and on the other hand, it constitutes one of the most efficient means of fostering the whole system of manufacturing proprietary compounds for popular as well as professional use, and their imposition upon credulous invalids, whether imaginary or real, to the aggregate value of millions of dollars annually. It would be a great gain to scientific medicine if every physician in prescribing would direct only remedies of officially recognized strength and purity, and would state the exact amount of each ingredient.

EXPERT EVIDENCE.

In the case of "Louisville, etc. Railway Co. vs. Falvey," Sup. Court Indiana, Cent. L. J., April 2, 1886, the following important ruling was made: The opinion of a physician as to the character and per-

manency of a personal injury is competent. In examining an expert, counsel may assume the facts to be as he thinks they are, and ask for an opinion on those facts. It is competent for a plaintiff, injured by the negligence of another person, to prove that he obeyed the directions of his physician. One who is injured by the negligence of another is bound to use care to procure surgical aid, and also to prevent the aggravation of the injury, but the degree of care required is only ordinary care. Where a passenger receives an injury in a collision caused by the negligence of the servants of a railroad company, and disease is excited or developed by such injury, the injury may be considered as the proximate cause of the disease. It is proper to instruct the jury that if the result of the injury was to diminish the plaintiff's capacity to earn money, that fact should be taken into consideration in estimating damages. A verdict will be set aside on the ground that the damages are excessive, only in cases where the damages are such as to induce the court to believe that the jury must have acted from partiality, prejudice, or corruption. The declarations of an injured person indicative of present pain are inadmissible.

SOCIETY PROCEEDINGS.

AMERICAN RHINOLOGICAL ASSOCIATION.

Fourth Annual Session, held at the Polytechnic Building, St. Louis, Mo., October 5, 6, and 7, 1886.

TUESDAY, OCTOBER 5.—FIRST DAY.

MORNING SESSION.

The meeting was called to order by PRESIDENT A. DEVILBISS, of Toledo, Ohio.

DR. H. F. HENDRIX, of St. Louis, made the

ADDRESS OF WELCOME.

He congratulated the Association on its healthy and growing condition, and upon the high quality of its membership, that it was not a local organization, but is spread north, east, south and west.

DR. A. DEVILBISS, of Toledo, O., then delivered the

PRESIDENT'S ADDRESS.

It was appropriate, instructive and interesting, and gave much satisfaction. He spoke of the purposes of the meeting; of the splendid progress made by the Association in past years; of the duties of the Rhinologist to the general practitioner and the community in which he lives; of the necessities of medicine; of the treatment of diseases of the nose and throat as compared with the past, and lastly, of the publication of the transactions of the Association.

DR. H. JERARD, of East Lynne, Mo., read a paper on

NECROSIS OF THE NASAL BONES.

The salient points of this paper were that "we have necrosis of nasal bones which is too often attributed wrongly to syphilis, and thereby harm is done to the patient and domestic infelicity produced. Also, that the necrosis is oftentimes *not* the *result* of a diathesis, but the *cause* of the systemic conditions. Further, that these conditions are produced in non-specific cases by too irritating treatment. Treatment must be preëminently soothing."

DR. C. H. VON KLEIN, of Dayton, O., did not think that there must be a specific disease in order to have diseased bone in the nose, and related cases to show that such was not the case. He recommended iodide of potassium as the constitutional treatment, and operative treatment locally.

DR. THOS. F. RUMBOLD, of St. Louis, Mo., had seen a case where he thought the necrosis was due to the use of pure carbolic acid. Treated antiseptically the case recovered.

DR. R. S. KNODE, of Fort Wayne, Ind., had never yet seen a case cured permanently.

DR. P. W. LOGAN, of Knoxville, Tenn., read a paper on

A MIXED FORM OF ATROPHIC AND HYPERTROPHIC CATARRHAL INFLAMMATION (HERETOFORE UNDESCRIBED), AND ITS TREATMENT.

He said there exists in mixed forms of atrophic and hypertrophic catarrhal inflammation of the upper air passages hypertrophy and atrophy of the mucous membrane of the nose, nose and pharynx, or nose, pharynx and larynx. He had observed numerous cases of the form of inflammation, some of which were apparently so slightly affected that some observers would, on examination, conclude that the affected structures were in a healthy condition. In other words, this mixed form of trouble does not present the usual characteristics of either the hypertrophic atrophic variety of catarrhal inflammation. In the mixed form of trouble he has usually found especially the atrophic element predominating in adults and in children, generally the hypertrophic element greatest, yet in both adults and children treatment adapted to atrophic inflammation is, he is sure, the correct treatment for the mixed form of catarrhal inflammation. Another valuable point made was that our treatment therefore must be directed to the relief of the atrophic condition always when atrophy exists, regardless of any hypertrophy which may be present.

DR. THOMAS F. RUMBOLD, of St. Louis, thought that the treatment of the mixed form should be milder than in either case. The subject was further discussed by Drs. von Klein, Jerard, Van Allen and Logan.

DR. O. F. BROWN, of Lexington, Ky., read a paper on

CHROMIC ACID AND TRI-CHLORO-ACETIC ACID IN THE TREATMENT OF HYPERTROPHIES OF PHARYNGO-NASAL CAVITIES.

DR. C. H. VON KLEIN had made use of this treatment with success. If diluted and mixed with iodo-

form it acts much more satisfactorily. He used one-quarter glycerine and three-quarters acid with about three to four per cent. of iodoform.

DR. A. DE VILBISS did not believe it safe to use chromic acid.

DR. O. F. BROWN said that if applied in small quantity and an alkali applied immediately afterwards there would be no evil effects.

DR. R. S. KNODE preferred chromic acid.

AFTERNOON SESSION.

DR. CARL H. VON KLEIN then delivered an address on

RHINOLOGY IN THE PAST AND OF THE FUTURE.

(Which will be published in an early issue.)

DR. I. W. FINK, of Hillsboro, Ill., read a paper entitled

THOUGHTS RELATING TO THE NASO-PHARYNGEAL TRACTS.

The writer held that the study of medicine as it is to-day is too much for one man to master. The naso-pharyngeal passage alone is a very important field of mucous membrane, and involves special organs of sense, olfaction, vision, hearing, and intellectual conception.

It is necessary to know what normal health is, in order to know what the opposite condition might be. In rhinological study of disease it is essential to know a healthy mucous membrane from a diseased one, and therefore it requires the most strict observation by the student of medicine to discriminate the two conditions of mucous membrane; a healthy from a diseased one; as well, also, the degree of inflammation present, in order that the treatment may be properly directed. Rhinological practice has a more important place than either the eye or ear.

The study of the sequences resulting from the diseased condition of the mucous membrane under consideration, is awakening a lively interest in the general practice of medicine, and has a first importance in the treatment of disease liable to arise from an unhealthy condition from the source we refer, "naso-pharyngeal membrane."

DR. J. R. VAN ALLEN, of Kansas City, read a paper on

ASTHMA, ITS CAUSE AND TREATMENT.

He said he was forced to believe colds the most frequent cause, and the nasal and pharyngeal nasal cavities the starting point of a very large proportion of the cases of asthma. He was led to this belief from having found existing in every case a very severe chronic inflammation of the nasal and pharyngo-nasal cavities, and from being able to trace every case he had had to this cause; and also from the marked relief he had been able to afford the cases presented to him by directing his whole treatment to the relief of their chronic catarrhal inflammation. He also described his treatment, and many interesting cases.

The paper was discussed by Drs. Gordon, Van Allen, T. F. Rumbold, De Vilbiss and Knodel. The

general opinion being that asthma could not exist without some nasal trouble being present.

WEDNESDAY, OCTOBER 6.—SECOND DAY.

MORNING SESSION.

SCARIFICATIONS IN NASAL HYPERTROPHIES,

by DR. A. G. HOBBS, of Atlanta, Ga., was read by the Secretary.

DR. N. R. GORDON, of Springfield, Ill., stated that terebine would take the place of eucalyptol in every respect.

DR. J. NORTH, of Keokuk, Ia., scarified, and then introduced a piece of slippery elm to keep up the pressure and act as a dressing.

DR. T. F. RUMBOLD, of St. Louis, preferred scarification to the galvano-cautery.

DR. A. DE VILBISS preferred the snare.

DR. H. MARKS, of St. Louis, read a paper giving his methods in the *Treatment of Catarrhal Inflammation of the Nose and Throat, including Diphtheria*.

AFTERNOON SESSION.

DR. H. F. HENDRIX, of St. Louis, read a paper on

COLDS IN VERY EARLY INFANCY.

He claimed that the principal cause of cold-taking by infants was a sudden change from a warm to a cold atmosphere. The infant is bathed by a careless nurse and allowed to take cold, which often runs into nasal catarrh or rhinitis. His most important preventative was warm clothes, with a warm room.

DR. J. P. MATTHEWS, of Carlinville, Ill., read a paper entitled

IS HAY FEVER (SO-CALLED) A DISEASE PER SE?

He intended to prove that as in hay fever there was no elevation of temperature, no fever existed, not only the term hay fever was a misnomer, but many of the names given to the affection were also misnomers. It gave synopsis of many writers' opinions on the subject, many of whom, with the essayist, believed that emanation and probably the pollen from plants was the sole cause of the trouble. He regarded the dermatitis produced by poison oak, or poison sumach (*rhus toxicodendron* and *rhus venenata*), and the irritation produced upon mucous membranes of the upper air passages by pollen, as analogous; both the result of plant emanation; the one affecting the cutaneous surface, the other the mucous surface. Also, that unlike constitutional affections, it requires no dyscrasia, only a susceptibility to the plant, as predisposing cause, and inasmuch as one member of a family may be susceptible to either the *rhus* or the pollen of plants (rag weed—*ambrosia* elation—most frequently) while another member of the same family is not, hereditary influences have nothing to do with it. If they be analogous, there can be no neurosis, as some authors claim. If there be no neurosis, no heredity, and not necessarily any dyscrasia, it can hardly be regarded as a disease *per se*.

The treatment recommended was possible preven-

tion. The use of a respirator, spraying the parts with vaseline in which is incorporated either cocaine or better, watery extract of opium, with one of Dr. Rumbold's spray producers; change of residence. The first to keep out the offending pollen, the second to protect the parts and soothe them, the last, and most effective, is to move to parts where the offending plant does not grow.

DR. J. R. VAN ALLEN, of Kansas City, thought that those cases where attacks occurred in the spring were the more amenable to treatment.

DR. T. F. RUMBOLD thought that nasal disease always preceded an attack of hay fever (pruritic rhinitis).

DR. MATTHEWS believed that there were cases where there existed no disease of the nasal mucous membrane before the contact of the vegetable emanations.

DR. RUMBOLD stated that it was the experience of persons whom he had consulted that change of location was only beneficial for a few seasons, and then they would have to hunt some new place for relief. It was his opinion that by proper treatment the case could be cured in time without recourse to the harsher methods of using the cautery or acids.

DR. VON KLEIN asked the question as to whether this disease was due to certain localities, atmospheric changes, or to plants.

DR. O. F. BROWN was of the opinion that it was simply a form of catarrh. He thought it to be a disease of the terminal nerve fibres after the mucous membrane was affected.

DR. VON KLEIN stated that he had had a hay fever patient who was only five years old.

DR. A. DE VILBISS had also seen a hay fever patient five or six years old.

DR. P. W. LOGAN stated that as the catarrhal inflammation is relieved the hay fever abates. Such had always been his experience.

DR. MATTHEWS thought he had seen cases in which he could detect no trace of nasal disease. He thought that very often what catarrhal symptoms were present were due to the irritation caused by the pollen of the noxious plant. He had used respirators with good effect in some cases.

THURSDAY, OCTOBER 7.—THIRD DAY.

MORNING SESSION.

DR. N. R. GORDON, of Springfield, Ill., read a paper on the

IMPORTANCE OF EARLY RECOGNITION AND TREATMENT OF NASO-AURAL CATARRH.

He called attention to the fact that most cases of aural catarrh had their beginning in affections of the nasal passages; that many cases of impaired hearing in children were due to the neglect of nasal catarrh, which impairment dates from an attack of cold in the head. He urged the necessity of prompt treatment in all cases of catarrh which involved the ear, as giving the most satisfactory results.

DR. THOS. F. RUMBOLD read a paper on the

TREATMENT OF PRURITIC RHINITIS (HAY FEVER, SUMMER CATARRH, ETC.)

In examining the patient I am careful not to cause the least irritation, either from sneezing, coughing, or from thrusting the nasal speculum up his nostrils. If the patient is fleshy and has a troublesome cough, it is best to allay this by using spray producer No. 1, spraying a half dram of vaseline and from 2 to 5 drops of the following mixture:

R. Pinis canadensis (Kennedy's).....	grs. iij.
Glycerinæ (Price's).....	3ij.
Acidi carbolicæ.....	gr. ss.
Ol. gaultheriæ.....	gtts. v.
Aquæ ferro.....	3vj.
M.	

Care should be taken that the spray-producer be warm both before and after the medicaments are placed in it. Even if the remedy be liquid it should be made warm; the heated spray more readily cleansing the surface, as well as producing a soothing effect on the inflamed mucous membrane. This application will immediately mitigate the irritated condition of the throat, and make gagging less liable. This application should be followed by spraying, with spray-producer No. 4, half a dram of vaseline and about 5 grains of the following mixture:

R. Vaseline.....	3j.
Eucalyptol (Merck's).....	gtts. v.
M. Cold.	

The same quantity and mixture should be applied with spray-producer No. 5.

In making applications with the last two instruments named, the point of the spray-producer should be placed just below and behind the pendant soft palate, alternately on each side of the uvula. The air pressure should not exceed 5 lbs. to the square inch. After a few treatments, it will be noticed—if the patient is recovering—that he will require a greater pressure, as the secretions become heavier, or more purulent.

The physician must so handle his instruments that he will not cause the patient's throat to contract, thus preventing all application. The tongue depressor should not be placed too far in the mouth, as this is apt to cause retching. If the patient breathes freely and easily, the soft palate will hang pendant and passive; a condition of these parts essential to successful treatment. If the anterior nares are not in too irritable a condition they should be sprayed with vaseline alone, using spray-producer No. 2, and a nasal speculum that will hold the nostrils widely dilated without causing irritation; not even the sensation of sneezing, as this causes more irritation than the vaseline spray can allay.

If the patient comes with his eyes red and suffused with tears, and quite a flow of watery secretion from the nostrils, at once anoint his nose, eyes, eyelids and eyebrows with vaseline. This will almost immediately allay the irritation of these organs, showing the close relationship between the integument and the mucous membrane. At this first visit I prescribe a laxative, tonic and diuretic and 10 grains of quinine, to be taken on going to bed. This completes the

first day's treatment, the effect of which is a very material mitigation of all the symptoms, every patient saying voluntarily that he feels greatly improved, and this is repeated several times.

At the second visit the patient will return with his former symptoms, but all of them less severe. Headaches and difficulty in clearing his throat in the morning will be less annoying. His sneezing also will be reduced at least one-half. This course is followed up every day through the season that the patient has his attacks. If the patient has his first attack on the 20th of August and comes for treatment the 1st of September, the treatment may have to be repeated for ten or twelve days. At the end of this time the enlarged turbinated processes will be greatly reduced and the nasal respiration be carried on without difficulty. After this, treatment every other day is all that is required. Upon inquiry it will be found that upon the recovery from former attacks there has been a large muco-purulent secretion from the nasal passages, and that this has been regarded as the harbinger of recovery. But if the treatment has been successful, this discharge will not be seen, showing that local application has prevented the inflammation from reaching such a severe grade that its recovery takes place.

Electricity is a valuable adjuvant in patients who are thin in flesh, and is of little or no benefit and many times an irritant to those who are corpulent. The galvanic current should be employed. The number of cells required depends upon the effect on the patient; that is, the well-known metallic taste in the mouth should be produced, proving that the nerves of these organs are under influence of the agent. An application that does not produce this effect will prove inefficient. I use a large wooden cup containing a sponge connected with the negative pole (cathode); this is applied over the solar plexus. The positive pole (anode) is applied from the seventh cervical vertebra up to the hair. After an application of about one minute, I take the positive pole in one hand and with my wet fingers of the other hand make applications over the bridge of the nose, the eyebrows and cheeks. The whole application should not last longer than three minutes. Patients are very fond of the effect of electricity, which is frequently more beneficial during acute attacks than after recovery. Quite a number believe the best effect of electricity is experienced three or four hours after its application. I have not applied the galvano-cautery nor chromic acid in any case since last December, and used the Jarvis snare, as modified by myself, in but three out of twenty-eight cases. I have used cocaine in four or five cases. My observation is that its application is always followed by persistent congestion.

I still hold to the views I expressed at the meeting in Lexington, Ky., in 1885, namely: that no patient should be operated upon until it has been found that the treatment by the spray-producer will not have the desired effect.

Atropine solution is far better than cocaine; a 5 per cent. solution is the strength I employ. I apply it by a small piece of cotton.

In reply to a question Dr. Rumbold stated that hay fever was a neurosis from an inflammation.

DR. O. F. BROWN had used chromic acid in every case of hay fever, and had always stopped the sneezing asthma and coughing.

AMENDMENT TO CONSTITUTION.

Amendment to constitution offered last year by Dr. Carl H. von Klein, of Dayton, Ohio, to adopt the constitution of the American Medical Association, was voted on and adopted unanimously.

The following were elected

OFFICERS FOR THE ENSUING YEAR.:

President—J. A. Stuckey, M.D., of Lexington, Ky.

First Vice-President—Carl H. von Klein, M.D., of Dayton, Ohio.

Second Vice President—Theodore North, M.D., of Keokuk, Iowa.

The Association then adjourned to meet on the last Tuesday in September, 1887, at Dayton, Ohio.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, October 7, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

RUPTURED FALLOPIAN PREGNANCY, LEFT SIDE.

DR. JOS. PRICE exhibited the ovary and distended tube, which had burst spontaneously. No fetus was discovered; a very free hæmorrhage into the peritoneal cavity had occurred. In the vast majority of cases the rupture is fatal. The cause of death is invariably hæmorrhage.

DR. PRICE also exhibited specimens from a case of

DOUBLE PYO-SALPINX, WITH CYST OF THE RIGHT BROAD LIGAMENT, AND ABSCESS OF THE OVARY OF THE SAME SIDE.

The specimen consisted of both Fallopian tubes and ovaries, and was a good example of pyo-salpinx, both tubes being closed at the ends and distended with pus. The right tube was long and very much distended, and with a large abscess of the ovary and a cyst of the ovary as large as a base-ball, occupied the whole of the right side of the pelvic cavity, where the entire mass was firmly bound down and gave rise to great suffering. The diagnosis in this class of cases is either made or it is not made. Dr. Price is quite sure Mr. Tait, before proceeding to an operation, is fairly certain of his diagnosis, and this generally presents but little difficulty. It is true that he operates early, as soon as he recognizes dangerous trouble. Dr. Price feels certain that delay with us is accountable for the large death-rate. Dr. Mundé says of Mr. Tait: "Now his wonderful dexterity and tactile sense come into play; for with these fingers he at once makes the diagnosis which he appears to pride himself on not attempting to make with accuracy in those cases demanding removal of the uterine appendages, the so-called 'Tait's operation,' except through the abdominal incision."

While at Birmingham, recently, he visited regularly

his large public clinic, and watched carefully his rapid examination; he cited one case to illustrate the fact that Mr. Tait made his diagnosis through the vagina. After passing a number of cases, displacements, etc., which he did not think of sufficient importance to ask us to examine, he came to one and kindly asked us to examine and express an opinion. Dr. Price examined and found the physical characteristics of pus. Mr. Tait's reply was "quite right." The patient was at once sent to Spark Hill for operation. One tube was found full of pus, the other partially filled, and the ovaries cystic. This case illustrates that Tait does not guess at conditions and resort to abdominal section for diagnostic purposes. A world of mischief has already come of such statements. Of course there are exceptional cases demanding exploratory incision. Tait says: "Save when the seat of such organic disease as will explain genuine suffering, the uterine appendages ought not to be removed, and that those who attribute all the pelvic ails and aches of women to the ovaries and tubes, and rush in to remove them, are dangerous people."

DR. LONGAKER considered the first case one of tubal pregnancy. Recurring attacks of peritonitis should direct attention to the probability of pyo-salpinx. The condition should be easily recognized, but is sometimes overlooked.

DR. HOWARD A. KELLY remarked that, in view of the increasing number of cases of hæmato-salpinx which we were now meeting, it was of the utmost importance that all those which came under our immediate notice should receive a more rigid examination and elaborate attention should be directed to the clinical history. He believed positive diagnostic signs would be discovered which will make our interference more a matter of scientific certainty. Dr. Kelly was not speaking of those cases of a minor degree of tubal apoplexy or hæmorrhage symptomatic of a grave dyscrasia, but of those in which, owing either to a closure of an outlet or to disease of the mucous membrane of the tubes or grave local circulatory disturbances, a mass collected forming a sausage-like tumor producing various symptoms, some of which are common to pyo-salpinx. There is always great local tenderness and often masses of exudate imbedding and obscuring the original tumor, and in cases of rupture often a peritonitis as rapidly fatal as in pus cases.

The suspicion that a tubal pregnancy lies at the bottom of the explanation in all these cases is negated by the fact that a majority of the cases are hæmato-salpinx of both tubes.

A very important symptom, which I learn was present in Dr. Price's case, was also prominent in my own case; that is, a stillicidium of bloody grumous material per uterus and vaginam, which is regarded by the patient as a prolonged menstrual period. This undoubtedly flows from the tube, and is altogether analogous to the free purulent discharge from the tubes of pyo-salpinx which he had seen. He intends, in his next case of this kind, to catheterize the tube and dilate and endeavor to relieve his case of hæmato- or pyo-salpinx in this way, if the

discharge exists in sufficient quantity to lead him to suspect a patulous uterine orifice.

Cases of hæmato-salpinx resulting in rupture and death have been reported; one is figured by Winckel.

There are several facts in connection with the life-history of pyo-salpinx which he would like to emphasize. In the first place, he has seen no case which was not the product of a gonorrhœal infection, and while not prepared to deny the possibility of a purulent change in the contents of a hydro-salpinx, for which Bandl contends, these cases, so ably worked up by Dr. Price, and his own observations elsewhere, all point to *gonorrhœa*. Again, *these cases with a history of such acute onset*, constant, agonizing pain, high temperature and often typhoid condition, are the advance stages of a florid gonorrhœa, and are found almost exclusively among the unmarried, and result from contact with a similarly active gonorrhœa in the male. They form a picture utterly different from that developing from the exposure of a wife to the discharges of a husband who has been told that a trifling gleet discharge amounts to nothing, or who has long appeared well, only noticing the discharge after occasional debauches or unusual sexual indulgence. *Here the disease assumes the insidious sneaking type*, commencing with little periodical pains scarcely noticed at first, a slight excess of menstrual flow with more pain after, and so on for months until perhaps an abortion or a pregnancy completed seems to open up channels for a more serious and general infection. I have had typical cases of this in my own practice. It will be often noticeable here that in view of the much greater suffering experienced after the puerperal period, the patient will forget what has gone before and blames her subsequent trouble on the mismanagement of the doctor.

The extreme importance of this whole question, second to none in the whole range of gynæcological investigation, suggests to the mind many pertinent inquiries. What parts of the female genital tract are the favorite seats of the disease? In what order are the structures attacked? May it linger long in one part and then, under some change of condition, attack another part? What is the resisting power of the virus to our various therapeutic agents?

The third question he believes he can answer satisfactorily. In addition to the well known cases in which the disease lingers indefinitely in the urethral tubules and the vulvo-vaginal glands, *he believes that in many of our cases of pyo-salpinx the disease has already lingered for a long time in the uterine mucosa, and has shown itself in the form of a uterine catarrh*. Since formulating this doctrine for himself it has necessarily carried him back to the treatment of many of his cases by topical intra-uterine remedies, a form of treatment which he had some time since abandoned as irrational.

A patient is now coming to his office from whose pelvis he literally quarried out a large stinking tubo-ovarian pus-sac. The left tube and ovary were unaffected, and he left them. She has a free purulent discharge from the uterus, for which the only rational treatment is active local measures.

It is important to recognize the fact that apart

from a slight irritation of the outlets of the glands at vulvar orifice, there may be no other signs of gonorrhœal disease than such discharge as issues from the uteri. The vagina may be perfectly sound. Braun and Schwartz lay especial emphasis on the fact that the flat epithelium of the vagina has great powers of resistance against the poison, while delicate epithelial structures, particularly the ciliated, are its favorite resting places.

We will apply our remedies with some success if we bear in mind the fact that the disease does not merely lie on the surface waiting to be wiped off to effect a cure, nor does it merely penetrate the tubular glands, but it invades the interior of the individual cells and attacks the nuclei; it penetrates the strata of connective tissue below, penetrates blood-vessels and lymph spaces and forms thrombi. Relapses then, even after the most energetic treatment, need not surprise us.

We find here, as in many other points, our forefathers did wiser than they knew; their therapeutic resources reached far beyond their knowledge of etiology. No wonder they used the most powerful acids and loved to leave a stick of solid nitrate of silver in the uterus to cure this most obstinate catarrh. If he cannot succeed in catheterizing some of these cases, he knows of no other way in which a perceptible deposit of pus once formed in a tube can be removed but by the radical operation. And let there be no delay here. Cases have been lost simply from the secondary consequences of carrying around this bag of pus in the abdomen. Dr. Veit alone lost two cases from brown atrophy of the heart.

DR. M. PRICE remarked that the good results in his brother's operation were due to free irrigation; from three to five gallons of warm water were used to cleanse the peritoneal cavity and to stream through it for ten or fifteen minutes.

DR. BAER made some remarks upon the value of intra-uterine medication. Although high authorities had denounced it as unnecessary and dangerous, he had continued to use it; he has never given it up as he has always found cases where it was needed, the method has been productive of good results in his hands and he never expects to give it up. It will not cure pyo-salpinx but may prevent it. It will be ludicrous to see the ultra-scientific return to intra-uterine medication after the denunciation to which it has been subjected. Dr. Baer prefers the injection of tincture of iodine, carbolic acid, nitric acid, or whatever application may be preferred, say about twenty minims by means of a hard rubber syringe to any of the cotton-wrapped or other form of applicator. No case of inflammation has followed this method of treatment in his hands, and he has less uterine colic than with the applicates, perhaps because less force is required no tenaculum or curette pressure is necessary.

DR. J. PRICE in closing the discussion remarked that in the first case there had been a missed period, and two or three weeks later a flow of blood commenced and was continuous for weeks with tenderness of the abdomen. By the microscope only can an exact diagnosis be made between hæmato-salpinx

and tubal pregnancy, and he had had no opportunity to make an accurate one. Rupture may occur early in tubal pregnancy.

An unhealthy condition of the endometrium is very rare. The abortive treatment of gonorrhœa as applied to the male urethra has resulted in orchitis and stricture. The case of pyo-salpinx was operated upon four weeks after an abortion.

DR. DRYSDALE, in view of recent strictures upon intra-uterine medication, would like to mention a case seen by him under Mr. Tait's treatment in 1883. The condition was endometritis, and Mr. Tait etherized the patient, dilated the uterus and applied the Paquelin thermo cautery thoroughly to the endometrium.

(To be concluded.)

Sparteine in Cardiac Affections—Parasitic Mesology in Man—Turpentine in Phosphorus Poisoning—The Galvano-Cautery in Chronic Metritis and Endometritis.

Basing his theory on the results obtained by M. Laborde by experiments on animals with sparteine, Professor Germain Sée has applied this remedy to the treatment of cardiac affections. He employs the sulphate of sparteine in doses of 10 centigrammes on an average in which quantity it augments the intensity and the duration of the ventricular contractions. Professor Sée considers that sparteine is a dynamic agent of the heart, the movements of which it regulates. In this respect it acts like digitalis and the lilly of the valley, but its action is more prompt and more durable. It immediately regulates the cardiac rhythm when this is altered, and has proved itself superior in this case to the other agents. It is indicated in grave, atonic affections, with slackening of the movements of the heart. All these phenomena appear after an hour or more and persist three or four days after the suspension of the medicine. During this period the strength of the patient increases and the respiration is easily performed. The urinary functions do not appear to be affected by the small dose employed. The sulphate of sparteine appears to be useful when the heart is affected in its tissues or when there is insufficiency in its action to overcome the obstacles existing in the circulation. When the pulse is feeble, irregular, arhythmic, the sulphate of sparteine reestablishes the normal state. When the circulation is slackened, the drug overcomes this functional defect in augmenting and in preserving the force acquired by the cardiac muscle.

At the Congress of the Association Française for the advancement of Science, recently held at Nancy, M. Verneuil read a paper on "Parasitic Mesology in Man," in which the author reverted to the question of auto-inoculation in regard to the importance of the influence of the various diatheses. When an in-

dividual affected with a certain diatheses receives a wound there occur manifest localizations of this diathesis which M. Verneuil terms traumatic auto-inoculation. For this three conditions are necessary: 1. A microbe. 2. A subject in a state of special receptivity. 3. A wound on certain points of the economy differing according to the nature of the diathesis. So that the rôle of the organ affected is not passive, but becomes, on the contrary, predominant.

Thus, the tubercular bacillus does not develop everywhere, and the tubercle does not break out indifferently. For instance primary tubercle has never been observed in striated muscles neither in the nipples, nor in the pituitary nor ocular mucous membranes, and yet these are permanently in contact with the bacillus. The observation is still more instructive as regards bones: The compact tissue does not accept tubercle, which on the contrary finds a marvellous soil in the spongy tissue. The articulations also are easily invaded, as well as the serous tissues. The same remark may be applied to syphilis. Indeed a tableau of all the organs and of all the viruses may be formed: A virus that would pollute one organ, would disappear in another. One organ which would favor the development of one microbe would kill another. This fact is well-known to experimenters.

They know for instance that the inoculation of gangrenous septicemia which does not succeed in the blood, progresses on the contrary with terrible rapidity when it is practised in the connective tissue. Luton, in 1880, had already enunciated a similar idea apropos of hypodermic injections but it is of importance to know what the preferred habitats of the different viruses are.

In a paper by Dr. Rondot, of Bordeaux, the author demonstrated, from clinical observations and experiments, the efficacy of "Turpentine in the Treatment of Poisoning by Phosphorus," when taken either immediately or even some hours after the poison has been swallowed. The turpentine and phosphorus combined and are eliminated without causing any other morbid phenomena than a local reaction on the alimentary and urinary organs. It is important to administer the turpentine at the outset, so as to neutralize the greatest quantity possible of the poison. Even if the phosphorus be not completely neutralized, the essential oil of turpentine renders the symptoms milder and favors recovery. Turpentine diminishes hæmorrhage and the nervous symptoms which follow poisoning by phosphorus.

Dr. Apostoli, who devotes himself specially to the female genital organs, read a paper on a "New Treatment of Chronic Metritis and in Particular of Endometritis by the Intra-uterine Application of the Chemical Galvano-Cautic." This treatment which, according to, the author, is simple and inoffensive, and which he terms a veritable therapeutic hysterometry, is nothing else than a mollecular galvano chemical scraping, acid or basic according to the cases, which provokes the formation of a new mucous membrane and constitutes a sort of intra-uterine exutory the action of which may be prolonged and varied at will. Its beneficial effect, which Dr. Apostoli observed in a great number of cases as manifest at the first sittings,

and becomes gradually accentuated and leads to a perfect cure. The patient is not condemned to absolute rest, and the treatment does not require other adjuvants. It has over surgical scraping the advantage of being dosable, localized, to be never instantaneous, and the being able to administer it in divided doses, which accumulate without danger, and at the will of the operator. DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Fifth District Branch Meeting—The Work of District Branch Societies—The Value of Statistics—Milk Supply of Large Cities—Lepto-Meningitis Infantum.

The second annual meeting of the Fifth District Branch of the New York State Medical Association, which includes the city and county of New York, the Hudson River counties as far north as Ulster and Dutchess, and all the counties on Long Island and Staten Island, was held in Brooklyn on the 12th of October. The President, Dr. J. G. Porteous, of Poughkeepsie, in his annual address offered his hearty congratulations on the success not only of this Branch, but of the parent Association, and the other Branches in the State. They had demonstrated, he said, the wisdom of the action taken at Albany on that February morning that all remembered so well; a morning not without its share of doubts and fears, which had long since been brushed aside by the wisdom and moderation of the brave men who led the new departure and stood firm for the faith.

No system of societies had been originated, he went on to say, which so thoroughly covered the ground desired, and so firmly united the members, as this of district branches—not so large as to be unwieldy, but large enough to be interesting and bring a working body of working men in contact with each other, and draw out their views in a characteristic manner; not so small as to foster the petty strife of the old county societies. He had recently seen a statement by one of the Censors of the Medical Association of Alabama, that the county medical societies of that State have a good deal of important work to do, and they do it. Most of the county societies in this State had a good deal of work to do, and did *not* do it.

In perhaps a majority the meetings were annual or semi-annual, the attendance small, and the principal business the all important one of electing officers. For years it had been only a form, and so much had this been felt by the more active members of the profession that in some parts of the State three or more counties would form an independent association, in which very good work was done. He said independent, because the State Society would not recognize them. But the District Branch Associations were still better—better organized, and, with a common head, working more harmoniously and efficiently. In this Branch, as in others that he had visited, the work had been earnest and conscientious.

The papers read had been of a character to invite discussion, and while often criticised, always in a kind spirit.

This matter of discussion he believed to be one of the most important in the Association, a really good paper often bringing out many more important points than even the author himself could have anticipated. Such discussion was of the greatest importance to the large body of general practitioners, who compose the main body of the profession, men to whose care the great bulk of the community entrust their many ills; as a rule, a quiet, shrewdly observant, practical class, more willing to be taught than to attempt to teach, men who while often by circumstances precluded from being original investigators in the broadest sense of the term, are still prompt to avail themselves of the advances made in any department of medical science which they can use for the benefit of their patients, and heartily willing to give full credit to any man who adds a tithe of usefulness to the profession.

The work of the whole Association, continued Dr. Porteous, had been carried on in a most conservative and deliberate manner; even the publication of the Transactions had not been in the least degree hurried or premature. The hand of death had made itself felt in their midst, especially in the removal of the honored President of the Branch, Dr. Gault Guernsey, his lamented friend, Dr. Austin Flint, and their distinguished colleague, Dr. Frank H. Hamilton. He would not attempt to eulogize them, as abler pens than his had found it difficult to do justice to their grand and noble characters. Had these most earnest and energetic Founders lived, no doubt they would have added much to the useful work of the Branch.

This consideration brought them face to face with the fact that they should enlist the young men of the profession in their cause, and teach them that there is something greater and more noble in the profession than the mere consideration of dollars and cents. Many of the Fellows were already feeling the weight of advancing years, and would like to know that good and true men were coming forward to take their places.

Dr. Porteous then took up the consideration of the question, What is to be the value of the statistics which are with great labor and considerable expense being collected by the State? Every member of the Association had more or less of this work to do, and he had no doubt that each did it in a conscientious and painstaking manner. But did all those to whom the law intimated this duty do the same? and if not, how could the defect be remedied? He had seen a report of death made out as caused by congestion of the kidneys, without the slightest allusion to the fact that the patient died in childbirth; and further investigation showed that the cause of death reported in the case of this woman's stillborn child was "puerperal convulsions." In another case, where the mother and child were buried in the same coffin, the mother was reported as dying of "heart disease," while no allusion whatever was made to the birth of the child, which was stillborn. No return of the lat-

ter was made until after the burial, and then only at the demand of the Registrar, when the cause of death in the infant was also given as "heart disease." Such reports were certainly misleading and must necessarily seriously impair the value of any statistics compiled from them; while in this class of cases something more than mere ignorance was shown, although this was likely enough to impair their value in many instances.

Dr. Avery Segur, of Brooklyn, who has been abroad during the past summer, gave a most interesting account of his impressions of medicine in England; among the subjects included in his remarks being the history of the Royal College of Physicians, and the Royal College of Surgeons, the study of medicine in England, the qualifications required for licensed practitioners and those entitled to the degree of Doctor or Bachelor of Medicine, the clinical advantages afforded by the great London hospitals, the Gulstonian, Croonian and Lettsonian lectures, and the benefits arising from the thorough organization of the entire profession of Great Britain in the British Medical Association and its Branches.

Dr. H. A. Pooler, of Goshen, Orange County, read a paper on "The Milk Supply of Large Cities, and the Improper Mode in which it is Conducted," in which he made a searching denunciation of the modern Herods who, urged on by the greed of gain, keep up a continual slaughter of the innocents by their iniquitous practices. In speaking of the adulteration of milk by the removal of fat and dilution with water, he quoted as follows from the report of Prof. C. F. Chandler, President of the New York City Board of Health, published in the second annual report of the State Board of Health (1881-2): "While a large proportion of the milk sold has been but moderately watered and skimmed, and is still above the standard of the poorest milk ($2\frac{1}{2}$ per cent. of fat), much of the milk has been *extended* and skimmed far below the standard. So openly are these frauds practiced that 'creameries' have been established in many localities, the names of seventy-three such establishments being known to the writer; of which sixty-three are known to send skimmed milk to New York City, all of which is sold as whole milk on its arrival." When such milk as this was further diluted by mothers before they gave it to their infants as a substitute for breast milk, it could be readily seen how greatly the children fed upon it must suffer in consequence.

Up to 1883 there was no law in the State prohibiting the shipping and sale of skimmed milk; but the passage of such a law was then secured, and inspectors were placed on the milk trains. Dr. Pooler told the judiciary committee of the Legislature that if they would pass the law he would guarantee to reduce the mortality among young children in the city of New York at least three thousand; and he was able to keep his promise. In 1879 the mortality in children under five years was 12,777, or about 50 per cent. of the births of that year. This was before the milk adulterations were carried on so extensively as afterwards. In 1880, however, the mortality in this class increased to 14,650; and while from 1878 to

1879 it increased only 300, the increase in the number of deaths from 1879 to 1880 was about 2000. The mortality in 1881 was 17,737, an increase of almost 3000 over 1880, and about 75 per cent. of the births. In 1882 the number of deaths was about the same as in 1881; but if it had not been for the work done in the autumn of 1882, he said, the mortality would have reached nearly 20,000; a close watch being then kept upon the dealers. In the winter of 1882-3 the skimmed milk bill was passed, and notwithstanding many discouraging circumstances, the mortality was reduced from 17,737 in 1881, and 17,520 in 1882, to 13,856, a reduction of some 4000.

But, unfortunately, in 1884 the good work was interfered with; because "politics laid its icy hand of death upon the embryo of a perfect reformation in the milk supply." Up to this time the labor and means employed had been to a large extent voluntary. An appropriation was therefore asked from the Legislature; but while this was granted, a Dairy Commission was also appointed, and this commission was manipulated so as to form a part of the great political "machine." There were other political changes also, and the withdrawal of Prof. Chandler from the head of the Metropolitan Health Department was an irreparable loss. Hence the mortality in children under five years increased from 13,865, in 1883, to 15,272, in 1884, an excess of nearly 2000. Dr. Edson, of New York, and Dr. Bartley, of Brooklyn, however, did all in their power with the limited means at their command, to keep the evil in check. In the mortality statistics quoted by Dr. Pooler he made no reference to the heat or coolness of the summers in the years referred to, and long-continued hot weather is always a most potent factor in the increase of infant mortality in the city of New York. Still, there can be no possible question that any improvement in the quality of the milk supplied to the poorer classes would always be attended with the happiest results in the saving of children's lives.

The latter part of the paper was principally devoted to the evils resulting from the feeding of cows with brewers' grains and distillers' mash, which, he said, were directly injurious to the animals themselves, and, while they stimulated them in such a way that the quantity of milk given was considerably increased, they produced milk of a very inferior quality. The facts showed that the action of this kind of food was to impoverish the milk in its most essential constituent, fat, and largely increase its most objectionable constituent, caseine. When the fat is not equal to the normal amount, the milk forms an exceedingly hard curd in its coagulation, which is known to the skimmed milk cheese-makers as "hickory curd." A number of beautiful micro photographic illustrations, projected upon a screen by E. W. Martin, Ph.D., chemist to the New York Board of Health, added not a little to the interest and attractiveness of the paper.

An extended discussion followed, and in the course of it Dr. A. N. Bell, Editor of the *Sanitarian*, called attention to the fact that milk from diseased cows sometimes contains a large amount of fat; this being

particularly the case, it is said, with milk from animals suffering from rinderpest. Among the other speakers was Dr. E. R. Squibb, of Brooklyn, who stated, what is undoubtedly a fact, that notwithstanding all the frauds that are practiced upon the community, the milk supplied at present to the cities of New York, Brooklyn, and Jersey City is, as a rule, of a better quality than was formerly the case.

The best paper of the evening was by Dr. Alfred L. Carroll, of New Brighton, Staten Island, the accomplished ex-Secretary of the State Board of Health. His subject was "Lepto-Meningitis Infantum," and the sum of his argument was that a malady quite frequently occurring in childhood, and often erroneously reported as tubercular meningitis, characterized by serous distension of the ventricles, and variously described under the names of "simple meningitis," "lepto-meningitis," and "acute hydrocephalus," but by most writers ascribed to hyperæmia and inflammation, is, on the contrary, essentially, due to cerebral anæmia; that the principal and most significant morbid factor is a varicosity of the choroid flexures, sometimes extending to those of the fourth ventricle, exerting Moxan's "stop-cock" action, perhaps, in many cases, and thus aggravating the arterial anæmia which gave it birth. Though it is possible that Dr. Carroll may be accused of an unpardonable sin by some of those who swallow German literature whole, for venturing to dispute the pathology of Huguenin, who holds to the inflammatory origin of the trouble, he successfully demonstrated the correctness of his position by the citation of many incontrovertible facts, and especially by the evidence afforded by his own post-mortem researches. His pathological studies have taught him to believe that tubercular meningitis seldom, if ever, occurs except as a part of a more generalized deposit, and that the majority of the cases ascribed to this cause in death certificates, but not verified by necropsy, are really examples of Huguenin's lepto-meningitis.

P. B. P.

DEFECTS IN THE PRACTICAL WORKING OF THE SECTIONS OF THE ASSOCIATION.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—It is painfully evident to every thoughtful physician who attends the meetings of the Sections of the American Medical Association, and then reads the reports published in THE JOURNAL of our National Society, that the work done here is *very unsatisfactory*. It is, therefore, highly desirable that physicians who feel an interest in the working of this National Association should take timely heed of this unfortunate condition, which seriously impairs the usefulness of this organization—if it does not even endanger its existence.

These introductory sentences are only preliminary to the presentation of the main question, viz.: What is now required to make a better showing for our Sections? In answer to this inquiry, it may be briefly stated that we should secure better papers, which should be carefully and scientifically discussed, and this discussion fully reported for publication.

This JOURNAL has already pointed out in its issue

of October 2, 1886, page 381, the chief causes which give rise to the production of unsatisfactory papers and their equally unsatisfactory discussion, while the author, in the same article, suggests a practical and efficient remedy for this evil. I cannot, however, agree with him when he asserts that: "To accomplish these results requires no change in the by-laws or organization of the Sections of our Association, but simply a better appreciation of the duties devolving upon the officers of the Sections and those who prepare papers." The fact that the duties required of these officers have not been generally so performed as to yield satisfactory results, should, I think, be accepted as argument in favor of some modification of the by-laws governing their selection, whereby we may secure some additional guarantee for a more efficient performance of their official duties. The new departure adopted at the last meeting of the American Medical Association, by which the nomination of the officers for the Sections is now made in these bodies, *is a modification in the wrong direction*. This system is open to all the objections which can be urged against our political primaries, as they are generally conducted in our large cities. Can it, therefore, be reasonably expected that it will give us efficient officers? Let us demand of our Sections work which will compare favorably with that done in any of the medical organizations of this country! *Let us have good papers, thorough discussions, and full reports for publication in THE JOURNAL*. The present system of work in the Sections furnishes only the papers for publication, while the discussions—which are frequently more valuable than the essay—are never fully reported by the Secretaries, and often not at all, and consequently cannot be printed in our JOURNAL.

This omission is so important in all its bearings upon the American Medical Association that it ought to be speedily corrected. *What is the proper remedy?* Is there any system of prodding whereby the Secretaries of the Sections can be prompted to the performance of their duties? The answer to these questions, I think, must be in the negative. Can we do better by the election of a permanent Secretary for each Section—or must we employ a stenographer for this work? It has been suggested to me that those who take part in a discussion should write out their comments, and thus supply these omissions; but this I regard as impracticable. In consideration of this subject it should be remembered that many of these remarks are impromptu, and are often suggested by the previous discussion, rather than by the paper itself. Consequently, it is impracticable for the participants in a discussion to place their views on paper prior to leaving their homes, and during the few days devoted to the meeting of the American Medical Association the time and thoughts of these gentlemen are too much engaged with other matters to reasonably expect them to supply this deficiency. Neither are the conditions for this work more favorable immediately after their return to their homes, where they are apt to find business engagements more pressing on account of their recent absence, and before the convenient time would come for the per-

formance of this work, the comments would have possibly been forgotten by the individual who was expected to write them out. However, a modification of this system has been found to work very well in some Societies where the Secretary supplies every participant in a discussion with a printed abstract of his remarks, with a request to make corrections and supply deficiencies. Very truly yours,

B. A. WATSON, M.D.

Jersey City, Oct. 23, 1886.

SHORTENING OF BONE IN DESTRUCTION OF SOFT PARTS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Seeing that in these days priority is considered of so much importance, may I be allowed to point out, that though Dr. Martel, of St. Malo, as mentioned in your issue of August 14, (p. 176), may have been the first to conceive the idea of removing a portion of bone in order to facilitate cicatrization in cases where there is extensive destruction of soft parts, he was not the first to perform or put on record such an operation. It was done in the Royal Infirmary of Edinburgh, in May, 1885, by Mr. Joseph Bell, in the case of a patient, who, during a severe attack of phlegmonous erysipelas, lost the greater part of the skin of the inside of the right arm from the posterior fold of the axilla, down to within three inches of the wrist-joint. He was sent into the Infirmary for amputation, his doctor considering it impossible that such a sore could be healed. Mr. Bell being loth to sacrifice the arm, tried skin-grafting, with the result that cicatrization progressed till only a wound about 3 inches long by 1 broad, remained on the inside of the elbow-joint. As this refused to heal further, Mr. Bell made up his mind to shorten the arm by removing a portion of the humerus. On May 27, 1885, about eight months before Dr. Martel's operation was performed, the lower three inches of the bone, including the condyles, cartilage and also the olecranon were removed. The result was a complete success, the patient recovering with a useful arm, soundly healed, with full flexion, extension, pronation and supination. The case was recorded in the *Edinburgh Medical Journal* for September, 1885.

I am, yours faithfully,

J. MAXWELL ROSS.

NAPHTHALINE IN RENAL AFFECTIONS.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—I noticed in a recent number of the *British Medical Journal*, under the head of Correspondence, the following: "M. de Pezzer treats certain renal affections with naphthaline, especially those that are accompanied with difficult micturition; and, when fetid urine is passed, the results are generally good. In pyelonephritis, M. de Pezzer gives a gramme and a half, also in cystitis and prostatitis, with retention of urine, likewise for stricture complicated by fistula." The above, unfortunately, has been quoted by several of our American journals.

To those who are not familiar with the action of naphthaline on the urinary organs I deem it my duty to say that if employed in the conditions recommended above by M. de Pezzer, even in much smaller doses—5 grains—it quickly excites intense irritation of the urinary passages. I have more than once observed the most violent cystitis excited by 5-grain doses of naphthaline. In one instance two 5-grain doses brought on violent vesical tenesmus, backache and fever, the vesical spasms recurring every fifteen minutes for two days, and the cystitis failed to yield to the ordinary measures for nearly two weeks.

In conditions of perfect health the urinary organs will often tolerate the use of naphthaline in considerable doses when given by the mouth; but I should especially avoid its administration in the conditions named by M. de Pezzer, ample experience having proven to me that in such conditions its action is most pernicious.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM OCTOBER 16, 1886, TO OCTOBER 22, 1886.

Capt. Daniel Weisel, Asst. Surgeon, relieved from duty at Ft. Fred Steele, Wyo., and ordered to proceed to and take station at Ft. McKinney, Wyo., reporting to the commanding officer of that post for duty. (S. O. 135, Dept. Platte, Oct. 15, 1886.)

First Lieut. Guy L. Edie, Asst. Surgeon, having returned from detached service in Dept. of Arizona, will join his station at Ft. McIntosh, Texas. (S. O. 144, Dept. Texas, Oct. 13, 1886.)

First Lieut. Alonzo R. Chapin, Asst. Surgeon, relieved from duty at Ft. Laramie, Wyo., and ordered to Ft. Washakie, Wyo. (S. O. 137, Dept. Platte, Oct. 19, 1886.)

First Lieut. Francis J. Ives, Asst. Surgeon, in obedience to instructions received from the division commander, ordered to report in person at hdqrs. Dept. of the Platte, for duty. (S. O. 146, Dept. Texas, Oct. 16, 1886.)

First Lieut. Wm. P. Kendall, leave of absence extended fifteen days. (S. O. 239, A. G. O., Oct. 14, 1886.)

First Lieut. W. B. Banister, Asst. Surgeon, assigned to duty at Ft. Wingate, N. M. (F. O. 97, Dept. Arizona, Sept. 29, 1886.)

First Lieut. Chas. F. Mason, Asst. Surgeon, relieved from temporary duty at Ft. Verde, A. T., and ordered for duty at Ft. Huachuca, A. T. (S. O. 99, Dept. Ariz., Oct. 12, 1886.)

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED OCTOBER 23, 1886.

Urquhart, F. M., P. A. Surgeon, relieved from duty at Cape Charles Quarantine, to proceed to Washington, D. C., with Str. "Woodworth." Oct. 20, 1886.

Wasdin, Eugene, P. A. Surgeon, promoted and appointed P. A. Surgeon, from Oct. 1, 1886. Oct. 20, 1886.

Williams, L. L., Asst. Surgeon, granted leave of absence for three days. Oct. 16, 1886.

THE ETHICS OF ABORTION, AS A METHOD OF TREATMENT IN LEGITIMATE PRACTICE.¹

BY J. E. KELLY, F.R.C.S.I., M.R.I.A.,

OF NEW YORK.

LATE SURGEON TO THE JERVIS ST. HOSPITAL; PROFESSOR OF SURGERY,
ETC., DUBLIN, IRELAND.

The object of this paper is to investigate the ethical relation of the physician to the production of abortion in legitimate practice, and to consider his duties and responsibilities, when the question would intrude itself without the possibility of evasion, as in those cases of deformed pelvis and uncontrollable vomiting in which the operation is regarded as the last hope of the afflicted female.

Owing to the recognized and stable position which abortion has attained in therapeutics, I have refrained from questioning its claim to be classed among the resources of medicine, and I have also excluded the consideration of its criminal or felonious aspect, much as I may marvel at the prevalence of a horrible crime which is devastating this fair land, and curtailing by the million, the development of its population and its power. This aspect of the subject has been treated by many able writers, whose experience, naturally, has been far greater than that which has been afforded me by the revelations attending a comparatively short residence in Boston. I have endeavored to avoid, as far as it is possible in dealing with a subject so involved, all arguments based upon the doctrines of any particular creed, as well as any special reference to medico-legal authorities, because I wish to induce my audience to approach the subject dispassionately, and to permit each individual to reflect upon it independently of the preconceptions derived from religious teachings and professional prejudice. In the complex conditions of modern civilization the most honorable and humane men are frequently constrained by their surroundings to entertain views and to perform acts from which, upon consideration, they would shrink aghast. This insensibility is largely the result of the accretion of thought and the consequent growth of habits and popular beliefs; of the confusion of the relative bearings of associated ideas, and the resulting perversion of personal opinion and human sympathy. We perform many acts of injustice and cruelty owing to the difficulty of disen-

tangling the great underlying principles, and in the struggle for existence, which suppresses all tendency to introspection, we are precipitated into psychological quagmires by custom, confusion, and self-interest. Such, I am satisfied, is the condition of the professional mind in relation to abortion, and I write this paper for the purpose of inducing the thoughtful physician to reconsider his duty and responsibilities, as well as to investigate the basis of the popular idea, that owing to the adoption of the most humane calling, a physician should be expected to produce abortion at the behest or for the benefit of any individual. I have appended a few suggestions indicating a possible method of relieving the profession from this unjust and odious responsibility, while extending to the parent and the foetus the fullest measure of human justice.

As a preliminary to the consideration of the "Ethics of Abortion" it is necessary to recall the salient points relating to the vitality and the individuality of the foetus, and to endeavor to determine at what point of intra-uterine life it attains a right to be regarded as a fellow mortal. It is unnecessary to remind you that as physiologists we cannot accept the dictum of Aristotle, who held that the foetus did not attain viability until the fortieth day after the fruitful coition, neither can we coincide with those legal authorities who hold that the *human* offspring is not a *human* being until it ceases to be *pars viscerum matris*, and is completely extruded from the body of the mother. It is satisfactory to know that the definition is not universally accepted, many judicial writers regarding it as erroneous and productive of crime, owing to the immunity from punishment which it affords to the evil-doer. On the other hand it is interesting to discover that theologians and biologists agree upon the period at which independent life becomes the attribute of the foetus. The former hold as a dogma, that with the act of impregnation, instantaneously originates an absolutely independent life which confers upon the individual the indestructible soul, with all its associated rights and responsibilities, while the latter insist that at the moment of the fusion of the male and female germs vitality is established and the essential components of the mature individual are represented, the development which subsequently elaborates all the structural details proceeding by the innate differentiation of the impregnated ovum.

I would remind you that at a very early stage of the so-called vegetative life of the foetus the essential characters of the vertebrate animal appear in

¹ Read before the Gynecological Society of Boston, Sept. 9, 1886.

rapid succession to the primitive groove which presents itself in the blastodermic membrane within a few days of impregnation. The vertebral column appears in the first week and arrives at the cartilaginous stage in the sixth; the intestinal tract is recognizable in the second week; the heart and lungs are visible in the third week and the duplex character of the former is apparent in the seventh; the cerebro-spinal centres appear in the third week, the brain being distinguishable in the fourth. This characteristic human organ is rapidly developed, and in the fourth month it differs only in size from its condition at birth, while the organs of the special senses as well as the sympathetic and sensori-motor nerves are developed simultaneously with the brain.

We must remember that immediately after impregnation, vital phenomena are manifested in cell-proliferation, differentiation, nutrition and organization. With the exception of respiration, all the functions are performed early in foetal life: the heart pulsates; the circulation is complete and independent of that of the mother; the intestines contract and the fæces are expelled; urine, as well as bile and the other intestinal fluids are produced; the skin develops hair and epithelium, while its secretions are produced in abundance. At a very early period we recognize the physical conditions essential to the manifestation of the simpler nervous phenomena, namely, a nervous centre connected with afferent and efferent nerves. In the fourth or fifth month mobility is very apparent in the well-known and complex symptom of "quickening," and from that period we have ample proof of reflex and, apparently, of spontaneous or sensori-motor phenomena. If we coincide with Locke as to the capacity for ideation which infants possess, it is difficult to deny similar powers to the foetus immediately before birth, and still more so to define the dawn of sensation and volition in an individual possessing all the essential organs in a condition differing only in degree from their more mature development. The capacity of the foetus to perceive pain is impossible of proof, yet it is but fair to recognize that this power is contemporaneous with the development of the sensory zone of the cerebrum, in the fourth month. Consequently we may reasonably conclude that at least after this period, abortion is a source of suffering to the foetus proportionate to its age and the violence employed in the operation. The conclusion at which we must arrive, a conclusion corroborated by the teachings of religion, is that from the instant at which impregnation occurs and the ovum receives life, the foetus is human, and at all periods differs in degree and not in kind from the infant and the adult. Therefore, we must regard it as a "human being" with an inalienable right to life, and that its destruction is homicide.

If you permit me to remind you that homicide includes the destruction of human life under every possible circumstance, and that it is divisible into justifiable, excusable and felonious, I shall endeavor to assign to abortion its proper position in this category. Here I may mention that for the sake of brevity and precision I have adopted the legal signification of "Abortion" which includes the destruc-

tion of the foetus at all periods and under all circumstances between conception and "full term." Justifiable homicide comprises all those cases in which life is voluntarily destroyed owing to a motive which renders the act meritorious, as in warfare; in obedience to the command of a properly constituted authority; by an official in the performance of a duty imposed upon him; in the prevention of forcible or heinous crime, or for the protection of the life or honor of the slayer or of some person dependent upon him. The justification is, however, limited by the most stringent conditions, and to slay the greatest malefactor extrajudicially is wilful murder. A judge without a commission from the authorities cannot command the execution of a criminal even after the most impartial trial; the execution must correspond accurately with the sentence. A homicide committed by an officer of the law must be absolutely necessary for the performance of an imposed duty; even an individual in self-defence or interfering to avert a great crime, must have adequate motives for his action. Any departure from these conditions converts the act into wilful murder. Homicide is excusable when it is caused by mischance or accident, except when the slayer manifests a wanton disregard for the safety of others; and when the life or valuable property of the slayer, who must not provoke the affray, is in imminent danger. Felonious homicide is always wilful murder, or murder of the first degree, unless alleviated into manslaughter, or murder of the second degree, by being the involuntary and unfortunate consequence of some act not strictly lawful, or occasioned by some sudden and sufficient provocation. Wilful murder is characterized by premeditation or malice aforethought, which, among many other conditions, includes the intention or, even without the intention, the knowledge of the liability of the act to kill or injure any person though that person be other than the victim of the violence.

Abortion is not justifiable homicide because it is not commanded or permitted by any authority, the law forbidding it under every circumstance, and all Christian religions agreeing in refusing to countenance the deed. It is not decreed by a legal tribunal or committed by a specially commissioned officer of justice in the performance of a necessary duty, or by the operator as a public executioner. It cannot be said to prevent the foetus from committing a violent or heinous crime; the life, honor, or property of the physician or that of any one having an ethical claim upon him for protection is not in danger. In addition, it is obvious that the restrictions which qualify the privilege are also in full force against the act. Abortion is not excusable homicide because it cannot be the result of mischance or accident; it is not performed in self-defence by the physician, nor can the contingency be considered as unprovoked by the parent. Abortion cannot be held to be manslaughter because the very nature of the case demands grave premeditation and definite plan of action, which constitute malice aforethought; sudden and sufficiently violent provocation is impossible on the part of the foetus, and abortion is performed with the obvious intention to commit an aggravated felony, and the

operator has a perfect knowledge of the fatal nature of the act. Thus, presenting all the essential conditions, we must look upon abortion as nothing less than wilful murder. But is it not still a greater crime? Crimes are divided into natural and unnatural, the latter consisting of all those acts which are contrary to the great fundamental and natural instincts of self-preservation and reproduction of species. Abortion is an act which is directly antagonistic to reproduction, and as such, like suicide and other crimes which are unnamable, it is unnatural. Consequently it is a greater crime even than wilful murder; a

"Murder most foul and most unnatural."

We shall now consider the relations of parents to their offspring, and the foundation of their claims to the life which they have conferred. Divesting this gift of its inscrutable and preternatural qualities, let us regard it in the light of an ordinary worldly benefaction. According to the statutes regulating Ownership, when a gift is of such a nature that it cannot be formally bestowed and accepted, any act conferring upon the recipient or donee the power of using the article constitutes him the absolute owner. Apparently this is the statute which approximates most closely to the transference of life from the parents to the foetus. Possession is another legal basis of ownership which, for the prevention of injustice, throws the onus of proof on the claimant, and, in addition, as the transmitted life is neither real nor personal property, a claim to its resumption cannot be based upon any existing law. The gift of vitality, which is essential to the existence of the recipient, is voluntarily or thoughtlessly discarded by the parents in the pursuit of pleasure and the gratification of a passion. The donors must be held to be cognizant of the probable effects of this act, and the deed is ratified by being sealed with the image of God which conveys to the foetus the infinitely greater gift of the immortal soul. Consequently the life must be regarded as the inalienable and lawful property of the recipient, who can be deprived of it only by an unjust and despotic act. Such are the usual conditions under which life is transmitted from the parents to the offspring, and for the gift the latter appears to be under no moral obligation, and least of all that of surrendering it. Filial duty is rather the result of subsequent solicitude and parental services which, accumulating during the periods of infancy and adolescence, render the claim of the parent upon the life of the offspring directly proportionate to its age. However, if we admit for a moment the right of the parent to the life of the offspring, it is easy to conjecture many cases after birth in which the resumption might be defended by all the arguments used in favor of abortion, in addition to the other considerations which I have just suggested. Let us assume, for example, that a parent reduced by hæmorrhage has, humanly speaking, but one chance of life, that by transfusion of blood, and that the only available source is her infant, to whom the abstraction of the requisite amount would be, without question, necessarily fatal. It may be contended that in this instance an essential element is absent, namely, that of mutual

danger and the necessary forfeiture of both the lives if one should not be sacrificed. Let us modify the situation but slightly by supposing them to be famishing castaways in mid-ocean, and that the parent sacrifices her child for her own sustenance. Then, indeed, the right of the mother to kill her offspring with the object of saving her own and, in her estimation, the more valuable life, must be regarded as at least as well founded as is that of the mother who demands the destruction of the child within her womb to free her from the fatal consequences of her voluntary act. A parallel contingency in real life occurred recently which resulted in the trial of two men for the murder of their companion. They were starving at sea in an open boat, and to prolong their own lives by drinking his blood, they hastened, by a few minutes, the death of an expiring boy by cutting his throat. After a most exhaustive trial, in which the case was argued by some of the most distinguished lawyers at the English bar, they were found guilty of wilful murder and sentenced to suffer the extreme penalty of the law.

Of the many arguments which are advanced in favor of abortion, that which appeals most strongly to the sense of the community is the propriety of preserving, at any price, the life of the mother, who is frequently a loved wife, a valued friend and the inestimable centre of a family circle. This is a plea which I should be the last to reject, but we must not permit any collateral considerations to blind us to the object of our investigation, namely, to determine the fullest measure of justice to which the mother and the foetus are entitled and the position of the physician in relation to the performance of abortion. It is often contended that the undeveloped condition of the foetus and its dependent and defenceless state detract from its claim to existence, but if we exclude the element of birth this is an argument which with equal propriety may be advanced against the rights of many adults, most children and all infants. Mental deficiency might be pleaded with equal justice in defence of the murder of many of our fellow-creatures, as the imbecile, the insane, and even the comatose, but, far from extenuating the act, their condition only aggravates any violence which is offered to them; while monsters, the cyanotic and the victims of arrested development could be as justly destroyed on the ground of incomplete physical conformation as the immature foetus.

By a modification of the arguments which are based upon the shifting and delusive assumption that abortion is sanctioned by being conducive to the benefit of society, it would not be difficult to defend a proposal for the stamping out of virulent epidemics, such as cholera and yellow fever, by the killing of those who are first stricken with the disease. Another defence of abortion is based upon the futile and deceptive comparison of the relative value of the lives of the mother and foetus. This is but an effort to contrast the known with the unknown, for the natural development of this unborn being may possibly result in a career greater than any with which the old world or the new has ever yet been blessed, greater even than that of a Cæsar or a Socrates, an

Aquinas or a Washington. It must be acknowledged, however, that the approximate value of human life is based upon its probable duration and the estimate of society. If we accept as a test the probable duration of life, we must decide in favor of the foetus, for although the probabilities are greater in a child of ten years than in an unborn babe, the latter, owing to the low mortality in pregnancy and parturition, has a better prospect of life than any adult. Assuming that the estimation of society or of the friends be accepted as a basis of judgment and action, almost invariably the mother's life will be that which the physician will be implored to preserve. It is possible, however, that in rare instances, as when a great inheritance, a title, or a dynasty depends upon a child's life, he may be commanded, at his peril, to sacrifice the mother and save the child. Law and religion are opposed equally to both the acts. Custom is more tolerant of the foeticide, but expediency, which is the sole sustainer of abortion, sometimes may vary its verdict and declare itself favorable to the preservation of the more valued, even though the younger, life.

It may appear to the casual or superficial thinker that the mother, at least, is justified by the first law of nature to destroy, by her own action, the life of the foetus, if she possess the requisite knowledge and skill, but we must remember the conditions which limit this natural right. The slayer must not provoke the affray or the "difficulty," and the Catholic doctrine adds the proviso that to justify the killing the victim must be an "unjust aggressor." Neither of these conditions is fulfilled, because the mother is generally a consenting and often an inciting party to the act of conception, and the proverbial innocence of the "unborn babe" makes aggressive injustice impossible. Therefore the mother has no right to destroy her offspring with the object of preserving her own life. The father has still less justification for interference, because, although it is his duty to protect his wife, he, at least, has been voluntarily accessory to the originating act, and his privileges are in other senses more limited than those of the mother.

We have considered the relations of all the individuals implicated in an abortion, with the exception of the physician, who must act either as a skilled agent or as a principal. If we regard him as an agent who has been engaged to perform a specific act, his rights and privileges cannot be in excess of those who employed him; and if, as I have endeavored to demonstrate, the mother or father have no right to destroy or to engage another to destroy the foetus, the physician must act upon his own responsibility, and we shall proceed to investigate his position. The duty of a physician may be summarized thus: He must perform every just and lawful act which is essential to the life and conducive to the physical welfare of the patient whose care he has undertaken. Let us consider for a moment the responsibilities which he incurs in producing abortion. He decides that the procedure is essential, notwithstanding the probability that, owing to the rarity of the operation, his experience may be defective and consequently his judgment erroneous and misleading.

Here I would remind you that in the practice of the more distinguished obstetricians, the proportion of intentional abortion appears to be inversely to their years, and it must be remembered also, that although the decision may occasionally be in the hands of an able and experienced physician, under existing conditions it is determined, more frequently, by the ordinary practitioner, who is often but poorly equipped for such a solemn responsibility. In addition, the case is decided not even by an honest, if ignorant, practitioner, but too frequently by the unreliable followers of one of the many "pathies" which help to swell the American death-rate, or by the incapable and unconscionable quack. The physician undertakes an operation which is necessarily destructive of one human life, and, owing to its dangerous nature, most hazardous to another, and possibly, as in cases of multiple conception, the operation may result in the death of three, or even a greater number, of human beings. Unless he permits his own judgment to be subordinated to the equally fallible human opinion of his employer, he voluntarily undertakes a deed sanctioned by no law, but always regarded, often perhaps too impassively, as a felony, and punishable accordingly. Without any commission, and frequently prejudiced towards a certain view, he constitutes himself the judge of a court from which time admits of no appeal; before him a dumb and defenceless prisoner is arraigned for the intent to inflict an injury of which it is unconscious; he ignores that impartiality so essential in an arbiter of life and death, and is simultaneously the judge and the counsel for the prosecution; he decides adversely to the accused, condemns him to the most frightful and painful death, and lastly, as the executioner of his own sentence, he sends an unborn fellow-being from a world he has never seen into that "great Beyond," which the strong man and the wise man dread to enter even, after the most prolonged and anxious consideration. In the saddest chapter of the saddest history, that of the Irish rebellion of 1798, one figure towers aloft by reason of his stature and his fiendish cruelty. His literally veracious epitaph ran thus:

"Here lies that brutal Hempoenstall,
Judge, jury, gallows, hangman, all."

I cannot discern how he differed from the physician who produces abortion, except that Hempoenstall held a special commission from the King of England authorizing his brutal iniquities, he was maddened by his turbulent surroundings and excited by the inhuman antagonism which resulted from his victims being matured men, capable of resisting him, and of being possibly all that his education and his prejudices depicted them, while the physician has no warrant compelling him to perform the deed, his victim is a defenceless and unoffending fellow mortal; his surroundings and his teaching tend to calm deliberation and just conclusions, his duty is to preserve the life of his patient by every just and lawful act, and, mark you, all mankind who, formally or informally, come under his care, are equally his patients, the foetus as well as the mother, and if he would not be a Bravo, neither fear nor favor nor remuneration can ever justify the sacrifice of ~~the~~ life

or interest of one patient for the pleasure or advantage of another. Finally, that great dictum which underlies all true religions, "Do no evil that good may follow," deprives him of every flimsy and inadequate plea suggested by that insolence of ignorance so essentially a human attribute, reaching its highest development in the pursuit—here, it can hardly be regarded as a profession—which often, with the most inadequate preparation, arrogates to itself and has conferred upon it, by an otherwise rational public, the greatest worldly responsibility.

While personally repudiating all sympathy with abortion in any form, I shall conclude with the following suggestions, which may be justified by the principle that "new circumstances demand new laws." The prevalence of abortion as an established procedure in modern medicine, the freedom with which it is practised and the enthusiasm with which it is advocated by gentlemen of great professional influence in this city, some of whom I heard in public indignantly denounce other individuals, medical, lay, and clerical, because they conscientiously refused to assist or sanction the destruction of the embryo, are the circumstances which convince me that no existing enactment, either human or divine, can prevent many physicians from practising abortion in good faith, and consequently that some "new laws" are needed which shall tend to limit its application to the minimum, and to alleviate, in the juridical sense at least, the repugnant act of abortion into "justifiable foeticide." Such a restriction, while affording every advantage compatible with justice to the mother, should insure to the foetus every possible security by adequate investigation and representation, in accordance with established legal procedure. Every court or tribunal consists of three essential elements, the plaintiff, the defendant, and the judge. The two first-named are frequently permitted to "appear" by proxy, and generally their interests are guarded by skilled advocates. In criminal law, where a fourth element is introduced in the person of the executioner, the greatest precautions are exercised to secure for the most notorious malefactor every advantage which can accrue from thorough investigation, the admission of favorable testimony, and the assistance of able lawyers, who are frequently supplied by the authorities. Even when a cadaver is discovered the State institutes a most exhaustive investigation in order to determine the circumstances connected with the death, and the climax is reached when the Law, having executed a criminal, makes a formal inquiry into the cause of his death!

If such care be bestowed upon the elucidation of the causes of death and the equitable trial of abandoned criminals, it is natural that we should inquire if the State does not neglect its duty by permitting this notorious and daily destruction of human life without a rigid investigation and the assertion of its unquestionable right to veto or to sanction each case, according to its merits. If the authorities could be awakened to the necessity of establishing a tribunal for the purpose of restraining those practitioners who are not deterred by ethical considerations or religious scruples, its construction should be an easy matter

for the practical legislator. According to precedent it might consist of the presiding officer or judge, a physician of the highest professional probity and juridical reputation; an able practitioner as the counsel or defendant of the foetus, the parent being represented by her personal medical attendant, and the fourth member of the court would be the executive officer. That such an officer as a State abortionist should be appointed is apparent, owing to the many instances in which no power could compel the attending physician to perform so repugnant an operation, while even if he were willing to undertake it, his opportunities might not afford him the essential skill and experience. It would hardly be in keeping with that rigid impartiality so desirable in a presiding officer if, as the executioner of his own mandate, he were to perform an operation for which he would necessarily be remunerated; neither would it be in keeping with the function of the physician to whom we have alluded as the representative or defender of the foetus, to destroy the life of his client. With such a tribunal the operation would be shorn of some of its most objectionable features.

A restraint would be imposed upon those who regard their personal judgment as all-sufficient and final, if the practitioner were compelled to report to the executive those cases in which he considered abortion essential; the members of the noblest profession would be protected from a degrading demand to commit a felony; the popular opinion which ascribes to the medical profession the odium of encouraging abortion, owing to the levity with which physicians frequently discuss the subject, would be exploded; without the sacrifice of dignity or emolument the physician would transfer to the strong arm of the law a great responsibility; without any infringement of her liberty the patient would have the advantage of supervision and treatment by skilful and experienced physicians in consultation with her own attendant; and finally, two classes of criminal abortion which occur but too often and without attempt at concealment, would be eliminated.

The first is that in which the patient, anxious to evade the trials of maternity, imposes upon the inexperienced or careless physician by simulating the alarming symptoms of pernicious pregnancy until he is persuaded that abortion alone can preserve her life; in the other class the practitioner, more or less above suspicion, justifies or cloaks a criminal abortion by averring that the evacuation of the womb is essential. An instance illustrative of one or other of these classes was disclosed in the course of a notorious divorce trial which recently scandalized this city. The attending physicians deposed that the abortion was essential, while other witnesses asserted that it was performed to avoid the expense and inconvenience of motherhood. A practical step towards the suppression of, at least, some forms of foeticide, would be inaugurated by rendering its performance more dangerous to those abandoned wretches who abuse the most precious human instinct, dishonor the fair fame of medicine, and defile the national reputation by their dastardly and incredible outrages against the sanctity of life.

THE EARLY DIAGNOSIS OF PREGNANCY.¹

BY E. S. MCKEE, M.D.,
OF CINCINNATI.

The opprobrium obsterici is our inability to make a prompt and positive diagnosis of pregnancy in the earlier months. How often are we confronted by one of our female patients with the query, "Am I pregnant?" Many a woman imagines that her doctor can look at her and tell whether she is pregnant. How often great things depend upon our decision. Our patient may wish to take a long and long-looked for journey, but will defer or abandon it if she is pregnant; or other affairs of import, as the question of operative interference may depend on our answer. In fact, fortunes, empires and lives hang on our decision. She who fears she is to be a mother, though not a wife, thinks her case of no less importance.

It is in the first months of gestation that the physician needs reliable evidence, hence we should endeavor to add to the means already at our disposal any symptoms indicative of the presence or absence of pregnancy. It is with this in view that I will endeavor to rehearse the symptoms, confining myself to those of the first trimestrium. Those symptoms well known will receive but passing comment. Those newer and as yet not fully established in our textbooks, shall have more attention.

First in the natural order, we consider the signs which may occur at the time of conception. Aristotle taught that a woman had conceived if there was no return of semen after sexual intercourse, and if the penis was unusually dry when withdrawn. Such is also the universal opinion of shepherds. Hippocrates said that the eyes sank in their sockets. Democritus, that the neck swelled. These, however, are of little value. Probably the only sign of any worth is the peculiar voluptuous sensation, and the more general erethism experienced by some females on fruitful intercourse. Many think they can tell positively by their feelings when impregnation has taken place. Though they may be correct in some instances, yet it is quite probable that in many others they are not.

Among the first symptoms of pregnancy are absence of menstruation, nausea, and vomiting, slight flatness of the hypogastric region, depression of the umbilical ring, tumefaction, accompanied by sensations of pricking and tenderness; increase in size and weight of the uterus; increased pulsation in uterus and vagina and decensus uteri; womb is less movable, uterine walls have the consistence of caoutchouc; the neck is directed downwards, forwards, and to the left. The orifice of the os tincæ is rounded in primiparæ, but more patulous in others who have had children. A slight softening of the mucous membrane of the lips and an œdematous appearance of the same. Various neuralgias and neuroses, disorders of digestion, and other symptoms, are noticeable. Many women have an abundant leucorrhœa of white or greenish color (granular vaginitis). What may be said of the first of these, ab-

sence of the menses, may be said of them all. There are numerous exceptions to any one, and the same condition may be produced by other causes. Hence very unreliable testimony. Thus, an ulcerated os may perfectly imitate the velvety feeling of the cervix; the breasts may enlarge from mere uterine irritation; and the womb may hypertrophy from congestion. Jacquimier noticed the slate, or purple, color of the vagina from embarrassed circulation in the venous capillaries of the mucous membrane. However, patients with uterine tumors, especially old women, and those who have piles and varicose veins on the legs, may have a violet colored vagina. The same may even be caused by impacted fœces; in fact, by anything which seriously impedes venous circulation. The smooth anterior vaginal wall mentioned by Barnes may also be caused by a uterine fibroid. So it is the size of the uterus, not its contents, which causes this condition.

Dr. Joseph Taber Johnson, of Washington, in a paper before the American Medical Association, in 1881, suggested that some of the principles of the telephone might be utilized in hearing the feeble sounds of the foetal circulation much earlier than is now possible. I do not know that any one has pushed this matter further. Certainly here is room for investigation. Dr. Routh was the producer of the instrument called the vaginoscope, or more properly, using a word from the Greek, coleoscope; an instrument consisting either of the common stethoscope or the simple or double instrument with elastic tube. To the distal end of this is affixed a wooden speculum. Sometimes he used a solid tube made of gutta-percha or wood in lieu of an elastic one. He thinks glass would be better, as it is a very good conductor of sound, and rather increases the pitch, is readily kept clean, and does not make a noise when rubbed against the clothing. The flexible tube may be passed per anum. He reports a number of cases which seem to bear him out. Verardina has also contributed largely to this subject. Dr. E. Kennedy, of Dublin, gives examples in which he has been able to hear the placental souffle at the twelfth, eleventh, and once in the tenth week. He has not been confirmed by others. Cazeaux says the foetal heart has been heard as early as the third month.

Dr. S. C. Dumm, of Columbus, Ohio, published in 1878 a new sure diagnostic sign of pregnancy. It consisted in finding the odor of the vernix caseosa upon the finger after a vaginal examination during the first or any subsequent month. In a recent communication to me the doctor says: "I think it is one of the clearest on the list, and if carefully paid attention to will reveal the condition inside of four weeks."

Dr. Eugene C. Gehrung, of St. Louis, wrote of palpating the ovum with the point of the sound. He says the sound should be used very gently and by skilled hands, to which we will all agree, if we consent to its use at all. It gives the sensation of pushing the sound against a bladder filled with water. This is not a positive sign, for in the earlier weeks of pregnancy the ovum is only attached to parts of the uterine walls, and the sound may easily glide by.

¹ Read in the Section on Obstetrics at the Thirty-Seventh Annual Meeting of the American Medical Association.

This same sensation might be produced by a polypos in the uterine cavity, as well as by some other foreign bodies. These cases, however, can generally be differentiated by the history. In a recent private letter Dr. Gehrung says that he proposed this not as an additional sign of pregnancy, but as a safeguard to the gynecologist. It will often save him the humiliation of causing an abortion. He says it is not to be thought of except as a last resort. The earliest period at which the sign has given him warning is at about the fifth or sixth week.

Kyesteine has been the means of determining many an early diagnosis, but still its presence is undoubtedly caused by certain pathological conditions. It has also been found in women not pregnant, and even in men.

M. Pinard, in 1877, treated of a swelling and softening of the gums in pregnancy, and later it is made the subject of an inaugural thesis by Didsbury. This begins about the second month, and is described by Didsbury as consisting of three grades. In the third the inflammation is so marked that it gives a violet red color to the gums. They are puffed out, and the interdental spaces stand out in marked relief. The tartar and the epithelial debris collect about the necks of the teeth, and the inflammation extends to the alveolar periosteum, when the teeth become denuded and finally fall out in a perfectly healthy condition. This gingivitis is located especially on the anterior and convex portion of the maxillaries. It is rare to see it go beyond the canines. The other symptoms which present, are pain and local hæmorrhages.

Jorissenne, in 1882, stated that he had discovered a new sign of pregnancy, and claimed to be able to diagnose that condition when there was no other sign present than the absence of one period. Long ago Graves formulated the law that in cardiac hypertrophy the radial pulse remains constant whatever the position of the body. Larcher and Ducrest, in 1828, described a hypertrophy of the heart which occurred in pregnant women. Larcher claimed that the arterial tract throughout the body elongated to supply the fœtus. This hypertrophy seems to be constant and considerable, and to be a purely physiological alteration to meet the increased exigencies of the case. The hypertrophy is limited to the left ventricle. Blot estimated the increase at one-fifth the whole weight of the heart. Löhlein, with more recent investigation, thinks the hypertrophy less than one-fifth. Receiving Graves's doctrine, Jorissenne found that whilst in the unimpregnated woman there is a variation of ten to twenty beats in the radial pulse, from change of position, in the impregnated it remains the same. He advises to proceed with deliberation, counting the pulse a full minute lying, sitting and standing, allowing a time between each change of position for the circulation to regain its equilibrium.

Dr. H. D. Fry has investigated this symptom fully and reported his cases. He found that the pulse varied with almost every change of position, and that absolutely no reliance could be placed upon this symptom as a diagnostic sign of pregnancy. I have

tested it in a number of cases myself with negative results. Dr. Fry has also written concerning a new early symptom of pregnancy, viz.: An increase of vaginal temperature. After discussing the question fully and relating his experiments, he arrives at the following conclusions: "That a vaginal temperature equal to or more than 99.7° is a strong presumptive evidence of impregnation; provided there are no pathological conditions of the uterus present and no increase of heat in the axilla." In a private letter not long since, Dr. Fry, after quoting the above, goes on to say: Now the results of my subsequent observations have led me to modify this statement somewhat, and I would substitute as more certain the following: "A rise of intracervical temperature to one degree or more above the temperature of the axilla. The reason is that in several instances I have found early pregnancy co-exist with a subnormal temperature in the axilla, so that while there was a difference of more than a degree in favor of the intracervical temperature, yet the latter only registered 98.4° in one case and 98.7° in another.

I have experimented, for more than a year, as to the vaginal temperature. While in many cases I have found this elevation of temperature, in as many more none could be detected; and again, elevations of temperature have been found where no morbid condition could be made out, and pregnancy was not present. As to the increase in intracervical temperature, my experience has been limited, but so far, has led me to believe it a more reliable test than the intravaginal.

To Hegar, of Freiburg, we are indebted for the new sign of great promise which bears his name. To Hegar's sign of pregnancy I had expected to devote the greater part of this paper. Owing, however, to the writings of Reinl, Compes, and Grandin, which have been so largely quoted by the American medical journals during the last two or three months, I fear I shall be speaking of something not new but quite familiar to all. This sign consists of an unusual resilience, compressibility, softness, bogginess, yielding and thinning of the lower uterine segment; that is, the section immediately above the insertion of the ligamenta sacro-uterina. This condition is not alone present when the remainder of the body, as is often the case, is firm and hard, but also quite prominent when this is soft and elastic. The shape assumed is fan-like, or that of a balloon, more than the usual pear shape. It has also been termed an old-fashioned fat-bellied jug. This enlargement is especially marked antero-posteriorly. The change is most apparent at the middle portion of the lower segment and in the median line, the sides of the organ being much firmer and more resisting.

Compes makes the examination as follows: The thumb is introduced into the vagina until it reaches the cervix, and the index finger into the rectum until it reaches beyond the ligamenta sacro-uterina; the other hand is placed over the abdomen immediately above the symphysis and pressed down towards the finger in the rectum. The rectal finger explores the cervix and the lower uterine segment in all its parts, and lastly, the higher parts of the uterus. The ex-

amination is facilitated by pulling down the uterus with a volsella and evacuating the bladder and rectum. While this is undoubtedly a very thorough mode of examination, it is repulsive both to the patient and physician, as well as a difficult and hazardous procedure. It is certainly possible in a great majority of cases to make out all that is necessary with a finger in one of the culs-de-sac and the other hand externally. In urgent cases, where this does not satisfy the physician, it would be quite proper to make the examination as above described.

Compes has examined a number of women, found the sign present, then put them under an anæsthetic and still found it present. He says the softened and enlarged uterine segment above the cervix has often been mistaken for a tumor, and that, in fact, laparotomy has been performed under this delusion.

There are two states which may simulate this condition, viz.: distended bladder and the uterus distended with menstrual blood. A distended bladder can and should be evacuated. An imperforate hymen or vagina, or the history of the case, would soon dispel the other question. Hyperplasia would show increased density. Sub-involution increases the longitudinal as well as the transverse diameters. The obstructed circulation from an anteflexed uterus does not impart that feeling of resiliency and compressibility. In marked retroversion it is more difficult to palpate the corpus uteri, and the sign may fail. Here also it is proper to examine per rectum.

Dr. Reinl, formerly assistant to Hegar, has reported six cases; by letter he tells of extended experience as follows: "Among twenty-two cases I missed this sign but twice, and found it earliest in the fifth week of pregnancy."

Dr. Compes, present assistant to Hegar, reports eight cases.

Dr. E. H. Grandin, of New York, has reported twelve cases. In a letter to me since this report he says: "Since the writing of my paper I have had six additional cases, all corroborated, and one of these a case of retroversion. . . . Personally, therefore, I record myself as being able to make the diagnosis prior to the eighth week by Hegar's sign alone."

My experience has been so recent that many of the cases have not had time to prove themselves. I will mention but two, one in which the sign was absent, one in which it was present.

Case 1.—Mrs. B., a widow, æt. 37, came to me March 20, 1886. She acknowledged the opportunity and feared herself pregnant, not having seen her menses for twelve weeks. I examined her for Hegar's sign, but failed to find it. I told her I did not think she was pregnant. Gave her tr. ferri chloridi, and asked her to return in a few days. She returned three times, each time expressing great fears of pregnancy. Each time I examined her, failed to find Hegar's sign, assured her she was not pregnant, and continued the iron. April 1st the menses reappeared, and were normal in amount and duration.

Case 2.—Mrs. R., a young married woman, æt. 20, a delicate blonde, the mother of one child æt. 2 years. She had been absent from her husband four months

visiting her parents at Washington, D. C. She last had her menses January 15, continuing five days, normal in amount and conduct. She returned to Cincinnati and her husband February 9. March 5 Dr. Ransohoff was called, and finding the case to be gynecological, referred her to me. She had not had a return of her menses since the middle of January. The nature of her case required a digital and specular examination once, twice or thrice weekly. March 10 she was slightly sick at the stomach. This had not occurred before, and did not recur, nor any other sign indicating pregnancy, besides the cessation of the menses, before the sixth week after her return to her husband. During the sixth week I made three careful vaginal examinations, and at each one was sure I found Hegar's sign present. I assured the patient that I was quite confirmed in the belief that I had frequently expressed to her, viz., that she was pregnant. On March 30 she complained of not feeling well. On the morning of March 31, the forty-eighth day after her return, she passed a large quantity of blood and a membrane, which she saved and showed me. This proved to be the major portion of an ovum, the remainder of which was found within the vagina.

Dr. Palmer, of Cincinnati, informs me that he regards Hegar's sign as possessing the greatest value in diagnosing early pregnancy, especially taken in conjunction with the change of position, at first sagging, then increasing anteversion at the end of the second and during the third month, both incident, of course, of the pregnancy.

As the shape of the uterus, enlarged by pregnancy, is one peculiar to that state, and is an enlargement largely confined to the body of the organ, it can thus be differentiated from the enlargements due to sub-involution, chronic metritis with hyperplasia or hypertrophy, or fibroid infiltration. The enlarged uterine body from pregnancy is likewise less dense than from hyperplasia or an intra-mural fibroid, and, to touch, presents a much greater degree of uterine pulsation.

In all these last named morbid conditions almost surely there will be a menorrhagia in some form, or a metrorrhagia, or both. It is extremely rare for a fibroid infiltration to involve both anterior or posterior walls alike; the enlargement is symmetrical.

The peculiar enlargement of the uterus described by Hegar, but noticed often by many before his description appeared, is best detected in the normal anteverted position of the uterus. Retroversion prior to pregnancy, as malposition is usually increased by pregnancy in the first month, presents conditions rendering it more difficult of recognition.

There remains to us, then, to again lament our inability, in many cases, to make a positive diagnosis of early pregnancy, to mourn the fallibility of the old and many of the new symptoms, to especially recommend the sign of Hegar, which until now has proven itself impregnable, and to plead for investigators in a field which should not be "barren or unfruitful."

VACCINATION, AND ITS PROTECTIVE QUALITIES AGAINST SMALL-POX.

BY D. H. BATCHELDER, M.D.,
OF PROVIDENCE, R. I.

Just ninety years ago Jenner took virus from the hand of Susan Nemes, who was or had been infected by milking her master's cows, and inserted it into the arm of James Phipps, a healthy boy about 8 years old. The boy passed through the several stages of vaccination in a most satisfactory manner, with pustules perfectly well developed and matured. But with this gratifying result the full test originally aimed at and so ardently desired by the distinguished discoverer, was yet but half complete. It was still needful and, indeed, all-important, to ascertain as a certainty whether or not the boy was made by this operation secure from the contagium of small-pox. Consequently, early in the following July, Jenner inoculated the boy with pure variolous matter taken immediately from a pustule. This operation was entirely abortive; not a sign or symptom of small-pox could be discovered. And I think it pertinent that May 14, 1796, be set down in the history of Medicine as the birthday of Vaccination, and its anniversary day. What the immortal Jenner did by his own hand, and sealed by his life-long and well-earned integrity, together with the then existing facts on which the discovery was based—and announced fully a century ago—should alone have been sufficient to settle the matter logically beyond a doubt. But it must still be regretted that there are still those who do not believe in vaccination. There is, in fact, quite a number outside the great mass of believers who still entertain negative ideas, and are rather skeptical as to the virus of vaccination as a protection against small-pox. And there is a larger number who are disposed—perhaps honestly—to associate with its peculiar workings within the system a large share of the morbid humors that are likely to be constitutional or otherwise; as though it sought outside of its own legitimate sphere of action some morbid ally, through which it might strengthen its power to accomplish mischief.

I now wish to record some experiments made by the writer with a view to the further substantiation of the doctrines announced by Jenner. These experiments were made twenty years ago, in April and May, 1866. They were written down as observed, and have remained under an unbroken seal until this day, May 14, 1886. I hope to prove by the result of these (I must say daring) experiments enough to convince candid minds, as I am convinced, of the fallacy and incorrectness of such vague and untested ideas. I well know that the world is not made up entirely of positives; and that there are some reasonable and tangible negatives. Yet, I am ready to say that I believe that the science of vaccination has reached a point, where it now stands, based upon experimental facts, and it is worthy of the confidence of the public. Considering the magnitude of the claim of the subject, it seems strange there could be found, after almost a century of faithful trial, one

person who would have the courage to even hint at an objection that might seem plausible. No person need study the history of small-pox farther than two hundred years in the past to learn of the ravages of the disease throughout central and southern Europe, where cities and villages were well-nigh depopulated. How can such a condition compare with the present? The disease is no longer there; it has nearly lost its hiding place. Its course is easily obstructed, and if it is not entirely subdued it is in measure deprived of its former terrors. It no longer depopulates cities and communities by tens of thousands; if it find its way into a city or town its "arrow of death" may be easily unbarbed, and its poison so neutralized that it soon dies out for want of susceptible subjects.

Sixteen years ago, while in conversation with Sir James Y. Simpson, just before his death, he said that "two hundred years ago where there were one thousand deaths from small-pox there are not twenty-five now, statistically; and this difference has been the effectual result of vaccination." Sir William Stokes, of Dublin, also said to the writer in 1870, that small-pox had lost 90 per cent. of its death-rate during the past one hundred and fifty years. Is there any other way to account for this difference than by the effect of vaccination?

During the year 1865, at the close of the late war, I was in charge of the health department of the town of Cranston. I was aware that the people of the place must be liable to exposure, and at times come in unavoidable contact with persons from whom they might contract small-pox. I therefore proceeded to vaccinate the people of the town. In the town was a wealthy man who made considerable pretensions to scientific attainments, but he absolutely refused to have his children vaccinated. I therefore resolved that I would once more test the protective qualities of vaccination. The virus used for the town vaccination was obtained from Dr. Henry A. Martin, of Boston, and at that time it must have been humanized virus.

In January, 1866, small-pox made its appearance in Cranston, and during the first eight months there were twelve families that suffered more or less from the disease. In this time there were thirty-nine cases in all, with three deaths. As I had vaccinated almost all the town the autumn before, the people were, as a class, well prepared for the disease. It was a year in which a large number of discharged soldiers were wandering over the country, looking for friends or relatives. In the town was a Swedish family, consisting of father, mother, and two boys. These were visited by a young Swede who came direct from New York City; he was not well when he arrived, became worse, and when I was finally called in I found a case of small-pox, four or five days advanced, with a profuse crop of pustules on the face and body. I found that no one living out of the house had been exposed to this person, and then I put a flag on the house, and shut off outside communication.

Here, I thought, was an excellent opportunity to carry into effect my determination to test the efficacy of vaccination. The two boys in the family were robust and healthy, one 10, the other 8 years

of age. I had vaccinated them the autumn before, and it took well. On the next day, about the sixth or seventh day of the disease, finding the pustules on the face pretty well filled, I charged six quill-points from the pustules on the face. I told the mother, who, with the father, had had smallpox in Sweden, that I thought it an act of prudence to inoculate the boys. She at once gave her consent, not knowing the difference between this and vaccination. I then inserted three quills into each left arm, the quills, charged from the variolous pustules. The boys were allowed free access to the patient's room, and I made daily observations on them for eight days, consecutively.

Second day, 12 M.—No change whatever in either boy; appetite good, no fever, no pain, pulse normal.

Third day, 12 M.—Slight acceleration of temperature in the older boy—98.5; pulse 78, complains of slight pain in head and back. Appetite pretty good; slept well. There was no change in the condition of the younger boy.

Fourth day, 12 M.—No material change from the condition of the day before, save that the older boy had less pain in the head and back. Both ate and slept well.

Fifth day, 12 M.—Condition of both boys apparently natural. The older boy was in what might be called his normal physiological condition. Neither one complained of pain, both ate well; there was no fever; pulse normal.

Sixth day, 12 M.—Same condition as day before. Wounds on arms have died out.

Seventh day, 12 M.—Same condition. Both perfectly well.

I felt sure that they had been thoroughly protected by the vaccination of the autumn, as they had now passed safely through a two-fold exposure. Could there have been a more satisfactory test?

In the latter part of May, 1866, I was notified of a suspected case of small-pox. On visiting the house I found a man, a discharged soldier, who had just arrived in Cranston, suffering with small-pox, with a crop of pustules at least five days advanced. I determined to again try the protective value of the autumn vaccination. The opportunity was as favorable as the one already related. The family of the house consisted of a man and wife, and four children—three boys and a girl. The parents had had small-pox in Norway, and I had vaccinated the children seven months before, and successfully.

They were well developed, healthy and robust children, the boys being 11, 9, and 5 years old, and the girl 7. Since the outbreak of the case no one had been into the house from outside. On the second day the pustules on the face were pretty well filled, and I charged a dozen or more quills with pure viscid lymph from the pustules on the face. The next morning I told the mother that I would revaccinate the children. She did not object, and I inserted three quill points into the left arm of each child.

Second day.—There was perhaps a slight increase in the heart's action in the oldest boy and the girl.

Third day.—No. 1 (oldest boy), wounds very little

reddened, and slightly elevated. Pulse 76, temp. 98.5. No fever. No. 2 (second boy) complains of some headache. Pulse 78, temp. 99, wound reddened, and surface covered with a dingy rash. Tongue slightly coated. No. 3 (girl) complains a little of headache; otherwise but little constitutional disturbance. Pulse and temperature slightly above normal. No. 4 (youngest boy) has on the arm a very light rash of a brownish aspect; complains of itching. Pulse 80, temp. 99; tongue coated; some headache and backache; not craving food. Some fever.

Fourth day.—No. 1 complains of slight pain in back. Pulse 76; temp. 98.5. Wounds a little elevated, but no perceptible fever. Takes food as usual. No. 2 complains of pain in head and back. Face a little flushed; pulse 80; temp. 99. Urine a little colored, and slightly reduced in quantity. Rash fading away. Tongue slightly coated. Goes about house and takes some food. No. 3 does not complain of any pain; head feels a little dull; wounds drying up; no fever, and but little constitutional disturbance. Pulse a little quickened, but temperature normal. No. 4. The surface is less itchy, and the brown eruption is leaving. Pulse 78; temp. 99. Wounds a very little reddened. A few pimples have appeared, two on the arm and three or four on the chest; some pain in back; urine a little reduced in quantity; but little general fever. Relishes food.

Fifth day.—No. 1 complains of no pain; has no fever; pulse 76; temp. 98.5°. Skin natural, wounds healed and scaled off. Has a good appetite and goes about house whistling. No. 2 complains of slight pains in back; some febrile action; pulse 78; temp. about 99; urine somewhat improved in quantity and color; eruption all gone; skin a little dingy; tongue cleaving a little; wounds not pustulated, but fading in color. Is about the house most of the time, and has a desire for light food. No. 3—Condition of general system normal; wounds dry and scaling off; tongue clean; pulse 75; temp. normal. She rests well and wants to eat. No. 4—Eruption all gone, although the skin still looks dingy. Pimples about the same; pulse 78; temp. a little elevated; wounds about same as yesterday. Pains mostly gone; fever much less. Is around the house and takes food.

Sixth day.—No. 1 appears well; wounds entirely healed; no inflammatory or febrile action; pulse normal; temp. normal. Prescribed a small quantity of sulph. magnesia and pulvis rhei. No. 2 is having no pain to-day, and is apparently free from fever; pulse 76; temp. 98.5; skin clearing; wounds healed and scaling off; urine becoming more normal; appetite good, and he rests well. No. 3 seems perfectly well; wounds healed and scaled off; no fever; general system in a normal condition; skin perfectly clear and healthy. No. 4 has no pain; wounds drying up, not pustulated but scaling off; pimples dry, with scales over them; febrile action has abated in a measure; skin clearer. Wants to eat, and is around the house.

Seventh day.—No. 1 is well in every respect. No. 2 has no fever, no pain, rests well and eats well; pulse and temp. normal; skin pretty clear. Ordered sulph. magnesia and pulvis rhei. No. 3 has no pain; no fever; urine clear; wounds well and smooth; tongue

clean and appetite good. 'No. 4—general condition normal; wounds perfectly smooth and well. Appetite good, and apparently perfectly well.

On the eighth day all the patients were well and around the house, apparently in as good condition as before the inoculation.

The foregoing embraces the history of six test cases in relation to the vicarious action of vaccine virus on the human system as a protective agent, inasmuch as it renders the system insusceptible to the primary lodgment or incubating action of the agent that communicates small-pox. I do not know that there is anything further to say than a few words necessary to clear away from the mind of the reader everything that might, unexplained, obstruct or cause to arise in his mind negative inquiries that might perhaps lead to unjust criticism. It should be distinctly understood that these six children were about what we would select as being quite as susceptible and as likely to imbibe any one of the morbid agents that represent the more virulent contagious diseases. They were, without exception, well and perfectly developed, and, as their histories showed, they had enjoyed physiological health without interruption; they were, therefore, perfectly safe and proper subjects upon which to make these tests for the purpose of obtaining incontrovertible results by experiments. In the second place, it cannot be denied that they had passed through the preparatory process of ordinary vaccination six months before in its most simple manner; and consequently were not prepared to order for such experiments, and no one had any knowledge of what might or would follow in six months.

These facts, when viewed in their proper light, at once place the whole transaction on a firm basis, and establish it as an occurrence under circumstances purely accidental. And, viewed in the above light, the matter must remain free from ordinary criticism so far as its being a fair test is concerned.

In relation to the exposures of the children during the experiments: they were of a two-fold nature. The subjects of the experiments were, after small-pox was introduced into their homes, exposed during every hour, and at a time when the disease was at its height of virulence. And secondly, no greater exposure could occur than to subject them to the introduction, into their systems, of the virus taken from the pustule. These facts must, then, stand upon a firm and well tested basis; and I hope they may be considered as a step in favor of the science of vaccination.

UNION OF A FRACTURE OF THE FEMUR, IN A GIRL OF FOURTEEN, AFTER TWO YEARS.¹

BY S. MARKS, M.D.,

OF MILWAUKEE, WIS.

Miss J., aged 14 years, who was suffering from a fracture of the right femur, of five month's standing, consulted me on the 5th of December, 1882. Her

general health seemed to be excellent; but the muscles of the lower portion of the thigh were shrunken, there was absolute ankylosis of the knee-joint, and the limb was shortened a little more than an inch. The point of the fracture was at the junction of the middle and lower thirds, where there was great mobility, but no soreness; there was little or no change in the bone.

The history of the case revealed a succession of incidents affecting this unhappy femur—two apparent fractures at an early period, with long delayed union and complete ankylosis of the knee-joint; the protrusion and removal of a section of the bone at a later period; and another fracture, still later, with still longer delayed union and the condition already described.

The history of the earlier fractures, as told by the father, is the following: When $2\frac{1}{2}$ years old the girl fell from a high chair, fracturing this right thigh bone at two points—one immediately above the knee-joint, and the other some three inches higher. A surgeon immediately applied splints, but the bone failed to unite; and some six months from the date of fracture a fragment of the bone was found protruding through the flesh. It proved to be a detached section of the lower portion of the bone, some three inches long. After its removal the soft parts healed kindly, and a little more than a year after the fracture was sustained the child was able to bear her full weight upon the limb. The muscles of the thigh at this time were shrunken, the knee-joint completely ankylosed and the limb shortened half an inch. From this time on the child enjoyed perfect health, the limb giving her no trouble further than the inconvenience caused by the ankylosis. No doubt the fracture described by her father as taking place immediately above the knee-joint, was the separation of the epiphysis from the shaft of the bone.

Years later a second accident involved this unlucky femur. Thrown from a buggy when eight miles from her home, she sustained a fracture at the junction of the middle and lower thirds. This was on the 29th of June, 1882, when she was 13 years and 7 months old—about five months before she put herself into my hands. A country practitioner applied a long splint, and the next day she was driven to her home in a wagon. Owing to her restlessness, the doctor found it necessary to redress the limb every three or four days. At the end of two months there was not the least union of the bone, and he discarded the splint and applied a light plaster-of-Paris bandage from the foot to the hip. For two months this dressing remained on undisturbed, at the end of which time it was split open and the limb found to be in the same condition as when it was applied. There was absolutely no trace of a union. The same dressing was reapplied and was not disturbed up to the time I was consulted.

Upon removing the dressing, five months after the accident, I found the condition already described—great mobility at the point of fracture, a shortening of the limb by a little more than an inch, and the atrophy and ankylosis which had continued from the time of her first accident. After rubbing the

¹ Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

fractured ends together with considerable force, a closely fitting flannel drawer-leg was drawn over the limb; and while extension was being made, a very heavy plaster bandage was applied, as snugly as was thought compatible with safety, extending from the foot up to and embracing the hip. After the plaster was thoroughly dried, she was placed in a wagon and taken to her home, twenty miles in the country. I directed her to move about on crutches and to bear all the weight she could upon the fractured limb. Although her father had promised to keep me informed as to her condition, it was nearly two years before I heard from the case again, and then accidentally and indirectly, to the effect that the bone had united and that she was walking without the aid of crutches. I immediately wrote to her father and in time received an answer from the young lady herself, giving the history of her case from the time I applied the bandage. For more than a year the dressing, which gave her great comfort, had not been disturbed, and she had followed my directions as to bearing what weight she could upon the limb. At the end of this time the bandage was cut open and sprung apart far enough to permit the limb to be examined. There was still a measure of mobility at the point of fracture, although very much less than when I had applied the dressing. The bandage was tightened again by rollers, and after that the limb was examined from time to time. In July, 1884, the motion at the fracture was hardly perceptible, and a month later the union seemed to be complete. This was between twenty-five and twenty-six months from the date the fracture was first sustained.

Since the above was written, the physician who treated the young lady immediately after the accident and who had her under observation after I applied the bandage, has informed me that her account is essentially correct: that the union of the bone is firm; that the limb is an inch and a quarter shortened, but that she is able to walk with ease and comfort.

The occasional instances of delayed union in the long bones, commonly limited to a few weeks beyond the usual period of consolidation, are almost always due to constitutional debility rather than to local causes—excluding cases of unnecessary meddling with the fracture. Almost always there is a constitutional taint. But in this case of extraordinary delay—extending far beyond any that has ever come under my observation—there was no evidence in the appearance of the subject of malnutrition. On the contrary, during the entire period she was apparently in perfect health. Her father was healthy, but her mother had suffered from epilepsy for more than twenty years. While, without doubt, the want of fixation of the fragments of the bone in apposition had something to do with the extraordinary delay, the fact of the delayed union in the fracture sustained when she was a child, and the delay in the second fracture even after the final bandage was applied, together with the atrophy of the muscles, indicate a local cause as an important factor. It is evident that there was a lack of proper nourishment in the lower portion of the femur and the tissues in that region, even while the general nutrition was excellent.

The case shows the possibility of union being delayed in fractures of the femur, even in youthful subjects, not only for months but years, and of finally uniting without surgical interference.

A SUPERIOR WISDOM TOOTH DISCHARGED FROM THE NASAL PASSAGES; WITH REMARKS.¹

BY JOHN S. MARSHALL, M.D.,

OF CHICAGO, ILL.

I am indebted to Dr. Emma F. Gaston, of Chicago, a member of this Association, for the history of the following very remarkable case, and which I present with a few remarks in explanation of the peculiar symptoms, the probable course taken by the tooth, and which finally resulted in its being discharged from the posterior nares.

"Mrs. B., aged 62, in October, 1884, suffered intensely from what she supposed to be 'a severe cold in the head.' The pain in the right orbital region was at times excruciating, but not more severe than she had often experienced in other portions of the face and right ear, during the previous ten years. Attacks of facial neuralgia and otalgia had been so frequent during these years, that she had become quite disheartened and had no expectation of ever being freed from them.

"Medical aid had only temporarily alleviated her suffering, and she had become 'tired of consulting physicians' about 'neuralgia.' In this attack the usual domestic remedies for a cold, and an anodyne application for neuralgia had been resorted to without alleviation of symptoms. The right nostril became slightly swollen and completely obstructed. Breathing was almost impossible when the lips were closed.

"After a few days of discomfort, the patient made an unusually great effort to relieve the nostrils, by alternately coughing, and blowing the nose. Suddenly she felt something fall upon her tongue. Spitting the mass into the wash-bowl, she heard a clicking sound, which caused her to examine it. Imagine her surprise at finding a large right superior wisdom tooth covered with fetid pus. The relief of the facial pain was immediate, 'the cold in the head' was explained, and probably much of the 'torture' she had endured periodically for years, was also accounted for.

"This very unexpected experience led the patient to recall an incident which occurred about twenty-six years before. In the year 1854, thirty years previous to the expulsion of this 'eccentric tooth,' she had all her upper teeth removed. Wore a 'temporary set' of artificial teeth for several months, then had a 'permanent set,' on gold plate, which she wore with great comfort, for four years. Then a tumefaction appeared upon the right superior maxilla, near the tuberosity; and she jested about 'cutting a wisdom tooth.' Consulted her dentist about the 'plate.' He found that in perfect condition, and assured her there was no prospect about a tooth, and was unable to assign any satisfactory cause for the suffering.

¹ Read in the Section on Dental and Oral Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

"After a few days the annoying swelling and tenderness disappeared, and from that time until 1884, no thought was ever given to those unexplained symptoms.

"In May, 1884, the patient suffered from an abscess in the right ear. After the abscess ruptured an unusual amount of hæmorrhage from the ear occurred. The patient became very much weakened by it, and a physician remained at her bedside for hours.

"Previous to this date she had gradually lost the power of hearing on that side, and was afterwards totally deaf in that ear. There had also been a slight fetid discharge from the nasal passages for several years, but which was supposed to be the result of a simple catarrhal affection."

Remarks: It would seem from the foregoing history that all the pain and discomfort in the right facial region endured by this lady for so many years, was the result of this erratic tooth, and the explanation I would offer is as follows:

The swelling and tumefaction mentioned as having appeared at the posterior portion of the right superior maxilla about five years after the extraction of the superior teeth, viz., twenty-five years ago, was undoubtedly caused by the eruption of this tooth, (and it must have been formed in an inverted position) which, taking a direction upwards and forwards, finally pierced the floor of the antrum of Highmore. The disappearance of the tumefaction, and all unpleasant symptoms speedily passing away, would I think, be a fair inference that this was what occurred. The tooth must, however, have remained in this position for several years, as I think the condition of the tooth would strongly indicate, for you will notice the crown is covered with a thick dark-brown deposit which is very rough upon its surface, while upon its roots there is considerably less, and they have the appearance of being exposed to the effects of the antral secretions for a much shorter period of time. The aural abscess, and this tooth, I think have a very close relationship as regards cause and effect; and I am of the opinion that the abscess in the ear was the result of an abscess at the roots of this tooth, and which discharged its contents into the meatus, and at the same time freed the tooth from its crypt in the maxillary bone and left it loose in the antrum.

The tooth being loose finally found its way to the anterior portion of this cavity and lodged there, and by contact with its nasal wall produced ulceration of this and the inferior turbinated bone, and thus found its way into the nasal passages and into the mouth.

The slight catarrhal (?) discharge which had been persistent for so many years was without doubt the result of the presence of the tooth in the antrum. The record of the case is valuable from the fact that it explains an obstinate case of persistent neuralgia of the trifacial nerve, and indicates the probable cause of a severe aural abscess. The symptoms of the case were, however, so obscure and indefinite in their character as to give no indications of their real cause, and the presence of a tooth or other foreign body in the antrum was not even suspected.

MEDICAL PROGRESS.

ARSENICAL TREATMENT OF MALIGNANT TUMORS.—DR. F. KOEBEL, of Tübingen, reviews the results obtained at the Tübingen Clinic (Prof. Bruns) in the treatment of certain malignant neoplasms by means of internal administration of arsenic.

As regards epithelial carcinomata various experiments were made at one time or another in inoperable cases of mammary disease, with local injections of arsenic; but in no cases were favorable results recorded.

Sarcomata, excepting those of the lymphatic glands, have likewise generally been regarded as incurable by means of arsenic. But the author gives a case of a man 39 years of age who presented multiple sarcomata in rapid growth when admitted to the hospital, and who was completely cured after three and one-half years' time by combined local and internal administration of arsenic. The diagnosis was assured by microscopical examination of an excised portion.

Lympho-sarcomata were not influenced in their course by arsenical treatment, as was proved by the observation of several cases.

The greater part of the paper is devoted to the consideration of malignant lymphomata, in the treatment of which arsenic has always played a conspicuous part.

In order to draw more correct inferences the author first reviews fifty-two cases collected from various sources, and then adds to this number seven cases of Prof. Bruns. He then proceeds to draw his conclusions. The ages of the patients varied equally between 7 months and 72 years. Males were twice as frequently affected as females. In twenty-seven cases the neck alone was affected, in thirteen cases the whole body. Statements as to the presence of leucæmia are incomplete. The treatment consisted in internal exhibition of Fowler's solution, increasing to a maximum of 40 to 45 drops daily, and in parenchymatous injections, gradually ascending to 0.4 or 0.5 ctm. daily.

As to the results attained complete cure was observed in seventeen out of the fifty-nine cases; but in five of these, recurrences are recorded; in the others no further notes are made. The time elapsing before the cure was complete varied from one to six months. Recurrences varied in the time of their appearance from two to eight months.

In fourteen cases the recovery was partial. In twenty-eight cases out of the 59, the treatment was altogether ineffectual. In some cases, however, the time allowed for observation was too short.

The author concludes that the treatment should be continued for at least two months in order to ascertain whether it will prove of avail or not, and recommends the trial of medicament treatment with arsenic in all inoperable cases of malignant lymphoma, and in certain ones of general sarcomatosis. Although many cases are not cured, some brilliant results have been obtained by this method.—*Beitr. z. klin. Chir. Mitth. aus d. Chir. Klin. zu Tüb.* II. Bd. 1. Hft. 4.—*Annals of Surgery*, September, 1886.

FATAL RESULT OF PEROXIDE OF HYDROGEN INJECTIONS.—A Norwegian surgeon, DR. LAACHE, has reported a case in which a fatal result followed an injection of peroxide of hydrogen into the pleural cavity. The patient was a man 28 years of age, who had had a portion of the ninth and tenth ribs resected for empyema. The operation had been successful and the wound progressed favorably, and two months after the operation there remained only a fistula about an inch and a half long. In order to hasten the healing of this, hypodermic injections of a 3 per cent. solution of peroxide of hydrogen were resorted to, as this method of treatment had given very satisfactory results in two somewhat similar cases in which it had been tried. Six injections, each containing 0.8 cubic centimetre of the solution, were administered without any particular effect. At the seventh however, the patient complained of pain and faintness, the pulse failed, the respiration became oppressed, clonic contractions occurred in the right arm, the head turned to the left, the jaws became tightly set, the face became cyanotic, and the patient died in ten minutes. The necropsy, which was not made till forty-eight hours after death, revealed nothing very striking. The heart was dilated, and contained liquid blood without air bubbles; some ecchymoses were found in the parts of the left lung, which were adherent to the chest walls. In the fourth ventricle of the brain an ecchymosis the size of a pin's head was seen. A number of air bubbles were present in the blood of the hepatic veins, and some were seen on cutting into the spleen and kidneys. The cause of death was therefore by no means clear. Dr. Laache suggests that it may have been the small extravasation in the fourth ventricle or shock. Dr. Wulfsberg, who took part in the discussion on the case at the Christiania Medical Society, thought it was probably due to the introduction of the drug into the circulation. He thought that the strength of the blood current might have carried the peroxide, if introduced into a vein, through the right heart and lungs almost unchanged, but that afterwards more oxygen might have been disengaged than the blood could absorb, and bubbles were thus produced, which may have been the immediate cause of death. Where animals have been subjected to injections of air into the veins bubbles are not always found in the blood. In these cases Dr. Wulfsberg thinks that death has been due to paralysis of the heart, for when examinations have been made immediately after death bubbles have been found in the coronary arteries. As so long a time had elapsed before the necropsy in Dr. Laache's case, these might have been absorbed.—*Lancet*, Oct. 9, 1886.

HYPNOTIC PROPERTIES OF BOLDO-GLUCINE.—Dr. René Juranville, of Paris, has published as a graduation thesis an account of some experiments and observations on boldo-glucine, an aromatic substance of the nature of a glucoside, obtained by M. Chaptault from the leaves of the pneumus boldos, or boldo fragrans, a plant belonging to the mominiaceæ, which has from time immemorial been employed by the natives of Bolivia, Chili and Peru in hepatic dis-

eases. The boldo-glucine used by M. Juranville is not the same substance as boldine, which is an alkaloid existing in very small quantity in the leaves, and which was isolated in 1874 by MM. Cl. Verne and Bourgoïn. The observations were directed to the hypnotic action of the glucoside, and were conducted on both animals and human subjects. Dogs were sent to sleep by intravenous injections of boldo-glucine, in quantities of from two to seven grammes. Observations were taken and curves constructed, showing that during the sleep produced the cardiac beats increased in rapidity, while the amplitude of the pulsations diminished; the arterial pressure was not affected. M. Juranville also gathered from his observations that anæmia of the brain was produced. His therapeutic researches were conducted on insane patients, the doses given being from 22.5 grains to 2 drachms, the substance being enclosed in gelatine capsules or introduced by means of enemata. It was not found easy to administer it in the form of draughts on account of their powerful odor. It gave rise to no disagreeable symptoms, and, indeed, appeared to stimulate the appetite and the digestive functions. The hypnotic effect was very definite, ten patients on whom it was tried being all sent to sleep, and in some cases their hallucinations being removed; the effect was not, however, permanent, the sleeplessness and hallucinations returning on the cessation of the treatment. M. Juranville concludes that though boldo is not a perfect hypnotic, it is likely to prove valuable in cases of neurotic or maniacal insomnia when other drugs have been tried without effect. Further study of its action is, of course, required before any very decided opinion as to its efficacy can be expressed.—*The Lancet*, October 16, 1886.

ANTISEPTIC PAPER DRESSING.—DR. DON ANTONIO MORALES PEREZ describes in the *Revista Médica*, of Seville, a simplified antiseptic or Listerian dressing consisting of bibulous paper heated to 110° C. and soaked in a solution of carbolic acid, boracic acid, or corrosive sublimate. This is placed over the wound in about eight layers, and covered with sheet gutta-percha or mackintosh, the whole being secured by an india-rubber bandage. The writer claims for this dressing the advantages of cheapness and portability, and thinks it will be found very serviceable in the field and in small hospitals.—*Lancet*, Aug. 21, 1886.

TREATMENT OF TYPHOID FEVER.—DR. F. PEYRE PORCHER, of Charleston, gives the following formula for a "fever mixture":

Spirit of nitrous ether.....	½ oz.
Potassium acetate.....	1 or 2 drachms.
Potassium chlorate.....	1 drachm.
Solution of ammonium acetate.....	1 oz.
Tincture of aconite.....	½ drachm.
Camphorated tincture of opium.....	2 or 3 drachms.
Water.....	to 4 oz.

A dessertspoonful to be taken every two or three hours as long as there is fever. Potassium bromide or morphine may be added if there is great restlessness or want of sleep.

SATURDAY, NOVEMBER, 6, 1886.

THE ABUSE OF INTRA-UTERINE MEDICATION.

Such is the title of an interesting paper read at a recent meeting of the Alumni Association of the Woman's Hospital, of New York, by DR. BACHE McE. EMMET. The subject which he discussed in the paper was that of uterine discharges, their nature, significance, and the indications for treatment furnished by them. He thinks that it is the general practice among the profession at large to mistake a symptom for a disease, and to treat it as such, in dealing with uterine discharges. Leucorrhœa, for example, is too often looked upon as a nosological entity, and actually as an individuality by the non-specialist; and he too often treats it as an ailment having one cause, its own special pathology, and a definite and positive course to be invariably run. There are very many practitioners who, when informed that a patient has leucorrhœa, recommend a wash or injection of some astringent, trusting that in some way it may hit the mark aimed at. The specialist, on the other hand, may think that "whites are whites," and that they must be attacked as such; and though he usually examines the discharge he sometimes wastes his time in speculating on the manifestation, without seeking the true cause and attacking it.

In dealing with uterine discharges the first thing to do is to make a proper classification; and Dr. Emmet gives the following: 1. Aqueous, serous, and mucous, forming in their combinations, milky, gummy, and ichorous. 2. Purulent. 3. Mucopurulent. 4. Sanguineo-purulent. 5. Bloody. 6. Bloody with mucus. "Aqueous discharge, which may be slight or abundant, at intervals or constant,

bland or acrid; what does it import? With it, especially if it has persisted for some time, we shall find the os uteri slightly open, the lips possibly a trifle everted and somewhat eroded, the cervical substance, in all likelihood, to some degree softened, the crown flattened from pressure upon the floor of the pelvis, the woman complaining of weight about the back, hips, and perineum, with a sense of heat either forward toward the bladder or low down in the back; even a desire to micturate often, together with, at the first, a tendency to constipation, later on the bowels being too free. The patient may give the history of having had some febrile movement, but it was slight, did not make much impression; at any rate, there is nothing of it present now; we have but local symptoms to deal with. An accurate observer will not content himself with having noted this much. He cannot, from seeing such a discharge, establish a positive diagnosis. It would be worse than indifferent reasoning for him to hold that, because there is a flux from the uterine mucous membrane, therefore it is diseased, and worse than indifferent practice for him to attack this lining membrane as the offending organ and blind himself to outlying conditions. Will he now explore the pelvis, he will find something positive to guide him, or he may find merely enough to corroborate or to overthrow a mental diagnosis made. Either he will find the pelvis engorged and tumid, the parts lying about the uterus œdematous and soft, the uterus only slightly enlarged, indicating a condition of *recent acute cellulitis*; or he will recognize that the uterus is enlarged beyond what the patient's history can in any way account for, be she multipara even, with subinvolution and all the attendants on multiple labors, and his mind will of necessity revert to commencing malignant disease of the body; or, again, the pelvic cellular tissue will be intact, the uterus normal, and he will discover an enlargement off to one side, presumably a dilated Fallopian tube which, somewhat constantly or at intervals, discharges its quantum of watery fluid; yet, even failing to find such an enlargement, the physician must bear in mind that it may have been; also that another possible source is from ruptured ovarian cysts and cysts of the broad ligaments, or from ascites."

The serous discharge must be considered with the aqueous, as it can only be differentiated from it by the various tests brought to bear on, and it will then connect itself with one of the special conditions referred to, especially ascites. "And with any of these conditions," says Dr. Emmet, "what will it avail the patient to have the mucous membrane of the uterine

cavity cleaned off, and then smeared over with a more or less noxious topical application, the whole to be preceded, no doubt, by the passage over it of a steel instrument called a 'sound?' Fortunately for her, in this case, the pathological conditions are mostly inert; but take it with the first instance, where we have the first stage of an acute cellulitis passed, and are now witnessing the transuding of watery fluid from an œdematous uterine tissue, but with the acuteness sufficiently near at hand to be readily awakened and lighted up into a sharp attack, with possibly fatal consequences; for is not the mere passage of a probe a violence done to such a uterus? is not, all the more, an astringent application, for such would surely be chosen in the given case, an offense to a suffering neighborhood? And think of the possibilities were a solution of iodine, however weak, carried to the fundus of such a uterus, the capillaries large, the lymphatics active, the Fallopian tubes erect, with congestion ready to assume violent inflammation on the slightest provocation. And such, unfortunately, is too often the result of like ill-judged treatment. What was in a process of resolution you have arrested on the threshold, and have dammed up fluids which were the expression of the first inflammatory action. Your treatment has intensified the pathological process; you have been the cause of an effusion of lymph which has now set, and the woman feels better. Of course she does, because the parts which would otherwise be tender by motion are now immovable, and everything is one block, so to speak. There is a time to come, however, and that is in the undoing of all this exudation, when the woman is to suffer far more than she could have anticipated, and there is no limit to the pathological developments which your misguided action may have set up."

The mucous discharges are more frequent than any other; and the mucus may be of greater or less amount, thin or thick, viscid or tenacious, each of which qualities and conditions should be carefully noted. "It is such a common thing for the physician, on meeting with such a flux, to at once say, 'Oh, yes, some endometritis,' and to first remove the mucus, either gently with a cotton pledget held in his forceps or twisted on a stick, or if gummy and adherent, by a syringe or piece of hard, dry sponge, and then to run his applicator, charged with medicament, up, no matter how far, into the uterine cavity. Is such a course rational? Can we say that there is endometritis, and if so, is it justifiable to attack a part of the mucous membrane, as that of the body, when in fact it may be absolutely intact and require no interference whatsoever? To establish in such a

case that there is endometritis, we should rather feel positive that we have a decided cause for it and that there is nothing outside which is at the bottom of the ailment, this being merely the symptom." Where shall we look for an explanation of this mucus? May we not look upon it as an effort of the vessels to disgorge, and not as a pathological process? And if this be so should not the discharge be watery or at least a thin mucus? "Yes, if we always saw the case in its early stage. Later, and as the cause is maintained, the lymphatics, capillaries, and uterine glands, being constantly called upon to discharge fluid, finally are more and more enlarged; the glands become hypertrophied, and then the material becomes more and more thickened, even to the point of being held in the mouths of the glands, constituting the gummy, tenacious mucus with which we have all had our struggles. By this time the glands may be said to be diseased, and a probe passed over them will even produce bleeding; but they are still diseased as a symptom, and will resume their natural functions once the disturbing cause is removed. They are diseased, and we have endometritis or endotrachelitis, and it may also call for treatment, but it is to be borne in mind that it is only as a secondary effect; otherwise the main factor will be overlooked, and the condition will prove intractable or yield only as time has removed the original cause; or, perhaps, as the treatment for the one may by chance have hit at the other, or again, as in our effort to cure the endometritis by heroic means we may have destroyed the very surface on which the disease has rested, even though, by so doing, we have introduced a still more dreaded element of trouble. Now, if we look further, and at the conditions which manifest themselves by this mucus, we have a scope embracing almost every one of the pathological conditions pertaining to the uterus and its appendages. Perhaps the very commonest of pelvic troubles is some slight amount of subacute inflammation about the cellular tissues in the neighborhood of the uterus or upon the peritoneal folds forming its ligaments. These two conditions, if present in however small a measure, produce a certain degree of prolapsus of the uterus; by the fulness of the cellular tissue or the thickening of the uterine ligaments, the one and the other is shortened or contracts, and, by so doing, they bring down the uterus to a different plane from that which it occupies in the normal state. This in itself doubles capillaries and veins upon themselves, stretching others, and congestion is the result. As has been seen before, the congestion, which is passive, seeks its own remedy by an exosmosis, and we have the

result in the direction of the freest outlet—viz., the uterine canal, in the form of leucorrhœa. Now, again, if this slight displacement is not recognized—and, being so slight, we may readily understand how it may escape detection—and the ordinary treatment, in this case also, is resorted to; see how absolutely futile it is, how positively harmful. How shall an intra-uterine application of an astringent arrest this flux except temporarily? How is it to be productive of any good effect on the cause of the discharge? And we readily see how, as an irritant, it may be productive of increased harm, unless, indeed, the mucus itself protects the lining membrane from the medicament."

However common the mucous discharges may be, the purulent or muco-purulent are seen often enough, and perhaps most frequently in conditions of impaired constitution, anæmia, subinvolution, prolapsus, etc., not to mention the discharge most commonly seen in old cases of injured cervixes. Every practitioner must have seen a number of these cases. Should we treat the parts because of the pyogenic condition? "Most assuredly we may; it is a local lesion, and may be largely overcome while still we are busying ourselves about the more general state which has such a positive bearing upon it. It is precisely because of these cases being so common, and their treatment being so self-evident, that we are in danger of error by overlooking other conditions which are simulated by it or which it masks—for instance, a venereal ulcer situated high up in the uterine canal. The discharge will be the same, but how much benefit will attend the true disease if we are directing our attention to the supposed surgical lesion of the uterine canal? And the very application which would prove serviceable in the one case—viz., nitrate of silver or acid nitrate of mercury—we would strenuously shun in the other. How necessary it is, then to do nothing by routine! Every day we hear at the clinics 'Oh, yes, endometritis,' and in goes the swab or applicator charged with iodine, Churchill's tincture, without so much as thought being directed to the patient, much less a further examination to determine beyond peradventure that the diagnosis is a correct one. Again, with an old laceration and subinvolution, the uterine canal containing pus, the same treatment pursued as indicated above; no improvement; recurrent attacks of pain and febrile symptoms, when a more perfect examination leads us to an old pelvic abscess or a chronic oöphoritis which is discharging its contents by the Fallopian tube, and so through the uterine canal. These cases have been known, and it is not too much warning to throw

out to practitioners who will do a little gynæcology to tell them to be on the lookout and make an accurate diagnosis."

In a certain variety of affections the muco-sanguineous and sanguineo-purulent discharges are common enough, and it is of great importance to ascertain definitely the precise origin of such discharges. "If we have pure blood flowing, it is needless to tell a physician not to dwell upon a condition of the uterine mucous membrane and content himself with making applications to it. Each and every one will have sought the cause: a displacement, a fibroid, granulations or fungous growths along the line of the canal, obstructed portal circulation through pressure or mitral regurgitation, breaking down of a vessel from ulcerative process, etc. Yet it is right to enjoin upon all to recognize that some such cause lies behind and is at play in every case, though the blood be not in sufficient quantity always of itself to call for the exhaustive examination. At a time when the uterine probe was in more general use—unfortunately, it is still too much handled to-day—it was the commonest thing to see an exploration followed by a drop of blood or two. What did it mean? No one inquired, and only one in many would inquire to-day. But the solution of iodine is passed in just the same, it may be to do good, but much more likely is it fruitless. The mere fact of using an astringent does argue that we consider the mucous membrane congested, but why should we, even in so small a measure, seek to reduce this congestion, which is nothing *per se*, but is the expression of something much more significant? It is true the cause is at times located in the mucous membrane itself—fungous growths, for instance—but many more times does it depend upon a general engorgement of the pelvic vessels, and thus of the uterus also, in which case we are glossing over the surface of vessels, and are as remote from dispelling the true condition as if making use of a medicated inhalation for the relief of a pulmonary congestion."

Pelvic disorders have a uterine discharge as a common symptom, as a rule, more often cervical than corporeal. It must be acknowledged that this condition is too often treated as a disease. Dr. Emmet's paper is one of practical value; and while we may not be able to endorse all that he says, we must look upon his remarks as a timely warning, which it would be well if both specialists and general practitioners would weigh them carefully. Misdirected intra-uterine applications are positively harmful. Why dilate the cervix to make applications when it is apparent that if any disease of the canal exist the cervix will be patulous, and the canal free?

THE WATER SUPPLY OF CHICAGO.

At a meeting of the Illinois State Board of Health, on October 29, DR. JOHN H. RAUCH submitted a report of the water supply and sewage disposal of Chicago, covering twelve months' systematic observation of the varying conditions affecting the water supply of the City, with a chemical analysis every week, and other interesting data concerning the City of Chicago, as well as Hyde Park, Lake View and Evanston. The analyses were made by Prof. John H. Long, and are therefore entitled to confidence.

The report shows that the sewage of the City can be prevented from contaminating the water supply, and that when this is done the City has the best water supply of any large city on the continent, if not in the world.

During June, July and August, careful and complete experiments were made to determine the rate of purification of the water in the canal and Illinois River in its passage after leaving the pumps at Bridgeport. Over one-half of the sewage-pollution disappears before reaching Lockport, twenty-nine miles below Bridgeport, and one-third of the remainder is lost in the next four miles by the mechanical agitation of the water by falls, wheels, locks, etc. At Joliet the pollution is diminished by nearly three-fourths, and is reduced in a proportionate ratio until it disappears altogether. As there was hardly any dilution of the canal during these months the loss of sewage between Bridgeport and Joliet is attributed to oxidization. At Channahon, ten or twelve miles below Joliet, the sewage disappears altogether. A comparison of the analyses of the waters collected at Ottawa and Peoria shows that causes entirely apart from Chicago sewage-pollution affect their purity. Although the free-ammonia determination is always in excess at Ottawa as compared with Peoria, the oxygen consumed figures during the period were greater at Peoria on two occasions, and the mean excess of these figures at Ottawa bears no relation to the excess of the free ammonia determinations. With 50,000 cubic feet of water passing into the head of the canal per minute the [Chicago] main river and the South Branch will be purified; no nuisance will result from sewage at Joliet and below, and the potability of the water in the Illinois River at Peoria will not be in the least affected from that source. An increase of water to 60,000 cubic feet per minute would take in addition the sewage of the North Branch after it has once been cleaned out, and would diminish the nuisance in the South Fork of the South Branch at least three-fourths.

In summer, when oxidation proceeds most rapidly,

the minimum quantity would have sufficed; but in winter, when oxidation is retarded by ice formation shutting out the light and air, by the low temperature, and by the impeded motion, it is probable that the maximum dilution would be necessary. Since the time when this estimate was made there has been a decrease of the wastes from certain industries, notably from the slaughter and packing houses. This diminution is likely to continue as these wastes are more fully utilized; so that it is probably safe to assume that the maximum concentration of the sewage effluent of the Chicago River has been reached, and that in the future a lesser rather than a greater percentage of dilution will suffice than the above figures would require.

The problem of preserving the water supply of Chicago and its suburbs from pollution and the inoffensive disposal of their sewage and wastes of all kinds requires that all sewage and wastes be diverted from the lake into the river and its branches; and that there be pumped from the river into the canal, or other waterway, an average of 12,000 to 13,000 cubic feet per minute for every 100,000 inhabitants. The diversion of sewage and wastes into the river will preserve the purity of the lake water even when taken at the present distance from the shore. This continuous pumping of 12,000 cubic feet per minute for every 100,000 inhabitants will effect a prompt removal of sewage from the river and its branches, so largely diluted, that, with the accelerated rate of oxidation caused by the mechanical agitation, it will be rapidly rendered inoffensive in the canal and will under no circumstances affect the potability of the Illinois River water. If the removal from the South Branch be effected by gravity a larger volume must be provided for for obvious reasons.

These are the two conditions of the solution of the problem. All else is a matter of engineering detail, embracing the change of fall of sewers (whether within or beyond the present city of Chicago) now discharging into the lake, or their abandonment and the construction of new ones discharging into pump-wells in low areas, the sewage to be thence pumped into the river; the exclusion or reduction of storm-water and overflow in the river from the Desplaines watershed and from the watershed of the North Branch; the utilization of the canal, or of the bed of the Desplaines, or of both, and other details.

Chief-Engineer Hering, of the Drainage and Water-Supply Commission, returned on October 29 from a tour down the Desplaines River. He reports the sewage was noticeable as far as Joliet, but that a chemical analysis has determined its existence as far

as La Salle. The proposition now being followed by the Commission is to carry the sewage of the city off by way of the Illinois and the Desplaines Rivers. All difficulty heretofore experienced by the overflow of the Mud Lake region during the spring freshets in the Desplaines will be obviated by constructing a canal from the river to Lake Michigan at or about Norwood Park. Mr. Hering is more disposed toward the river plan. It is claimed that oxidation of the sewage can be increased to such an extent that the impurities of the river will not be offensively apparent for any great distance. Mr. Hering will also make a general observation of the fluctuations of the lake, and to obtain correct data as to the operation of the currents there, simultaneous observations will be made wherever the atmospheric influences warrant it—at Chicago, Milwaukee, St. Joe, Grand Haven, Michigan City, and other available points. These observations are valuable in view of the proposition to move the crib further out into the lake. If it can be shown that the crib can be so located as to be beyond the reach of turbid water, and to insure cooler water during the summer, it will be of great benefit.

NEXT ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION.

As the summer has passed, and the season favorable for literary and scientific work has fairly begun, we desire again to call the attention of the profession generally, and of members of the Association especially, to the necessity of commencing, without further delay, the work of preparing papers and reports for reading and questions for discussion, in the several Sections. The scientific and practical value of the annual meeting will depend almost wholly on the degree of research and faithfulness exemplified by members in completing in good time such contributions as they intend to make. To merely think about it and yet delay actually commencing the work until a few weeks or days before the time of meeting, is pretty sure to result either in doing nothing, or in putting together some ill-considered propositions to be read as a "brief abstract," with the expectation of taking time to write it out for publication afterwards. The eight Sections of the American Medical Association fairly include the entire field of medicine with all its specialties, and in the membership of the Association are included as elegant writers, active investigators, and skilful practitioners, as exist in any of the special separate organizations of this or other countries. And to the ambitious workers the annual meetings of the Association not only afford more general audi-

ences for each Section, but the papers obtain, through the columns of *THE JOURNAL*, a much wider circulation in all parts of the country, than they could get through any other channel. Less than seven months intervene before the next meeting, which is to commence on the first Tuesday in June, in Chicago, where every local preparation will be made for as profitable a meeting as the Association has ever held. Let all who intend to make contributions remember that early notice should be given both to the Chairman of the Committee of Arrangements and to the Chairman or Secretary of the Section for which the contribution is designed. For the convenience of all parties, we again publish the addresses of these officers as follows: Chairman of the Committee of Arrangements, Charles G. Smith, M.D., 125 State St., Chicago; Section of Practice of Medicine and Materia Medica, Chairman, J. S. Lynch, M.D., Baltimore, Md., Secretary, J. B. Marvin, M.D., Louisville, Ky.; Section of Surgery and Anatomy, Chairman, H. H. Mudd, M.D., St. Louis, Mo., Secretary, A. M. Pollack, M.D., Pittsburgh, Pa.; Section of Obstetrics and Diseases of Women, Chairman, F. M. Johnson, M.D., Kansas City, Mo., Secretary, W. W. Jaggard, M.D., Chicago, Ill.; Section of State Medicine, Chairman, G. H. Rohé, M.D., Baltimore, Md., Secretary, Walter Wyman, M.D., U. S. Marine Hospital Service; Section of Ophthalmology, Otology and Laryngology, Chairman, X. C. Scott, M.D., Cleveland, O., Secretary, J. H. Thompson, M.D., Kansas City, Mo.; Section of Diseases of Children, Chairman, DeLaskie Miller, M.D., Chicago, Ill., Secretary, W. B. Lawrence, M.D., Batesville, Ark.; Section of Oral and Dental Surgery, Chairman, J. S. Marshall, M.D., Chicago, Ill., Secretary, E. S. Talbot, M.D., Chicago, Ill.; Section of Medical Jurisprudence, Chairman, I. N. Quimby, M.D., Jersey City, N. J., Secretary, H. H. Kimball, M.D., Minneapolis, Minn.

PRIVILEGED COMMUNICATIONS.

In the case of "*People vs. Murphy*," Court of Appeals, N. Y., Crim. L. Mag., April, 1886, it was ruled that when a physician is sent to a prisoner after a crime has been committed, and she accepts his services professionally, disclosures made by her to him are privileged communications, and this rule applies to all actions, civil or criminal. The opinion of such physician as to whether an abortion has been committed, founded partly on such statements, is also inadmissible. Although the prisoner was a party to the crime (abortion), and relatively to it was an accom-

plice of the accused, and, so to speak, a co-conspirator with him, yet her declarations, narrative of a past occurrence, and constituting no part of the *res gesta*, were not admissible.

SOCIETY PROCEEDINGS. *

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, October 7, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.
(*Concluded from page 500.*)

DR. B. F. BAER presented the specimen and related the following history of

A CASE OF FIBRO-SARCOMATOUS TUMOR OF THE OVARY.

Mrs. —, aged 36 years; married; two children, youngest 15 years of age. About July, 1885, she first noticed that the lower portion of her abdomen was increasing in size, especially in the left iliac region, and she was troubled greatly with flatulent dyspepsia. She had suffered for many months before with pain in the left iliac region, and on November 29 she was seized with what she characterized as terrible pains in that region. She was compelled to take to her bed, and her physician said she had pelvic peritonitis. She remained in bed three weeks, when she became able to be up, still suffering considerable pain, however, with diarrhoea and an occasional discharge of blood from the rectum. She now noticed a hardness in the lower left iliac region. This continued to increase in size, while she grew weaker and began to lose flesh. At this time she passed into the care of another physician, who ordered her back to bed and blistered the surface of the abdomen. She remained in bed four weeks, but the growth failed to diminish in size; on the contrary, it continued to increase. On February 10 she was able to get up and began to feel stronger, but suffered from excessive tympany, together with nausea, loss of appetite, and great pressure upon the rectum and bladder. She also suffered from severe dyspnoea.

On March 30 she was suddenly seized with cramp-like pains in the region of the tumor. These continued for a few days, with almost entire absence of sleep and with continuous nausea. The pain gradually subsided, but she was losing flesh and strength. She had another attack of pain, with such dyspnoea as to leave her recovery a matter of doubt. Ten days later she first consulted me. On examination, I found the abdomen greatly distended and tympanitic, except in the left hypogastric region, which was dull on percussion. Palpation revealed an irregular lobulated mass, apparently having pelvic connections. The uterus occupied the right anterior portion of the pelvis, crowded over by the mass in the left pelvic region. This mass was hard and firm and nodulated, extended into the hypogastric region, and was apparently closely connected with the uterus, as well as with the other organs of the pelvis.

The previous history of the case, together with the

physical signs present, led me to suspect the presence of pus, possibly suppuration in a thick-walled ovarian cyst. The uterus measured two and a half inches in depth. Its connection with the tumor did not seem more than ligamentous, and the apparent rapid development weighed against fibroid tumor of that organ.

The indications were plain. The patient entered my private hospital April 9, ether was administered, and an exploratory incision was made. This revealed a nodulated mass having the color and appearance of a thick-walled ovarian cyst; but it seemed to be solid throughout, and was firmly fixed in the pelvis. Its size could not be reduced, and the incision was increased to six inches, the tumor separated from its adhesions and lifted from its nest. I was much gratified to find that it had a very small pedicle, which was tied and the tumor was removed.

The patient bore the operation badly, and it was thought that she would succumb on the table; it was hours before the pulse could be felt at the wrist, but she rallied, and the next morning she seemed to be doing quite well. A free discharge of bloody serum had taken place through the drainage-tube. After alternate sinkings and rallyings, she died on the evening of the second day from shock, from which she had not entirely recovered since the operation. There was not the slightest evidence of inflammatory action. The discharge from the drainage-tube had ceased and the wound was healing nicely.

This case is interesting on account of the character of the tumor. "A true fibrous tumor of the ovary is a thing of very rare occurrence," says Wells, and he goes on to say: "It will be found that many cases reported as ovarian fibroids are in reality tumors beginning in the uterus, which overgrow and involve the ovary so as to disguise its natural appearance, or conceal it altogether." Doran says: "I have never found a solid ovarian tumor to be formed of pure fibrous tissue, and strongly suspect that fibroids of the ovary are identical pathologically with fibroids of the uterus. All the solid tumors that I have seen removed at operations have proved to be sarcomatous or cancerous."

Dr. Formad, who kindly examined this specimen for me, sent me the following report: "The solid tumor of the ovary showed, upon microscopic examination, to be a fibroma with decided sarcomatous change—a fibro-sarcoma." A peculiarity of this tumor is its nodular character.

DR. KELLY remarked that true fibroid of the ovary is very rare, and the specimen here presented is not, in his opinion, fibroid, but sarcoma. The only fibroid he has seen was one which he examined last spring. That tumor was about one centimetre in diameter, and, although attached to the ovary, lay in the grasp of an adherent fimbriated extremity which cast some doubt upon the origin of the small growth. The so-called fibroid appears to be in every way analogous to the "fibroids" of the uterus, and a useful diagnostic expedient is the appearance of bundles of "sympathetically" enlarged fibres running from the hilum into the broad ligament.

DR. BAER also presented the specimen and related the history of

A MONOCYST OF THE OVARY.

Mrs. J., aged 29; married four years; sterile. Puberty at 14 years of age, and menses always normal. Seven years ago, she first discovered that the lower portion of the abdomen was increasing in size. This continued very slowly during the next three years, and at the time of her marriage it was large enough to be perceptible to her friends. It ceased growing until six months previous to the date at which she first consulted me, April 14, 1886, when she seemed to be in excellent health; no loss of flesh; no pain; complexion ruddy, and appetite good. Menstrual flow increased and accompanied with uterine tenesmus during the last two months, and she had begun to complain of pressure and over-distension. When the patient was in the dorsal position the abdomen did not flatten out, and it was symmetrical and smooth. Dulness on percussion over the anterior and lateral surfaces of the projecting portions of the abdomen, with resonance in the line of the colon. There was marked fluctuation in the dull region. Vaginal examination showed the uterus anteverted, of normal size, not freely movable, yet not closely adherent to the tumor.

Diagnosis.—Probably cyst of the broad ligament, from the long existence of the tumor, its slow growth, symmetrical development, together with the fact that it had not influenced the patient's health during its growth until it had attained such size as to interfere with respiration. Its removal was advised, and the operation was performed at my private hospital, April 27. An incision three inches in length was made. The tumor was rather darker in appearance than is usual in cysts of the broad ligament. It was now tapped, and a dark grumous fluid drained away. The tumor collapsed, and was easily drawn through the incision, when its pedicle was found to consist of the entire broad ligament and to be very short, holding the base of the tumor deep in the pelvis. I was compelled to enucleate the cyst, leaving a broad open pedicle or surface, which I ligated *en masse*.

An accident now occurred from which the patient almost lost her life from hæmorrhage, viz.: slipping of the pedicle ligature. The mistake was in endeavoring to make a pedicle of the broad ligament, which had been laid widely open by the enucleation of the tumor, and which was not a proper pedicle. The mass was too great to be held by ligature, and was treated by bringing the edges together by interrupted sutures, of which ten were required. The hæmorrhage was checked by grasping the vessels in clamp forceps until the sutures were placed. There were no after-symptoms. The patient is now entirely well.

I call attention to the monocystic character of this tumor, its location in the broad ligament, and to the character of the contained fluid—dark-colored and thick, not clear and limpid, as is usual in cyst of the broad ligament proper.

The report of Dr. Formad is: "The cyst is a monoculular one, developed from the ovary undoubtedly. Its lining is characteristic of ovarian cysts—epithelial, and whatever scrapings from the wall could be obtained showed the ovarian cells of Drysdale. The fluid was dark, grumous and turbid, which ex-

cludes cysts of the broad ligament or parovarian, as the latter kind of cysts have always a limpid, clear liquid."

DR. BAER also presented the specimen and read the history of

A CASE OF BURSTING CYST OF THE OVARY.

Mrs. E. G. was sent to me by her physician, Dr. James Simpson. She was 47 years of age, and had been married twenty-seven years, but had never been pregnant. Puberty at 14 years, menstruation always painful. She stated that twelve years ago she had felt a "lump" in the left iliac region. This was painful, especially during the menstrual period. In the fall of 1885 the lower portion of her abdomen began to enlarge, and within a few months it had so increased in size as to render locomotion and respiration difficult. On January 1, 1886, while riding in a street car she was jolted in crossing a railroad track. She was at once seized with great pain in the abdomen, accompanied with pallor and faintness. She was taken home and placed in bed. A short time afterwards she began to vomit a fetid fluid, which came up in large quantity and at regular intervals, and at the same time she passed fluid of the same character from the bowels. The next day she had, in addition, attacks of profuse perspiration. She also had a slight metrorrhagia, the first evidence of menstrual flow since January, 1884. The abdomen rapidly diminished in size and within a week had regained its normal dimensions. It was three weeks before her strength had returned sufficiently to permit her to go about. She soon noticed that her abdomen was filling up again, and within a month it had become as large as it had been on January 1st. During the first week in March she was again seized with pain of the same character, and followed as before by vomiting, purging, diuresis, and diaphoresis and reduction of the abdominal distension. All of the symptoms were more marked in the second attack. Six weeks afterwards she was as large as ever, and she then came into my care.

She presented an appearance of great pallor and commencing emaciation; the "facies ovariana" becoming plainly perceptible. She was very nervous and excited for fear of a repetition of the phenomena that had occurred before.

On examination in the dorsal position, the abdomen was rather projecting, not flat, and was larger on the right than on the left side. It was smooth throughout, and gave a dull sound on percussion over the whole anterior surface, resonance existing in the line of the colon. There was marked fluctuation throughout the dull portion. Vaginal touch showed the uterus to be situated high, as if it were drawn upward. It was not freely movable, and the external os too small to admit the sound.

Diagnosis.—Ovarian cystic disease. Immediate operation advised.

On July 22 the operation was performed at my private hospital. Incision three inches, in median line; wall of the tumor thin and dark colored. The trocar was passed and the contained fluid, dark in color, drained away. The cyst collapsed and was

easily drawn through the incision. The pedicle was short and broad, consisting of the broad ligament, and requiring enucleation of the tumor before its ligation could be accomplished. It was now found that another tumor existed on the left side. This had a peculiar shape, being elongated and deeply seated in the pelvis, as though it were entirely subperitoneal. The peritoneum extended out from the the uterus, spreading over the tumor and approaching the abdominal wall, as is sometimes seen in a fibroid tumor of the uterus which has pushed that membrane upward in its growth. The cyst extended along the line of the colon, and at first I was not sure that it was not that organ greatly distended by gas. I soon determined that it contained fluid, and that its general appearance, color, etc., were similar to those of that just removed. It was emptied, by means of the trocar, of a fluid similar to that of the first tumor, and the tumor collapsed. I hesitated as to the proper course now, because of the large and broad base of this cyst, and its close adhesion to the descending colon. I first thought of stitching it to the abdominal incision and inserting a drainage-tube into it, and was soon afterwards sorry that I did not follow out my first idea. I began an attempt at enucleation, and this was attended by so much hæmorrhage from the large surface which it was necessary to dissect, that I was compelled to desist. I had separated at least six inches of the descending colon from the cyst when I found that the latter dipped down so deeply into the pelvic excavation that I concluded it would be hazardous to finish the enucleation. I was in a quandary, for I had only two-thirds of the lining membrane of the cyst in my control, and I finally did what I was never compelled to do before, and what I may be criticized for doing in this case. I drew up as much of the cyst as was possible, threw a ligature around the mass, tied it as a bag, and cut away the external portion; thus leaving a large quantity of the lining membrane still within the pelvis. The oozing of blood from the large open surface was checked by ligatures and compressive forceps until all bleeding had ceased. The toilet of the peritoneum was then made, a drainage-tube inserted, and the incision closed. During the next few hours there was a free discharge of bloody serum through the tube, but the next morning it had ceased. On the third day the tube was removed. The patient made an excellent recovery, and went home on the twenty-third day.

The points of interest in the case are: 1. The bursting character of both of the cysts. 2. Their monocystic character and probable ovarian origin. 3. The deep attachment of the one on the left side and its partial removal only.

"Bursting Cysts of the Abdominal Cavity" is the title of a very instructive paper which was read before the Gynæcological Society in 1881 by Dr. Wm. Goodell, and in the paper itself and the discussion which followed it was shown that this character of tumor is not so rare as the experience of a single individual might indicate. In addition to the cases which Dr. Goodell himself reported, three in number, there were no less than ten of the members present

who had met with cases of similar character, some of the gentlemen as many as six or seven. Only two or three of the cases reported died as the result of the discharge of the fluid into the abdominal cavity. This appeared to prove that the fluid of an ovarian cyst was not so irritating to the peritoneum as had been supposed. Dr. Goodell took the position that these cysts were of the broad ligament or parovarium, and not true ovarian cysts, and as a consequence the fluid was bland and unirritating, being readily absorbed and discharged through the emunctories. This view is probably correct for the majority of cases, but there are others where the evidence furnished by operation has proved the origin of the bursting cyst to have been in the ovary. The monocystic character of the tumors in this case, and their location beneath the peritoneum, within the folds of the broad ligament, would seem to indicate that they originated in the parovarium and not in the ovary; but the character of the fluid and its rapid secretion are in favor of an ovarian origin. An interesting feature in this case is the fact that the fluid was discharged by vomiting and purging as well as through the bladder and skin, showing that it must have been emptied into the abdominal cavity as well as into the intestinal tract. From the close attachment of the tumor on the left side to the colon, it is probable that this cyst discharged itself into that organ and was thus thrown off by vomiting and purging. While the fact that diuresis and diaphoresis took place at the same time in such quantity, and that the abdominal distension entirely disappeared, would lead to the conclusion that both cysts must have burst simultaneously, the one discharging into the bowel, the other into the peritoneal cavity. This is interesting, if true, and probably unique. At least I have not been able to find a record of a similar case. I examined this patient recently and found only a slight induration on the left side. She has been quite well.

DR. HARRIS mentioned a case of bursting cyst that had been sent to Dr. Atlee for operation after the cyst had burst once and refilled. The day had been fixed for operation, but menstruation coming on a postponement was made, and the cyst again burst and the woman died in collapse. Ovarian tumor had been diagnosticated.

DR. PARRISH mentioned a case of rupture of an ovarian cyst which occurred in the "old woman's ward" at the Philadelphia Hospital. The rupture was spontaneous while the woman was in bed. She died in a few minutes from shock. In another instance in which rupture had not been suspected, one cyst, the contents of which were colloid, had burst, another ovarian cyst was found and removed. There was no evidence of acute inflammatory action.

DR. BAER exhibited a

FIBROID POLYPUS OF THE UTERUS.

The patient had suffered from metrorrhagia for two or three years. Labor-like pains were followed by spontaneous expulsion of the tumor, which was supposed, by three physicians, to be an inverted uterus; it was replaced in vagina and tamponed. Dr. Baer found the uterus in normal position, and removed the tumor by means of the spoon-saw.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Oct. 18, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. R. W. BISHOP read a paper entitled

IS ALOPECIA PREMATURA CONTAGIOUS?

Dr. Bishop thought this disease due to micro-organisms upon the shafts of the hair, and that it is contagious. He has made a series of experiments, assisted by Dr. Oscar Lassar. A typical case was that of a perfectly healthy young man whose head was nearly bald on top. The hair from the diseased surface was brittle and came out easily when pulled. Microscopic examination revealed a large number of fungi on the scalp and the shafts of the hair, the root being free from the parasite. The diseased hairs were cut and mixed with vaseline, which was rubbed on the skin of healthy rabbits, and in two weeks the hair entirely disappeared from the parts which had been rubbed. Experiments were continued, and it was found that the hairs from the inoculated animals possessed increased virulence.

The patient was treated as follows: The head was thoroughly washed for fifteen minutes with tar soap, which was removed with warm water. The head was then exposed to a warm water douche, which was gradually cooled until the water was quite cold; it was then rubbed with a rough towel until dry, and afterwards washed with a solution of corrosive sublimate 1 : 500. This was removed and a $\frac{1}{2}$ per cent. of l. thol applied, and, after this, 1 $\frac{1}{2}$ per cent. carbolic oil was applied very slowly. The treatment was continued daily for eight weeks, and the result was a fine growth of new hair with beginning pigmentation at the end of three months.

DR. JOSEPH ZEISLER thought this was a disease which possibly might be produced by vegetable organisms. He knew of Dr. Bishop's experiments, but still there were strong objections to the value of these experiments. Michelson made some experiments by using a mixture of vaseline and rancid oil and rubbing it on the skin of guinea-pigs, and after these inoculations the animals got bald on the places anointed, although neither sick hairs nor scales were used. There are older experiments which show that animals fed on old cheese or hard boiled egg get bald. Another point was, that the disease is so frequently met with in men and so rarely in women, between whom there are plenty of chances for contagion. It is an ascertained fact that the disease most frequently occurs in men who in their earlier years (17 to 25) suffer from pityriasis of the scalp, so that there certainly is a causal relation between this affection and alopecia. After all, he thinks that the contagiousness of this disease is still an open question.

DR. FRANK BILLINGS made some remarks on

HOSPITAL PRACTICE IN VIENNA, WITH EXHIBITION OF NEW URINE TESTS, NEW INSTRUMENTS, ETC.

The hospital at Vienna contains about 2,500 beds. The number of deaths per year is about 3,000. Prof. Nothnagel, who presides over the first medical clinic, has from 80 to 100 patients in his ward continuously.

Histories of the patients are written by assistants and left in charge of the nurses. Temperature charts are kept of important cases, the temperature being taken every two hours. Daily clinical and microscopical examinations are made of the urine in all important and grave cases. Dr. Billings gave an illustrated description of the tests employed. He said that in the Vienna hospitals some form of tuberculosis is found in nearly 70 per cent. of the deaths. The treatment of acute diseases is generally expectant, and in typhoid fever, milk and other liquid diet is used. Previous to 1879, when the city obtained its water from the Danube River, typhoid fever was almost epidemic in Vienna. In that year they put up new water works, and since that time not one case has developed in the city. The obstetrical department is divided into three clinics, with 3,000 confinements in each clinic yearly. Four cases of sublimate poisoning occurred last winter. The autopsies showed ulceration throughout the alimentary tract with charred, black appearance of the mucous membrane throughout the colon and rectum. The solution used in these cases was 1 to 4,000, bichloride of mercury. Abortion is treated by rest in bed with non-interference, unless too severe hæmorrhage occurs, when tampons are used. In the gynecological department Prof. Braun performs laparotomy every Wednesday. Where a part of tumor is left in the stump, the prognosis is bad even when treated externally, because of the low vitality of the tumor tissue, which becomes necrotic. In operations about the anterior vaginal wall no anæsthetic is used. In the surgical wards of Profs. Billroth and Albert, closest attention is paid to cleanliness. The operating rooms are constructed with floors inclined to the centre, where a grating allows all blood, water, etc., to flow away. The floor is thoroughly douched every day. Sponges, silk sutures and towels used in operations are boiled in a 5 per cent. solution of carbolic acid for one hour, then placed in a 5 per cent. solution for fourteen days. Cutting instruments are polished and placed in a 2 $\frac{1}{2}$ per cent. solution of carbolic acid during the operation. Instruments used in operations for abscesses, etc., are heated in flame and sent to the instrument maker to be repolished. A 10 per cent. solution of carbolic acid is used for irrigating wounds during operation. For partial amputation of the tongue a bloodless method is used as follows: First, a double stout suture thread is passed through the centre of the tongue from below upward and backward, beginning at the frænum; the two threads are twisted and tied upon the side firmly enough to control the vessels. The part is then amputated smoothly by taking out a triangular section. Two deep, and a sufficient number of superficial sutures close the wound after the vessels are secured. A bacteriological laboratory is connected with the pathological department, and cultivations of bacteria are made from typhoid fever, pneumonia, erysipelas, glanders, septicæmia and other diseases. Experiments with bacterial cultures are made upon lower animals. Nearly every department of the hospital now has a bacterial laboratory, and the search for new forms and confirmation of already discovered bacteria goes on with enthusiasm.

DR. C. W. PURDY said that in testing the urine for evidence of kidney diseases, the only proteids of any significance were serum albumin and globulin. The presence in the urine of peptone, hemialbumose, etc., points to morbid conditions outside of the kidneys, and whatever light they may shed upon general conditions, they afford us no information whatever as to the state of the kidneys. He mentioned this because so much had been written of late on peptonuria, and the various transition proteids, that an impression seemed to have arisen that the presence of these in the urine was of scarcely less importance than that of serum albumin. The only bearing these non-homogeneous proteids have upon the subject is the fact that their occasional presence in the urine may, with certain tests, be mistaken for serum albumin, unless great care be exercised.

He believed the most delicate of all tests for albumin in the urine to be the potassia mercuric iodide with citric acid; but that it had not met with general favor thus far on account of the errors liable to arise through its use. It is necessary to discriminate between the precipitates formed by this test with peptone, alkaloids, above all with mucin, and that formed by serum albumin. It is true that heat clears up the precipitates due to peptones and vegetable alkaloids, but not so with mucin, the latter being practically indistinguishable from albumin. He has lately, however, come upon a method which he believes will correct not only the errors due to the presence of mucin, but also those likely to arise from the presence of alkaloids and peptone when precipitated by this test. The method is very simple, viz.: after having applied the reagent to the suspected urine, if a precipitate be formed, add hydrochloric acid in volume equal to the quantity of urine tested; if mucin, peptone, or vegetable alkaloids be the cause of the turbidity, it promptly clears up; while if due to albumin the precipitate becomes flocculent and settles, but does not dissolve. A considerable number of experiments have shown him that hydrochloric acid in volume equal to one-half the quantity of urine tested quickly clears up the peptone, alkaloid and mucin precipitate, while it requires at least two volumes of hydrochloric acid to dissolve the slighter traces of albumin in urine when precipitated by the mercuric test.

With regard to sugar testing: In addition to the test brought forward by Dr. Billings, two new ones have recently been introduced, both of which are of such exceeding keenness that they are claimed to be able to detect 0.00001 per cent. of sugar. These tests are, alcoholic solutions 15 to 20 per cent. of alpha-naphthol, and thymol. Two drops of either of these solutions are added to two cubic centimetres of urine, and the mixture briskly shaken; sulphuric acid is next added in quantity equal to the volume of urine, and again briskly shaken. In the case of alpha-naphthol a deep violet color is developed in the presence of sugar, and dilution with water throws down a violet blue precipitate, soluble in alcohol with a yellow color, or in caustic potash with a deep yellow. In the case of thymol a dark red color is produced, and, on adding water, a precipitate settles,

which dissolves with alcohol, forming a yellow color more decided if ammonia be added.

Dr. Purdy often had samples of urine sent him, which though loaded with albumin, no casts could be found therein. These were samples of urine which had been long passed—perhaps several days before, alkaline fermentation having occurred, and the urine rendered alkaline quickly dissolves the casts. In searching for renal casts it is of the greatest importance to have the urine as freshly passed as possible. His method of examining urine for casts is as follows: First, he prefers to have the urine passed at his office. If the urine be neutral or alkaline in reaction, he renders it frankly acid by the addition of dilute acetic acid. In all cases he adds a solution of resorcin to the urine which prevents change for weeks. The urine thus treated is set aside in a conical glass, carefully covered and allowed to stand for from twenty-four to forty-eight hours; at the end of this time, a few drops—not more than ten—are taken up by a glass tube from the bottom of the glass, and one or two drops placed upon a glass slide and examined under the microscope. He had had no difficulty in finding casts by this method if they were present in the urine even in sparse numbers.

DR. FRANK S. JOHNSON described a new form of *Hæmoglobinometer*, viz.:

THE HÆMOTER OF VON FLEISCHL.

It consists of a stand with a horseshoe base, an upright, a stage, and a well divided perpendicularly in two equal compartments and closed below by thin glass. One-half of the well is to hold blood of known dilution, the other half is for clear water. This well fits an opening in the stage. Beneath the stage is a plane white reflector. On the under side of the stage is a frame that can be racked back and forth. Set in it is a narrow wedge-shaped piece of ruby glass whose width is one-half that of the opening in the stage. The thicker end of the wedge gives by transmitted light the color of a dilution of blood containing the maximum amount of hæmoglobin. The thinner portions correspond with the color of a dilution of blood poorer in hæmoglobin. The percentage of variation from the normal amount of hæmoglobin is estimated by comparing the color of the blood solution with some part of the ruby wedge. Only artificial light can be successfully used for the examination.

With the instrument are several capillary tubes for measuring the amount of blood to be used for comparison with the colored glass standard. The necessary amount of water for making the dilution is measured in one of the chambers of the well.

The blood for examination is best obtained by pricking the ball of an uncompressed finger and forcing out a drop by gentle pressure. The amount needed is taken in the capillary tube. One of the halves of the well having been previously half or two-thirds filled with water, the blood can be easily washed from the measuring tube into it. Then both halves of the well are accurately filled with water so that the upper surfaces are plane. A small pipette is furnished for this purpose. The well is then so

adjusted that the half holding water is above the colored glass, and that holding the blood solution receives its light directly from the white reflector. The next step is to so adjust the ruby wedge that the light it transmits corresponds in color with that passing through the blood solution. The observer then reads off the percentage of the normal amount of hæmoglobin as indicated by a scale graven upon the metal frame carrying the glass wedge. The average percentage of hæmoglobin in the blood of healthy individuals varies greatly with age and sex. The average is from 12 to 13 per cent. The percentage of this amount is ascertained by comparison with the color scale. This result should be corrected as far as possible for the known variation of hæmoglobin in healthy blood. Taking as the normal percentage that found in the blood of healthy individuals between 25 and 30 years of age, it is found that in the first few weeks of life the percentage is greatly in excess; but after six months or a year, it is below the adopted standard, reaching it again at about 25 or 26 years of age, and that after the thirtieth year, the amount is below the normal but is variable.

The instrument recommends itself to the ordinary practitioner. It does not entirely replace the hæmocyto-meter, but in all cases where it is only necessary to watch from time to time the rise and fall of the hæmoglobin in the blood, it can be done much quicker and more accurately than by the hasty counting of the corpuscles by the microscope.

DR. J. J. M. ANGEAR thought that it is necessary to count the globules, because we have conditions where the red corpuscles are normal in number but deficient in hæmoglobin, hence the necessity of both instruments.

DR. C. E. WEBSTER, Chairman of the Pathological Committee, exhibited a spinal column and said that it showed caries resulting in the entire destruction of the bodies of one of the vertebræ, without the protection of the characteristic deformity before the removal of the ligaments, no curvature being noticeable.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, September 9, 1886.

THE PRESIDENT, H. O. MARCY, M.D., IN THE CHAIR.

H. J. HARRIMAN, M.D., SECRETARY.

DR. J. E. KELLY, read a paper entitled
THE ETHICS OF ABORTION, AS A METHOD OF TREATMENT IN LEGITIMATE PRACTICE.

(See page 505.)

DR. L. F. WARNER said that the paper did not admit of criticism, but deserved candid and unqualified approval. He believed that no woman ever used means for procuring the death and expulsion of the foetus without realizing that it was a moral wrong, and that every woman who did or consented to the act thereby lowered herself morally beyond recall.

DR. SYMINGTON BROWN remarked that the paper was an admirably drawn up special plea, which might

have done credit to a lawyer. Dr. Kelly had set out by disclaiming all sectarian bias; but the fact was that the whole plea was based on the authority of the Church, and, like many similar arguments, could not hold water. He was aware that this was not the place to discuss such a question, and did not deny that the Church had a right to dictate to its own members; but he emphatically denied its right to dictate to him. He thought that Dr. Warner had failed to grasp the real aim of the paper, which was not directed against *criminal* abortion, but against abortion itself under all possible circumstances. The mere fact that the word "criminal" is prefixed shows that there must be a kind which is justifiable. The physician, after consultation, is the proper party to decide what is best to be done, and the patient has a right to veto his decision. For his part, he only recognized one rule to be governed by, and that is, the welfare of his patient. He would like to ask Dr. K. how his argument would apply in a case of extra-uterine pregnancy? During the early months, a current of electricity suffices to destroy the foetus without injury to the mother. Is not a child alive outside as much as inside the uterus? Yet no conscientious gynecologist scruples to kill the foetus under these circumstances; and, in my opinion, he is fully justified in so doing, because the welfare of the patient demands it. Would the essayist allow both the mother and foetus to die in order to save his own conscience? According to the tenets of the paper he would.

As regards the legal tribunal to the verdict of which Dr. K. inclined, as a last resort, to refer cases of abortion, he would simply remind him that law is not infallible any more than medicine, and that innocent men have been hung on circumstantial evidence. He hoped that this Society would not indorse the idea that it is wrong, *under all circumstances*, to produce abortion.

DR. A. P. CLARKE said that many women are depressed and nervous during gestation, and need the encouragement of their physician in order that they may withstand the temptation to secure a miscarriage. To treat these patients judiciously so as to tide them safely over this critical period of depression, is the duty of the physician. Dr. Clarke believes that criminal abortions are less frequent than formerly.

DR. CHAS. R. WHITCOMB thought that the physician was, to a certain extent, the custodian of the public morals, and should not assume to act as judge of life and death. He agreed with the conclusions of Dr. Kelly's paper, and did not consider abortion justifiable under any circumstances.

DR. E. W. CUSHING said that the arguments of the speaker were very old, and extremely well wrought out, as some of the acutest minds of the Catholic Church had been at work on the subject for centuries. The syllogism appeared perfect, and the conclusion inevitable; yet, in reality, the reasoning is somewhat sophistical, for one of the premises on which it rests is shaky. In substance the writer says that killing an infant to save the life of the mother is homicide; well, so it is. Moreover, that the only jus-

tifiable homicide is under certain circumstances which he describes, viz., self defence, command of civil authority, etc. Here is the weak point; where is his authority for excluding another category, *i. e.*, where the physician fulfils the unwritten law of civilized life and organized society, in taking a foetal life to save another, the mother's, just as a General may send one man or body of men to certain death in order to save other and more important parts of his army.

Now, either we have to squarely admit the authority of the Roman Church to settle all matters of morals, or each man must help himself by the light of his conscience, guided, by the average opinion of his time and community, and by the consensus of the competent. Now we of the medical profession are the competent, and the consensus on this question is overwhelmingly affirmative.

The Protestant churches have no opinion officially on this question, as on many others, where medicine and morals come so near together that the Catholic church has seen fit to decide what is right and wrong. Let any one read Father Gury, or any of the ponderous Latin works on Roman Catholic moral theology, and he will find other points where modern society differs decidedly from the church. Judged strictly thereby we should most of us be damned anyhow, and in settling these questions we have to do as Nelson did when he put his blind eye to the telescope to read the signal to retreat, and, continuing the fight at his own risk, saved the battle and his own neck.

No one abhors criminal abortion more than I do, and I know that Dr. Kelly's Catholic friends will, in a generation or two, have the majority side of this whole question, for what with frequent abortions, and the studied prevention of conception, equally reprobated by the Catholic church, the Catholic birth-rate hereabouts is six to one of the Protestant, without counting the fact that every twelfth marriage in New England ends in a divorce, nearly all of these divorces being among Protestants. So that in a few generations New England will be a strong Catholic country, like Belgium. Now, however, this is not the case, and neither our civil organization nor our professional duties can be subjected to rules which, however logically they are worked out by men who never had any wives nor children, can be brought to a *reductio ad absurdum*, as here to-night, where Dr. Kelly maintains that it is wrong to kill a small extra-uterine foetus by electricity, even when by not doing so we know that the child is nearly sure to die, and the mother is only saved, by exception, in rare cases.

In regard to the laws making every procurement of abortion a criminal matter, it is in the interest of the mother, primarily, that they are passed and enforced, for the legislators and courts do not in practice hold that the life of the mother must be sacrificed or greatly endangered to save that of the foetus.

In regard, however, to abortion, it is evident that something must be done to check the most crying outrage and evil of our civilization, and any way in which physicians can help educate the community to a proper sense of the gravity and danger of the act or process of abortion should be welcomed.

Dr. Cushing did not believe that special courts could be established or worked, but would favor a regulation providing that in all cases requiring abortion or craniotomy the medical examiner of the district must be notified, and made a consultant, or at least exactly informed as to the necessity for the operation. In cases where the emergency does not admit of even a few hours' delay—and they are few—a formal notification should be required within twelve hours; in fact, the whole matter should be surrounded with the formality due where the life of a human being is involved. Until such legislation is procurable it ought to be the first and plainest duty of every physician proposing to kill a foetus to get the best medical advice available, in consultation, and to remember, in cases requiring craniotomy, how successful the Cæsarean section has become in these modern times.

DR. H. C. WHITE said that to every medical man there comes a supreme moment when he is above the mandates of Church or State, and must act upon his own responsibility, according to the best light that he has. Under these conditions, how much less wrong is it to allow two lives to be lost than to save the more valuable one by sacrificing the life of an unborn and perhaps not viable foetus? He said that abortion and craniotomy should not be performed until the best available counsel had been consulted, but that under circumstances where such aid could not be secured, he need not hesitate to sacrifice the life of the foetus if he considered that unfortunate step necessary to save the life of the mother.

THE PRESIDENT said that he had listened to the paper and its discussion with more than ordinary interest. On his own part, he would be very glad to accept the views of the writer, since it saved the assumption of a grave personal responsibility, and reduced the question to a formalistic one. In the early days of the Church, when medical learning was, at the best, very imperfect, and the induction of abortion, or miscarriage, was followed by most grave dangers to the mother, the wisdom of the measure to save the life of one at the cost of that of another was a very doubtful expedient; and it was very likely safer to trust to nature. He did not understand that there was anything in the creed of the mother Church to prevent the saving of one life if it was evident two must be sacrificed by non-interference. To the Catholic mother, the baptism of the child was an important rite, and he had often performed it under the direction of the clergy. Under certain conditions this simplified the question. He had, however, recently seen a case, in consultation, of vomiting in pregnancy where death followed a few days later from exhaustion. His advice of inducing abortion had not been accepted, as the family were Catholics, acting under the special direction of their clergyman. In a considerable number of instances he had induced abortion where he felt he had thereby saved the life of the mother. In a certain class of cases he should not feel justified in refusing his services.

The suggestion of the author of submitting all this class of cases to a Board of medical men, specially appointed, presented some manifest advantages. It

would shift the responsibility from the general practitioner, and at the same time secure a much safer result to the patient by ensuring competent service. It would not be pleasant to contemplate such a "Board" of legally constituted executioners, and out of large cities would be impracticable. For good reason, it may be assumed abortions for the real purpose of saving the life of the mother are now rarely undertaken, except after a careful consideration of the whole subject in consultation.

DR. KELLY, in closing the discussion, said that he had but little to add to the paper which he had read. His desire was to induce the discussion of the subject, and he had succeeded most agreeably. He was pleased that so many of the speakers coincided with his views, and he would reiterate his convictions that the foetus, although incapable of defending itself, should have extended to it the same degree of justice as that which every other individual receives from his fellow-men, and that it is unjust and unwise to impose upon the members, fallible or infallible, of the medical profession the duty, appalling upon reflection, of sentencing, single-handed, and executing a living and sentient fellow-mortal. The expressions of the speakers indicating their belief that it is their duty to perform abortion in certain cases, convinced him that they had not considered the subject in all its bearings, and he should be pleased if his paper induced them to reconsider their position of one-sided justice. Laws were not made for the just man, but for those who are unrestrained by higher or nobler precepts. Freedom of action requires careful limitation, as without this the convictions of a madman could be quoted in extenuation of his freaks, and it would be illogical to permit the individual to indicate the line at which freedom of opinion should give place to legal or religious restraint. There are many acts, some of them most repugnant, which are perfectly legal, and yet no self-respecting man would think of performing them. Legality, necessity and expediency do not afford sufficient excuse for acts which are naturally, initially and fundamentally wrong. The declaration of our unalterable conviction of the probity of our acts may sometimes deceive or satisfy those in whose interests those acts are performed, but it does not appease the "still, small voice within."

DR. H. O. MARCY exhibited specimens of

WOOL FOR SURGICAL USE

prepared by the Globe Pharmaceutical Company of Boston, and said: Absorbent cotton, as is well known, is the pure fibre, freed from the vegetable oil which, in an extremely thin layer, covers each filament. For certain surgical purposes, this is unequalled by any other material. However, the fibres mat together in such a way, that the secretions from wounds permeate the dressing imperfectly, and drying, cause an incrustation which prevents the escape of fluids and thus retards rapid repair, even in aseptic wounds. More recently, wool fibre has been recommended and received the approval of a considerable number of prominent surgeons. The wools which I have used have been so imperfectly prepared that I have found them objectionable. These specimens

from the Globe Pharmaceutical Co., of Boston, merit your commendation as being clean, free from oil and therefore absorbent, although in a less degree than cotton, and aseptic. The fibre is carefully carded and is separable into sheets as desired, and impregnated with mercuric bichloride 1-2000. As a vaginal packing, by its elasticity, it often aids materially in the retention of a replaced uterus, while it is more comfortable than the cotton tampon, and more easily permeated by fluids. Because of its greater porosity, it admits of a much freer drainage, thus rendering it especially adapted as a dressing for wounds, fitting irregularities and much less liable to displacement. As a padding for splints, especially with fixed dressings, *e. g.*, plaster, it leaves little to be desired. Wool receives and retains the various antiseptics better than cotton, particularly iodoform, which is distributed through it better than through cotton, even when woven into the thinnest gauze fabrics. Wool dressings, when properly prepared, deserve to receive a permanent place in the armamentarium of the modern surgeon.

DOMESTIC CORRESPONDENCE

POTASSIUM CHLORIDE.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—After reading Dr. A. F. Pattee's article on "Potassium Chloride," in *THE JOURNAL* for July 24, 1886, I concluded to give it a trial in several stubborn cases, and the result has been all that I could wish. In myalgia, or pseudo-rheumatism, it has proved very efficacious; in induration left after pelvic cellulitis, and in glandular enlargements, I have found it a valuable remedy.

Yours truly,
G. W. WILBER, M.D.
Philadelphia, Pa., Oct. 22, 1886.

BOOK REVIEWS.

TRAITÉ DES RÉSECTIONS et des Opérations Conservatrices qu'on peut pratiquer sur le Système Osseuse. Par L. OLLIER, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Lyon, etc. Tome Premier; Introduction—Résections en Général; avec 127 Figures.

A TREATISE ON RESECTIONS and Conservative Operations on the Osseous System. By L. OLLIER—Professor of Clinical Surgery in the Faculty of Medicine of Lyons. Vol. 1, Introduction—Resections in General. With 127 Figures. 8vo., pp. vi—664. Paris: G. Masson. 120, Boulevard Saint Germain. 1885.

It was Professor Ollier's intention not to issue the two volumes of his work separately; and it could be wished that our European confrères would all have such intentions and carry them out. But in this case so many difficulties and obstacles arose which delayed the completion of the second volume that the first

has been issued long in advance of the second. And now that the great author has passed away it is with some solicitude that we await to see if the second will come at all. The first volume is devoted to an exposition of the general questions and rules which should serve as guides for all resections, and nothing is omitted. It also contains the operative principles of which the applications are reserved for the second volume when the subject of particular resections is taken up. Necessarily the questions of method should precede those of procedure. "To-day, when thanks to asepsis and antiseptic methods," says the author, "the most useless and irrational operations may be attempted with impunity, it is particularly necessary to determine the indications for operations, and to thoroughly recognize the remote and definite results of every surgical procedure. . . . In surgery success justifies nothing in itself. The ability to do certain operations without great danger does not give us the right to practise them. . . . Since the development of antiseptic methods the operative mania, the *prurigo secandi*, with which certain surgeons have been attacked, has certainly lead to many useless operations. In judging of the value of many resections and other conservative operations which may be done on the bony system, the immediate result is insufficient." We would gladly quote more from this preface, so full of medical common-sense.

In an introduction of 119 pages the author reviews the history of resections (46 pages), and gives the fundamental physiological facts relating to these operations. His account of his experiments on bone and periosteum is exceedingly interesting, and well illustrated with 33 cuts.

In the first chapter of the book proper the author deals with the technique, indications and general results of resections. The second chapter, of almost 50 pages, is devoted to a discussion and description of the instruments used in resections, and has 47 illustrations, many of them of American instruments. The third chapter deals with the general rules in 60 pages. The fourth chapter, of 33 pages, deals with the post-operative treatment of resections. The fifth chapter, 100 pages, deals with reparative processes, and regeneration of bone after resections. The general indications for resections are given in a short chapter of about 23 pages. A chapter of 70 pages is devoted to the indications for pathological resections. The traumatic indications are given in a chapter of 34 pages. The remaining 140 pages are devoted to orthopædic and osteoplastic resections, and to the remote and general results of the operation. Throughout the book bears the mark of the hand of the great master of bone surgery, and is a monument to his great learning, patience and surgical skill.

MISCELLANEOUS.

NEW YORK STATE MEDICAL ASSOCIATION.—The third annual meeting of this Association will be held in Lyric Hall, New York City, on November 16, 17,

and 18, under the Presidency of Dr. E. M. Moore, of Rochester. The meeting promises to be one of the most interesting medical gatherings ever held in this country. There will be a general discussion on gunshot wounds of the intestines, on pulmonary tuberculosis, and on puerperal eclampsia.

COCAINE ADDICTION.—If any reader of THE JOURNAL has met with a case of cocaine addiction and will send me the fullest details at his command, I will thank him for the courtesy, reimburse him for any expense incurred, and give him full credit in a coming paper.

J. B. MATTISON, M.D.

Brooklyn, 314 State St.

NOSTRUMS IN GERMANY.—The *New York Evening Post* says: "What a commotion there would be among our patent-medicine venders if the New York police followed the example of the Berlin police, who are continually issuing warnings to the public, of which the following is a specimen: 'The tradesman, Paul Heider, of this city, Anklamer street 28, is selling under the name of "Harz Mountain Tea" a mixture of lavender flowers, sassafras root, peppermint, and several other plants, weighing 50 grammes. His price is 50 Pfennigs, and he advertises it as a remedy. Official analysis has shown that the real value of one of these packages is hardly 10 Pfennigs.'"

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 23, 1886, TO OCTOBER 29, 1886.

Major Warren Webster, Surgeon, leave of absence on account of sickness further extended one year on account of sickness. (S. O. 244, A. G. O., Oct. 20, 1886.)

Major J. S. Billings, Surgeon, granted leave of absence for eight days. (S. O. 246, A. G. O., Oct. 22, 1886.)

Capt. John V. Lauderdale, Asst. Surgeon, leave of absence extended one month. (S. O. 249, A. G. O., Oct. 26, 1886.)

Capt. Jos. K. Corson, Asst. Surgeon, granted leave of absence for one month, to take effect when his services can be spared. (S. O. 246, A. G. O., Oct. 22, 1886.)

Capt. E. B. Moseley, Asst. Surgeon, relieved from duty in Dept. of the Columbia, and ordered to report in person at hdqrs Div. of the Pacific for assignment to duty. (S. O. 87, Div. Pacific, Oct. 16, 1886.)

Capt. B. D. Taylor, Asst. Surgeon, from Dept. East to Columbia Bks, Ohio.

Capt. L. S. Tesson, Asst. Surgeon, from Dept. Texas to Dept. East.

First Lieut. C. C. Barrows, Asst. Surgeon, from Dept. Arizona to Dept. East.

First Lieut. P. A. Egan, Asst. Surgeon, from Dept. Arizona to Dept. Texas.

First Lieut. F. V. Walker, Asst. Surgeon, from Dept. East to Dept. Texas. (S. O. 244, A. G. O., Oct. 20, 1886.)

First Lieut. E. C. Carter, Asst. Surgeon, granted leave of absence for six months, with permission to apply for an extension and to go beyond sea, to take effect when his services can be spared. S. O. 244, A. G. O., Oct. 20, 1886.)

First Lieut. Chas. S. Black, Asst. Surgeon, granted leave of absence for two months, on surgeon's certificate of disability, to take effect when his services can be spared. (S. O. 244, A. G. O., Oct. 20, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING OCTOBER 30, 1886.

Diehl, Oliver, P. A. Surgeon, U. S. N., granted three months' leave from 26th inst.

PUERPERAL ECLAMPSIA.

A History of My Personal Experience during a
Practice of Thirty-five Years.¹

BY BEDFORD BROWN, M.D.,

OF ALEXANDRIA, VA.

PRESIDENT OF THE STATE MEDICAL SOCIETY OF VIRGINIA; MEMBER OF
THE STATE BOARD OF MEDICAL EXAMINERS.

I do not propose in this paper to present any very novel views or discoveries in regard to the pathology or treatment of puerperal convulsions, but I wish to tell you what methods I have found best for the relief of this affection, and what I have not found good, during a professional experience extending over a period of thirty-five years.

A history of the results of the close and studious observation and of the experience of any man of ordinary powers of thought and intelligence on any single subject of importance is always worth something to his fellow-workers in the profession, and may prove of sufficient interest and value to be placed on record. The only apology I have to offer, in presenting this paper, is the simple desire to perform my share in the work of contributing to the success of this Society, trusting that others may be stimulated to follow the example.

The amazing rapidity and suddenness of the onset of an attack of eclampsia, the brief time allowed us within which to work for its relief, and the great mortality of the disease, unite to render it one of the most appalling affections to which the female is liable. Authors estimate the rate of mortality at 33⅓ per cent. We thus perceive that puerperal eclampsia in its rate of mortality approaches that of some of the most deadly of the acute diseases. These facts invest the history of this affection with peculiar interest. I know of no scene in the experience of the physician better calculated to arouse the sympathy, to elicit the commiseration, and to excite anxiety and alarm, than a violent attack of puerperal convulsions. Just at that period when friends and patient are full of hope, and anticipating a happy deliverance from a protracted burden and the pleasures of a joyful maternity, in a moment of time, in the twinkling of an eye, the angelic countenance of her who as wife and mother has

entwined herself around our hearts in the tenderest cords of love and affection, is suddenly changed from a picture of loveliness and beauty to one the most hideous and repulsive. As often as it has been my lot during the past thirty-five years of my professional career to witness these distressing scenes, and to pass through them from beginning to end, I have never been otherwise than profoundly impressed with the gravity of the occasion. We know that puerperal eclampsia, unlike most of other convulsive diseases, is not a self-limited affection. In this affection, when nature is left unaided or trifled with, she is unequal to the emergency. Without prompt and efficient medical aid, life must surely succumb to the attack. Hence, whatever is done must be done quickly, but with judgment and discretion.

The pathology of puerperal eclampsia is manifestly of a complex character, in which are involved many important structures and functions. Hence, in our study and management of the disease, we should be guided by the condition of the circulation, the temperature, the renal functions, the secretions generally, the intellectual faculties. Those who have investigated the morbid anatomy and pathology of eclampsia have detected positive indications that death may result from a variety of causes in the form of local lesions, and not always simply from the direct effects of uræmic poisoning. Active congestion, serous effusion in and thrombosis of the brain, acute meningitis, œdema of the lungs, true asphyxia—all of these are either the result of puerperal nephritis or eclampsia. It has been my rule in these cases to study the particular tendency to death, and to use all means to avert it.

Condition of the General Circulation.—One of the most prominent features of eclampsia, apart from the convulsive symptoms, is seen in the unbalanced state of the circulation. Probably it is fair to estimate that during each convulsion and a good portion of the intervals, two-thirds of the entire blood of the body accumulates in the venous system. The suspension of respiration during and after each paroxysm produces an universal stasis of blood of the whole venous system.

Another conspicuous morbid change in the condition of the circulatory organs in puerperal convulsions, arising from the combined influence of acute nephritis and the plethora of pregnancy, is an increased arterial tension and blood pressure. In my entire experience, this phenomenon has been present in more or less degree in every case.

¹ Read at the Annual Meeting of the State Medical Society of Virginia, October 17, 1886.

The impulse of the heart is always increased in force, and often in area. And while the cardiac sounds may be healthy in tone and rhythm, they are decidedly higher in pitch. The pulse is bounding in character, more frequent in rate, with a certain degree of fullness, firmness and tension reminding us of a genuine inflammatory type.

Now let us for a moment inquire the meaning of these peculiar pathological phenomena. Has this state of things any significance as an indication? Does all this development in circulatory force imply in reality increased blood pressure, or merely an explosion of nervous energy stimulated by the extraordinary occasion? Or does it mean, in truth, that the left ventricle, abnormally increased in muscular power and nervous force by the combined influence of pregnancy and acute nephritis, is sending a column of arterial blood through the system with at least 25 per cent. increase in gravity and force?

We are called upon, here, to decide the question whether these peculiar phenomena of the eclampsia circulation are merely indications of nervous excitement, or whether they are actually due to increased arterial tension and power, and portend danger to the structure of the brain itself from excess of blood pressure. During the progress of eclampsia, numerous superficial arterioles before imperceptible may now be observed in a state of vigorous action, pulsating forcibly and rapidly. If this be an indication of increased arterial tension and blood pressure, then this increase of force must be brought to bear upon the blood-vessels of the brain with irresistible power. Hence the brain, in these cases, appears to be the central point upon which morbid action and force are concentrated. I believe it to be our imperative duty, in the management of eclampsia, to guard the brain carefully against all danger if possible.

We have mentioned in a cursory manner the arterial pressure present in acute puerperal nephritis and eclampsia, and the greatly increased action of the heart and arterial system. It now remains to treat of the venous pressure which is always induced in these cases by the convulsive movements and interruptions to respiration, and the dangers arising from this source. Venous obstruction and pressure begin with suspension of the respiratory act. Obstruction in the pulmonary circulation throws the column of venous blood, charged with carbonic acid, back on the pulmonary artery, then on the right cavities of the heart, the venæ cavæ, the sinuses of the brain, the hepatic veins, the liver and its great portal circulation. We thus are to some extent enabled to realize the extent of this enormous venous pressure on the vital organs, and the injury sustained by the organism from the accumulation of carbonic acid poison during each act of convulsion. This is a brief and imperfect statement of the mechanism of blood pressure, arterial and venous, as found in puerperal eclampsia.

The danger from this increased arterial tension and venous obstruction is the production of active and passive engorgement of the brain and lungs, apoplectic extravasations of blood, cerebral thrombosis, serous effusion within the cavities of the brain, actual meningitis, compression of the cerebral structures,

and œdema of the lungs. These lesions constitute a not infrequent cause of those grave and fixed cases of puerperal coma arising in eclampsia. As stated, œdema of the lungs is a frequent accompaniment of puerperal eclampsia. It is a complication of sufficient importance to merit a passing notice here. The great difficulty of respiration, the brief and hurried inspirations, the lividity of complexion, the copious secretion of mucus in the bronchial tubes and trachea, indicate the enormous obstruction and engorgement in the pulmonary circulation and the effusion of serum in the connective tissue of the lungs. Auscultation will in these cases usually reveal the presence of extensive subcrepitant râles. In a case of puerperal eclampsia with profound coma under my charge, extensive subcrepitant râles existed throughout both lungs. The respiration was the most labored, rapid and painful ever witnessed by myself.

I find that puerperal eclampsia may be accompanied with two opposite conditions of the blood and general circulation: Plethora, with its excess of red corpuscles, fibrin, and redundancy of blood mass, may exist; or a state of extreme anæmia, or hydræmia, with increase of white corpuscles, diminution of red globules, increase of serum and albumin. I am convinced that the former state predisposes to active congestions of the brain, while the latter tends to produce serous effusions in the brain and lungs. I am also persuaded that a thorough realization and appreciation of these facts may enable us to take measures to avert these tendencies. I have time after time seen the spasmodic and comatose symptoms of puerperal eclampsia relieved by a timely bleeding, full catharsis, a few doses of veratrum, and the labor terminate by natural means, while the consciousness of the patient was restored, and yet the urine was loaded with albumin.

Hydræmia is a very frequent concomitant of puerperal convulsions. While the complexion is always pallid in these cases, the extremities anasarctous, the patient debilitated, easily exhausted, and prone to difficulty and oppression of respiration, the temperature is often one or two degrees above the normal standard. The pulse is quick and bounding, and the arterial tension decided. The condition is essentially one of febrile anæmia.

Pyrexia.—In a considerable proportion of cases coming under my observation increase of temperature has been present; occasionally not more than half a degree, but not infrequently one or two degrees. It is probably due to a combination of causes, and I think is an important indication. On the contrary, an abnormally low temperature I regard as indicating a dangerous condition. I think that the clinical thermometer can be used here, as in other affections, as a valuable prognostic. Increase of temperature usually denotes active congestion, extravasation of blood in the brain, meningitis when the general condition is plethoric, and serous effusion in the brain or acute œdema of the lungs when hydræmia is present. In a case of acute œdema of the lungs in eclampsia the temperature rose 10°.

Treatment.—In beginning the treatment of puerperal eclampsia it is an important question to decide

whether we should not place the patient under anæsthetics, dilate the os uteri by mechanical means, and deliver with instruments at all hazards; or by appropriate treatment subdue arterial tension, relieve blood pressure and congestion, eliminate from the system the ammoniated poisonous materials in the form of urea, and control reflex excitability and spasmodic tendency, thereby placing the patient in a position of safety, and then permit nature to finish the work.

I have on many occasions pursued the latter course with the best results. The three most important principles to be carried out in treating puerperal eclampsia are, I believe, the prompt reduction of arterial pressure or tension, elimination of effete matter from the system, and the absolute sedation of the reflex functions of the spinal cord. Thus it will be seen that, inasmuch as the pathology of eclampsia is complex in character, involving various and important elements, in like manner our method of treatment must, to a considerable extent, be varied. In my opinion, we cannot in safety depend upon any single remedy. Thus, I have found it unsafe to trust either to depletion, anodynes, anæsthetics or cathartics alone. In my past experience, whenever I have departed from this rule in the treatment of eclampsia, I have had cause to regret my course.

General Depletion.—I will repeat my statement here, that of the twenty-five cases which have come under my observation during the past thirty-five years, in all there existed more or less arterial tension and increased blood pressure, which constituted a factor of importance in the progress and termination of the disease. With a view of averting the evil consequences of this influence on the circulation of the brain, I am convinced that depletion is a remedy which cannot be dispensed with in the treatment of eclampsia. I can say with truth that all my cases in which depletion was resorted to early, freely and judiciously, have recovered with a single exception. In this case, after moderate depletion, anæsthetics were used too freely, to the exclusion of other remedies. One of the earliest and most manifest effects of depletion is that of unloading the engorged venous system, the lungs, the right cavities of the heart and the cerebral circulation. If the combined influence of inordinate action of the heart and excessive engorgement of the venous sinuses of the brain, be permitted to continue, the delicate structures of that organ must suffer irreparable injury from pressure and profound coma result. In these cases of profound coma with stertorous breathing, frequent and bounding pulse, increased temperature, when the scene is varied by repeated paroxysms of spasms, let us not be misled in our treatment by any false theories in the pursuit of a vacillating policy. There is absolute safety in the lancet judiciously and timely applied under these circumstances. The state of pregnancy, above all other conditions, is the most tolerant of depletion. The enormous quantity of blood often lost during labor without serious results sustains this opinion. The measure must not only be resorted to early to avert impending danger to the cerebral structures, but copiously, to break down permanently arterial pressure. From sixteen to twenty-four ounces will

probably suffice to cause a decided amelioration of the symptoms. As a usual result, the action of the heart will be slowed, the pulse will become soft. The impulse of the organ will be diminished, temperature will decline, coma will be partially relieved, consciousness will return temporarily, and cyanosis will diminish. But depletion cannot accomplish everything. There may be a return of trouble. But when these desirable objects have been obtained even temporarily, we have a favorable basis for the application of our eliminative, anæsthetic and sedative remedies.

The Use of Mercury in Eclampsia.—I have lived sufficiently long to have passed through various phases and changes of professional opinion in regard to the pathology and treatment of disease. I have seen theories and systems rise up and rejoice in professional favor, then decline and pass away, to be again revived and adopted. Thus it will be seen that while our profession is steadily marching on in the line of progress, we operate somewhat in a circle. Those of us who began their professional career thirty-five or forty years ago, remember full well the mighty sway which mercury held over the mind of the profession. It entered largely into the therapeutics of almost all diseases. At a subsequent period we witness its sad disgrace, downfall and almost violent expulsion from the practice. It was hooted, jeered, denounced and universally condemned in fashionable practice. But again we see professional opinion, beginning this time in scientific Germany, taking another tack and now paying court to this once wretched outcast and recalling it to favor; not, probably, as extravagantly as of yore, but more rationally and conservatively. I have lived to esteem it my best friend, then to regard it as a suspicious subject, but finally one of my most valued agents in battling with disease. In the therapeutics of puerperal eclampsia and nephritis I esteem mercury a valuable agent as a cathartic and alterative. This opinion is based upon sound experience. As an evacuant and stimulant to the entire system of emunctories and secretory organs it has no equal. It stimulates and gives impetus to the secretory functions of the kidneys, liver and intestines. It exerts a remarkable alterative action on the constituents and organism of the blood, often arresting the disorganizing influence of disease.

The first case of puerperal eclampsia which came under my care, in the year 1851, was treated by means of depletion, mercury and ergot. The case was an exceedingly violent one, but recovered. Calomel was given in scruple doses every three hours until it acted as a cathartic most copiously. It also acted as a diuretic. After the birth of the child the patient remained comatose for twenty-four hours. Notwithstanding the patient had been effectually salivated, her restoration in every particular was speedy and uninterrupted.

At a subsequent period, when it became fashionable for high medical authorities to condemn the use of mercury in acute nephritis in any form, I abandoned its use for a time in puerperal eclampsia, but with a decline in my former success. I have again returned to its use in puerperal eclampsia, with equally

good effects. To obtain the favorable action of the remedy it should be administered in scruple doses every three hours until its cathartic and diuretic action is procured. I would again call the attention of the profession to the diuretic action of mercury. In acute nephritis, whether from cold, scarlatinous poison or puerperal causes, I have repeatedly witnessed the action of mercury on the functions of the kidneys, arousing them from a state of inactivity when other remedies have failed.

Cathartics.—Prompt, decided and thorough efforts to establish elimination of the uræmic poison from the system is probably one of the most rational as well as indispensable means of removing the real mischief. The renal outlet is in a manner closed. Thorough elimination through the skin is too uncertain in so great an emergency. For the relief of effusion in the brain, œdema of the lungs, venous engorgement, and uræmic coma, copious purgation is one of the most effectual remedies in our possession. And there is no class of patients which tolerate catharsis better than these eclamptic females. This fact may be laid down as a law in the therapeutics of eclampsia. In all of my cases which recovered cathartics were used boldly and fearlessly. In all the fatal cases they were either not used at all or sparingly. This I deem a fact of practical importance. I have never had cause to regret their prompt and free administration, but often deplored their too limited use. They not only eliminate from the system urea and other effete matters, but remove that redundancy of serum and albumin with which the system of the eclamptic patient is charged, thereby diminishing blood pressure and the tendency to congestion and serous effusion in the vital organs.

My practice in these cases is to give 15 or 20-grain doses of calomel, repeated in two or three hours, followed by drop doses of croton oil in mucilage every hour until copious catharsis is obtained. Subsequently, if the desired relief to congestion and coma is not secured, the dose of mercury is repeated every three hours until further action on the abdominal organs is obtained. At this stage the cathartic and wonderful alterative influence of the remedy on the entire system, in giving relief to the morbid processes, may be calculated on with almost a certainty. In some cases I have given calomel in combination with gamboge with good effect, where there existed great torpidity of the intestinal canal and kidneys.

Anæsthetics.—In the administration of anæsthetics in puerperal eclampsia I have found it safe to act upon the rule that these agents should not be used for the purpose of maintaining a prolonged state of unconsciousness or insensibility, but are in reality designed to control inordinate reflex action, and in that way quiet all convulsive movements. In treating eclampsia we do not wish to produce coma, but merely a suspension of spasmodic action until the morbid causes are removed by depletion, cathartics, and delivery. I think in administering anæsthetics in convulsions we sometimes make the mistake of acting on the same principle which governs us in the use of these agents in surgical operations, viz.: to obliterate all consciousness and sensibility completely

for a protracted period, thus inducing a genuine artificial coma. In the progress of eclampsia the tendency is always towards coma. Hence, I regard it a principle in the treatment of this disease that all things should be avoided which tend in that direction. Nevertheless, anæsthetics are of infinite value in the treatment of convulsions. I find that they act best when used just in the beginning of each convulsive seizure in sufficient quantity to abort the paroxysm. If given much during the intervals, in my experience they increase the tendency to coma, and pushed to the extent of increasing this tendency, the effect becomes dangerous.

Some of the best successes which I ever had were before the introduction of anæsthetics in the treatment of this disease. It is desirable, if possible, for the mental faculties to emerge from each paroxysm lucid and clear. Chloroform in moderate quantities modifies reflex action and controls spasm. But in larger quantities frequently given it destroys all consciousness and impairs the recuperative energies of the brain, endangering the respiratory and vaso motor centres. Chloroform does not eliminate the poison urea, the prime cause of the trouble, from the system. Neither does it reduce arterial tension, blood pressure, and the tendency to congestion and œdema. I have seen eclampsia patients die from coma under chloroform treatment, with all the symptoms of congestion and blood poisoning. As a sedative in eclampsia I have found chloral a valuable agent when given in drachm doses *per rectum*. I regard it as a more efficient anti-reflex agent than chloroform when combined with the bromides. It does not depress the respiratory and vaso-motor centres as chloroform, and is very efficient in controlling reflex action, and gives time for the operation of more permanent remedies.

The object of anæsthetics, anodynes, and sedatives in puerperal eclampsia is not to depress too much the vital powers of the brain or the medulla, so as to endanger the faculty of consciousness and function of respiration, but to suspend for a time the reflex functions of the cord, which from some unexplained reason are thrown into an inordinate state of erethism in puerperal nephritis. Just how this very desirable object can be attained is a matter of exceeding interest and importance. The wonderful developments in our knowledge of late of the therapeutic and physiological actions of remedies on the nervous system, I am satisfied will point to us a way. I am sure that this end has been accomplished in my own practice.

Thus, to be able to strike that happy medium in our practice which can relieve disease without inflicting injury, is a fortunate attainment. For some years past it has been my method to give moderate quantities of chloroform in the beginning of and during the paroxysm, and then permit the patient to rest. This proceeding will usually abort or modify greatly the attack. In seeking for a sedative agent of great anti-reflex powers without action either over the powers of consciousness or sensibility, probably *veratrum viride* stands foremost. This drug, while exerting a wonderful influence over the vaso-motor system,

slowing the action of the heart, reducing arterial tension and blood pressure, is also equally active in controlling the reflex power of the cord, which under these circumstances has lost all powers of inhibition. With chloroform given in this way, chloral and the bromides, and veratrum, I believe we can so manipulate these agents in these cases as to suspend reflex action without the induction of coma or arresting the respiratory function.

These potent agents in eclampsia constitute our brakes to arrest the uncontrolled and unregulated machinery of the nervous system, and once more bring it back to methodical working.

I can say here, in all truth, that in numerous instances in my experience where the above mentioned principles had been judiciously applied, where the system had been prepared by depletion and cathartics, mercurial and otherwise, the convulsions, however violent, and the coma, however profound, have yielded, consciousness and perfect sensibility have returned, and the case being left to the powers of nature to finish the delivery. Furthermore, in relation to the action of veratrum, it regulates the unbalanced circulation, and in this way relieves engorgement and active congestion. The tincture of veratrum I find in these cases is given with greater advantage hypodermically in 10-drop doses every two or three hours until the object is accomplished.

Ergot.—In my first six cases of eclampsia, after complete relaxation of the os uteri and perineum had been secured by depletion and cathartics, and the foetal head had descended into the cavity of the pelvis, ergot in infusion was given in large doses per rectum to complete the labor. In all of these cases the results were favorable, the labor being speedily and easily terminated. Under the circumstances, I believe the practice not only right and proper, but good, as proved by the results. I observed then the favorable action of the ergot on the nervous centres, as a sedative on the reflex powers, and as an agent to lessen hyperæmia, a therapeutic property of ergot then unknown, but now well established. I observed that while the pains of labor grew much more forcible and frequent, the congestive symptoms of the cerebral circulation diminished, and the patient became more conscious.

Under similar circumstances I would not hesitate now to administer the ergot for the purpose of terminating the labor, with the expectation, also, that the therapeutic action of the remedy would diminish cerebral congestion and reflex action, and in this way relieve the brain. I therefore cannot otherwise regard this drug than as a valuable adjuvant to our therapeutic armamentarium in the treatment of this affection.

Instrumental Delivery.—There are cases of labor in which no treatment seems capable of accomplishing relaxation of the os uteri, while the head remains above the brim of the pelvis, and in which the labor pains are totally inefficient, while the eclampsia symptoms are not modified or relieved by treatment. Prompt and speedy delivery here becomes our only resource. The only question under these circumstances to decide is the safest and best method. Happily, we now possess instruments which were

formerly unknown, that are capable of accomplishing complete dilatation in these cases with safety to the patient, when the forceps can be applied under anæsthesia.

The instrument which I prefer is the Molesworth dilator. It is easily managed and is adapted to all cases. I find it admirably adapted to the dilatation of the os uteri for removing the dead foetus or retained secundines in abortion. Thirty years ago I attended the case of a very large and robust young female slave in her first labor, in which there existed a perfectly impacted head, and notwithstanding the pains were frequent and violent, there was no progress. In this condition of affairs the patient was seized with a fearful attack of convulsions. I am sure it was the most violent attack which ever came under my observation. The nurse informed me that she passed through 120 paroxysms. Copious depletion, purgation, and mercury with tinct. of veratrum to reduce the high arterial tension and control reflex action, succeeded in subduing spasm. Delivery by means of turning and the forceps was attempted, but failed. I finally succeeded in delivering the woman by means of the vectis of a dead child weighing sixteen and a half pounds. I should have mentioned that in this case there was absolute suppression of urine, as none could be found in the bladder. This fact is of interest, and shows conclusively that the life of the patient was saved through the active eliminatory treatment to which she was subjected. Though in labor forty-eight hours, with suppression of urine for twenty-four, the kidneys began to act after the mercury and veratrum had made their specific impression on the system. Though somewhat salivated, the patient made a satisfactory recovery.

I regard this case as a fair example of what can be accomplished for the relief of these cases of eclampsia with profound coma and suppression of urine. The establishment of a copious drain of effete matters through the intestinal canal by means of cathartics acts as a vicarious discharge in place of the secretion of the paralyzed kidney. I will make a passing allusion here to a condition that occurs in the progress of bad cases not unfrequently. It is characterized by great prostration, excessive frequency and fullness of the pulse, cold extremities and pallid complexion, and either great restlessness or stupor. I have found no remedy to act so favorably in reëstablishing reaction of the depressed circulatory and nervous powers as tinct. of belladonna in 10-drop doses, given either with $\frac{1}{8}$ of a grain of morphia to correct restlessness, or without it when contraindicated, every two or three hours.

With the design of illustrating more clearly the foregoing views relative to the pathology and therapeutics of eclampsia, I will cite briefly the history of certain cases:

Case 2.—This, the second case which came under my observation, occurred in the year 1852. The subject was a young married woman remarkable for her vigorous and healthy physique and fine constitution. She was attacked with violent eclampsia in the very beginning of labor, and soon lapsed into coma. The convulsions were both rapid and pro-

longed in duration. The os uteri was rigidly contracted. The urine was scanty and almost suppressed, but was not tested, as at that period not much importance was attached to that question. Our knowledge of the relations of eclampsia and nephritis was exceedingly crude at that time. The pulse of this patient was frequent, very firm, hard and full. The temperature was above the normal standard. Acting on the principle that this state of the circulation endangered the brain, twenty-four ounces of blood were promptly abstracted from the arm. This procedure modified the intensity of the symptoms manifestly, and afforded partial relief to the oppressed brain. Calomel was then administered in 10-grain doses every two hours until it acted on the bowels moderately. This was followed by 1-drop doses of croton oil every hour until most copious purgation was obtained. The convulsions were now in great measure subdued, but partial coma continued. At this stage there was complete relaxation of the os uteri, the pains were regular, and the foetal head had descended to the cavity of the pelvis. With the design of facilitating labor the infusion of ergot was given per rectum, with the effect of terminating it speedily, and relieving the existing coma. In a few days moderate salivation ensued.

I will mention here the manner in which the kidneys responded to the mercurial influence. When the mercury began to act as a cathartic the renal functions also began to return and continued to improve, notwithstanding the patient was laboring under salivation.

Case 25.—This case is presented here because of its analogy in every respect, in features and treatment, to case No. 2. The patient was a young married woman with her first child. She was pale, rather anæmic, and anasarcaous. The urine contained 60 per cent. of albumin. The first dilating pain ushered in a most violent and prolonged convulsion, which left the patient in deep coma, with stertorous breathing and intensely swollen face. The paroxysms continued every thirty minutes. The pulse in this case was strong, bounding and rapid. The temperature was 102°. After attempting to subdue the convulsions by means of chloroform without success, blood to the amount of twenty-five ounces was abstracted. This speedily abated the violence of the case. Calomel was then administered in 20-grain doses every three hours, in combination with 2-drop doses of croton oil, until copious purgation was secured. In the meantime 10-drop doses of tinct. of veratrum viride were also given every three hours. The only hypnotic which the patient took during this time was 2 scruples of chloral by enema.

The combined action of the cathartics and veratrum very promptly controlled spasmodic movements, relieved the brain and restored consciousness completely. Such was the favorable condition of the patient now, there being complete relaxation of the os uteri and perineum, the foetal head rapidly advancing, the case was left to the powers of nature to finish, which they did satisfactorily. The mercury and depletion, as in the former case, tended decidedly to promote the renal secretions and relieve engorge-

ment of the kidneys. I cite this case as an example of the powers of depletion, purgatives, mercury as an alterative, and veratrum viride in controlling reflex action, subduing spasm, relieving coma, restoring consciousness after twenty-three violent convulsions, and enabling the patient to pass through a perfectly natural labor with ease. This is the last case which came under my observation.

Case 12.—Mrs. C., a young married lady in her second pregnancy, at term was attacked, while asleep in the night, with violent convulsions, and immediately passed into a comatose condition. The pulse was frequent and rather hard. There was almost total suppression of urine. The small quantity found in the bladder contained a large proportion of albumin. After a very moderate bleeding, chloroform was used almost exclusively to control the convulsions, by the advice of a medical friend. Finally, while the spasmodic symptoms ceased, profound coma ensued, in which condition she was delivered with forceps. The patient died without having recovered consciousness. I believe if the patient had been subjected to the cathartic and alterative mercurial treatment similar to the former cases, the result might have been different.

Case 7.—This case occurred in 1857. The patient was a very robust young female slave in her first pregnancy. She was attacked with violent convulsions during the stage of dilatation. The pulse was firm, full and frequent. There was considerable increase of temperature. The comatose symptoms were continuous. The urine was exceedingly scanty. The os uteri was rigid and undilated. Twenty-five ounces of blood were abstracted, with very decided amelioration of the symptoms. One scruple of calomel was given every two hours until it acted copiously as a cathartic. These measures not only relieved the high degree of arterial tension, but caused complete relaxation of the os uteri and perineum. The foetal head having descended into the pelvis, ergot in infusion was given per rectum, which speedily terminated the labor.

The patient recovered consciousness while under the influence of the ergot. I regard the results in this case as a further vindication not only of the value of the eliminative treatment in eclampsia, but also of the good effects of ergot on the nervous centres and as a parturient in these cases. The mortality in all the cases treated amounted to one in five.

PUERPERAL FEVER, AND THE EARLY EMPLOYMENT OF ANTISEPTIC VAGINAL INJECTIONS.¹

BY GUSTAV ZINKE, M.D.,

OF CINCINNATI, OHIO.

In bringing up this subject, I do not intend to enter into the details of puerperal fever, but simply to consider the value and necessity of antiseptic, or, simply, warm water injections, as recommended for prophylactic purposes in normal cases of labor oc-

¹ Read in the Section on Obstetrics, at the Thirty-Seventh Annual Meeting of the American Medical Association.

curing in private practice. Let it be well understood that my remarks shall apply to this class alone.

The basis of this paper is the report of a case that occurred in my own practice last fall, and which I consider a very interesting one with regard to cause, symptoms, and course.

Mrs. —, æt. 26, American, small in stature, well formed, was at the end of the eighth month of pregnancy. The progress of gestation up to that period was without an untoward symptom, and indeed, the patient enjoyed better health during that time than ever before. Previous to this period of pregnancy, she was under my professional care for about a year, for treatment of ulcers of the rectum, rectal abscesses and retroflexion of the uterus. There also existed old pelvic cellulitic deposits posterior and to the left of the womb, which made the repeated manipulations (necessary for the replacement of the body of the womb) exceedingly painful at the time. She had had one miscarriage, which occurred about a year or so before she came under my care. She, as well as her husband, is inclined to date the uterine displacement from the time of said miscarriage; and further, it seems that the physician who then attended her discovered some abnormal features at the time from which, as he predicted to the husband, his wife "would have any amount of trouble in the future."

During my last visit for the purpose of replacing the womb, I found the introduction of the sound impossible, and all efforts at reposition had to be abandoned, owing to an increased tenderness that portended an attack of cellulitis. For quite a period following this last attempt, the treatment consisted merely of frequent and copious hot water vaginal irrigations, while rest and a light nutritious diet only were prescribed. From this time forward there was a steady improvement in her condition.

Some time in February, 1885, she became pregnant. During the period of gestation she made a ten weeks' trip through the West, and returned in apparently better health than she had enjoyed for years. At the end of the eighth (calendar) month she was delivered of a well-formed, healthy female child. The immediate cause of her premature confinement may be surmised from subsequent events.

On October 27 she had been up and about as usual, and in the evening went with her husband to an entertainment. On her return, although quite well, she began to feel steady, bearing-down pain, which continued to increase slowly but persistently. I was called to her bedside about 2 A.M. October 28. With the symptoms just described and the knowledge of advanced pregnancy, I suspected that labor had set in. Examination readily revealed that the womb was pushing into the true pelvis; the cervix was still closed and of considerable thickness, but flabby, and readily admitted the point of the index finger.

What was to be done to prevent premature labor? Give ergot to cause contraction of the os? I decided, no. If labor should proceed notwithstanding, unpleasant complications might be the consequence. So I determined to do, what I had often done successfully before, namely, to give small but often repeated doses of codia and chloral hydrate. The

former for the relief of pain, the latter to produce sleep. The following prescription was given:

R Chlor. hydrate..... ʒ i
Codia sulph..... gr. i
Syr. simple.....
Aque menth. pip..... aa ʒ iss

M.S.—Two teaspoonfuls in half tumblerful of water every hour until relieved.

Two hours later I was again summoned, and on my arrival, upon investigation found the os dilated to the extent of a silver dollar; membranes intact, pains natural and occurring every three or four minutes. Child in the first vertex position, and living. Labor progressed favorably until about nine o'clock the same morning, when she was safely delivered, without an accident either to herself or child. The only aid rendered was:

The rupturing of the membranes when the os was fully dilated; the administering of chloroform during the expulsive pains; the tying and severing of the cord; the delivering of the placenta (which followed spontaneously, and almost immediately after cord was severed); the washing of the external genitalia; the applying of moderately tight bandage, and in rendering the patient comfortable in bed.

In all respects the labor was a most natural (though premature) one. Having assured myself that the nurse in attendance fully understood the manner and comprehended the importance of keeping the patient and the bed clean, I left, to return the same evening.

At 6 P.M. of the first day, October 28, patient had rested well and felt first rate, only complaining of slight after-pains.

October 29.—She had a good night; passed urine freely; was without pain; lochia natural in quantity and quality; after-pains not annoying; the patient in a cheerful frame of mind.

October 30, 9 A.M.—Stated that she felt well; was almost free from after-pains; lochia free and inoffensive. Temperature 98.5°. Pulse 90. At 7 P.M. I was informed that she had a chill lasting one hour (4 to 5 P.M.) T. 106°, P. 130; no pain worthy of mention anywhere; abdomen soft and not particularly tender, being sensitive only to deep pressure over uterine body; lochia free and inoffensive as before. Ordered 15 grs. of quinia and ¼ gr. of bimeconate of morphia. Nine P.M. she had another chill lasting half an hour. T. 107.5°, P. 150. She complained of pain in left inguinal region, which was sensitive to palpation; per vaginam a slight swelling and doughiness was detected with difficulty. An additional dose of 22½ grs. of quinia was given, and Prof. Palmer was requested to see her in consultation. His thermometer agreed with mine (107.5°), but he was unable to count the pulse. He gave it as his opinion that the chill and fever were septic in origin, probably there was something within the uterus; advised continuance of quinine in large doses, also hot water antiseptic injections, and if temperature did not quickly fall from these means, to wash out the uterus.

From the fact that the patient had passed through a perfectly normal labor and without injury to her-

self, and because the lochia was not suppressed and still inoffensive, and because she was in such extreme physical and mental misery, I demurred against uterine irrigation. I felt sure the trouble was not within the uterine cavity, for never did I see the secundines follow so perfectly and easy as here. We however concluded to await the results of the quinia and the vaginal injections previously administered; and determined that should the temperature not yield to the remedies employed, uterine irrigations were to be made; until then, 10 gr. doses of quinia were to be given every four hours to prevent a return of the chills, and to reduce, if possible, and to keep down the temperature.

October 31, A.M., T. 101.5°, P. 126. No pain, slept most of the time. 7 A.M., T. 103.5°, P. 116. 8 P.M., no pain, T. 104.7°, P. 102. Quinia 10 gr. continued every four hours. Lochia free and inoffensive as usual; copious carbolyzed injections of hot water repeated every four hours.

November 1, 8 A.M., T. 101°, P. 95. Bowels acted twice spontaneously. No pain, lochia uninterrupted and natural; abdomen tender to deep pressure only. Her breakfast consisted of a few sups of coffee and small portion of graham meal. Dinner of chicken-broth and milk toast. At 8 P.M., T. 101°, P. 78. Quinia was discontinued.

November 2, 8 A.M., T. 103°, P. 88. Diet during preceding twelve hours, two egg-nogs and a glass of lemonade with ½ oz. of brandy. During the day she called for and received a piece of tenderloin, a roll, a piece of bread, and one and one-half cups of coffee. There was still slight tenderness in the hypogastric region on gentle pressure and when she moved. Lochia diminished, lighter in color and free from odor. Expressed herself as feeling better. Digital examination revealed slight swelling and tenderness to the left and front of the uterus. Patient being averse to quinia, I ordered 2 gtt. of the tr. verat. vir. in two teaspoonfuls of brandy to be given every hour; continued the application of warm cloths over abdomen, and copious, carbolyzed warm water injections. 8 P.M., T. 105°, P. 83. Skin hot but moist. Felt no pain. Lochia almost white in color but normal in quantity and not offensive. Patient, much against her will, took another 10 gr. of quinia and the tr. verat. vir. with brandy was also administered during that night. At 10 P.M., T. 104.5°, P. 110. Although I was certain that the cause of the high temperature was not within the uterine cavity, as first suggested by Prof. Palmer, and in order to protect myself and satisfy the friends of the patient, I washed out the uterine cavity with the use of a reflux uterine catheter, with warm carbolyzed water. This was followed by some pain, but there was no decline in the temperature, neither was there a removal of anything that might be suggestive of trouble in that organ. This was done but once.

November 3, 8:30 A.M., T. 101.4°, P. 90. Patient slept during the night. Abdomen soft, tender only on deep pressure; had a natural stool. During the day she received, at proper intervals, a little coffee with toast and part of a baked apple. At 2 P.M., she complained of a slight chilly sensation. T. 104.2°,

P. 100. Absolutely refusing to take any more quinine, administered only the warm applications, the tr. verat. vir. (gtts. 2) every hour, and hot carbolyzed injections were continued. At 9 P.M., T. 104.2°, P. 108. A free, loose, but somewhat painful movement of the bowels at 8 P.M., one at 2, and another at 4 A.M. in the morning.

November 4, 8 A.M., T. 103.2°, P. 116. Patient had a restless night. Phys. exam. revealed a movable and painless uterus; the swelling and tenderness in the left inguinal region hardly noticeable. Continued the poulticing and to aid her digestion, to the want of which I attributed the diarrhoea, gtt. 5 of diluted hydrochloric acid after eating. At 5:30 P.M., T. 105°, P. 110. Her food during the day consisted of ½ glass of egg-nog and an equal amount of Hof's Malt Extract. At 10 and 7 P.M. she had several watery stools of brown color, each preceded by griping pains. To stop both pain and stools I gave ⅙ gr. of morph. sulph. hypodermically, for the fever 30 gr. of salicylate of soda. At 9 P.M., T. fell to 100.2°, P. 104, and she expressed herself as feeling much better.

November 5. Patient slept well during the night, had had no stool since last visit, and had partaken liberally of egg-nog, milk and malt, when awake. 8 A.M., T. 103.2°, P. 115, another 30 gr. dose of salicylate of soda. Breakfast consisted of ½ cup of coffee, a small bit of tenderloin, milk toast, and baked potato. Had a good day; no pain. Injections and hot external applications continued. Lochia had ceased, the water being returned from vagina almost as clear as before being used. 7:30 P.M., T. 103.6°, P. 124. Salicylate of soda gr. 30.

November 6. Patient passed the night fairly. 9 A.M., T. 103.4°, P. 118. Appetite not so good as day before, therefore stopped the use of salicylate of soda. Abdomen flat and soft, painful to deep pressure over hypogastric region; local condition about the same as at the last examination. Diet consisted only of milk, egg-nog and Hof's malt. 8 P.M., T. 104.8°, P. 150. Took again 30 gr. of salicylate of soda, which reduced temperature to 102.2°, P. 118 in one hour and a half.

Comparing the local manifestations with the range of temperature and pulse, I became daily more convinced that the malady was not of a local character. Of course there were physical signs of pelvic cellulitis, but they were not present in the beginning, nor did they ever assume a serious nature. Indeed, the cellullitic condition diminished while the temperature and pulse continued high, having a distinct morning remission and evening exacerbation. From the first I held and never could free myself from the thought, that some element other than septicæmia, through the parturient canal, was the active agent in the production of the disease; that possibly, nay probably, the body had been invaded sometime prior to her confinement and that labor simply precipitated its onslaught on the system.

What could it be? Was it typhoid or remittent fever? If the former, it lacked the characteristic diarrhoea, rose-spots and stupor, although the patient slumbered more during the later stage of illness

than before. This I attributed, however, to the repeated doses of salicylate of soda; neither were the early symptoms of the disease like those of typhoid, though at this time I was informed by the husband, that about a month prior to her confinement the patient had complained of languor and chilliness, for which, several times she requested some quinine, but received none. Was it then remittent? In all probability. Had all the symptoms described (with the exception of those within the pelvis) occurred previous or after the lying-in period, it would have been diagnosed as such, by any physician who has had the opportunity of observing this affection, as it occurs in this part of the country. But the consultant had not fully concurred with me in my view of the case. He admitted that there might be some malarial complication, but that the main cause was sepsis.

On the morning of the 13th of November, the seventeenth day after confinement, temperature had fallen to 99.5°, P. 105. Digital examination revealed nothing new, only that the swelling and pain were

Returning in the evening I learned that the patient had refused to receive the injection as well as the external applications of iodine. Under the circumstances I concluded to retire from the case, and left with the request to send for another physician.

During the eleven days following my last visit, the temperature and pulse only were recorded by the husband. The first six days the patient was without a medical attendant, and then another physician was called in. Although I had requested the husband to see that a record be kept throughout her illness, it was not done. She continued to be sick for some time, the patient dining for the first time thereafter, at the table on Christmas day. Duration of disease: Two months.

The questions that present themselves for consideration are:

1. Was this a case of puerperal septicaemia, remittent fever, or something else?
2. Whatever it was could it have been avoided by the early use of antiseptic vaginal injections?
3. To what extent is the use of antiseptics, scien-

less than when last examined. But the same evening, the temperature rose again to 104.8°.

The next day, November 14, it was 101.4°, P. 115, and still rising. I felt that something must be done to control this ever recurring high temperature. Another consultation with Prof. Palmer was held. He again examined the patient and gave it as his opinion that the trouble was principally of local origin, and the result of sepsis with an intercurrent cellulitis, and that, probably there was some malarial complication. He strongly urged resort to quinine, and if the patient refused to take it, to give the bisulphate clandestinely per rectum; he also advised externally tr. of iodine, to continue the hot water vaginal irrigations, and to observe a light nutritious diet.

tifically and practically, justified or necessary?

In my opinion it was not a case of septicaemia in which the poison entered the system through the parturient canal. Those who have followed carefully the report of this case will bear me out in this statement. If the disease was of septic origin at all, the point of production and its entrance into the system was not in this avenue, but was rather to be found within the old cellutic remnants in the parametrium, or the attenuation and tearing of a still existing rectal ulcer, or, possibly, to a hearth of encapsulated dried-up pus within the perineal body or around the rectum, the result of anal fissures and rectal abscesses, from all of which the patient had suffered not only during gestation, but for quite a time previous to that period. But from the course the fever took, and from the fact

that the temperature receded invariably after the administration of quinine, I was inclined to believe that it was malarial in character; and this view was further sustained by a knowledge of the fact that, during her pregnancy, the patient made a long trip through the West, sleeping many times upon the ground without shelter. Besides, there were positive malarial manifestations in the case a month prior to confinement.

If we are to accept that a continued fever, occurring, no matter from what cause, during the lying-in period, is invariably to be denominated, puerperal fever; then of course all further discussion is unnecessary. But it seems to me, that puerperal fever *per se*, should admit of and embrace no disease other than one that can only occur during the puerperal state, proper. At present, however, it may mean septicæmia, erysipelas, measles, diphtheria, malaria, indeed any acute disease that may find its way into the system, and manifest itself during the lying-in period and being masked by it. Since it has been satisfactorily proved to most modern writers and teachers, (and practical experience only serves to encourage this view) that some, if not all acute infectious diseases may be productive of puerperal fever so-called, it behooves us to differentiate well before we pass judgment upon what has caused its occurrence in each particular case. In this instance after a careful examination into the history of the patient, and the cause of the disease, it is my opinion that nothing but a clear case of intermittent fever can be made out of it; the pelvic pain and swelling by it, and, possibly, the previous existence of pelvic cellulitis. At times it may, and in this case it did, become a serious question whether or not, the appearance of this unpleasant complication could not have been avoided by certain so-called precautionary measures. If, for instance, a case of puerperal fever occurs in consequence of septic absorption through an injured parturient tract, as for example a lacerated cervix, vaginal vault, or perineum (be it in consequence of a natural or artificial labor), or that portions of the placenta, or of the membranes were left behind, the physician in attendance might, in a measure, be held responsible if he failed to employ antiseptic washes. This, too, would hold good in cases where there is a suspicion of gonorrhœa by the presence of an ambiguous discharge prior to delivery.

I am well satisfied that all those cases of puerperal fever, which find their inception in an external cause through the obstetric-channel, may, to some extent, be successfully mitigated or prevented by the early and frequent use of vaginal antiseptic injections. On the other hand, however, diseases like scarlatina, measles, diphtheria, etc., which find their way into the system through other avenues, and which perhaps have existed within, prior to labor, may be precipitated by the event, and thus, suddenly make their appearance in the form of so-called puerperal fever where it was least expected.

The practitioner thus surprised, may not, in the beginning, recognize the true origin of the trouble. His first thought will be that the genital organs are the seat of the difficulty. He will, in all probability,

be led to believe that there alone is the cause, and, indeed, his suspicion may become strengthened by the presence of pain and the swelling in and around the uterus and the vagina. He may forget, too, for the moment, that in all cases in which puerperal fever is due to the presence of a malarial or an erysipelatos, or a scarlatinal poison, the symptoms may be like those caused by septic abortion through the parturient canal. This certainly demonstrates that, while there is hardly any doubt that the seeds of any of the infectious diseases find the puerperal patient a fruitful soil for their multiplication and reproduction, we are not always able to trace them to their true origin. In the case just reported, I feel justified in the belief that nothing could have been done at the time of confinement or immediately following, that would have averted the attack. I firmly believe in the preventive value of antiseptics, but to a certain extent only. Antisepsis in normal cases of labor need and ought not mean anything except:

1. Ordinary cleanliness throughout and in every respect.

2. The avoidance of frequent examinations and unnecessary aids; needless exposure in supporting the perineum (which, after all, is a doubtful procedure), as well as during the tying of the cord, the delivering of the placenta and process of washing after completion of labor.

To wash out the vagina (to say nothing of the uterus) immediately after normal labor, is, in my opinion, meddlesome midwifery, and ought to be pronounced as such. It does not benefit the patient, it prevents nothing, and may do harm. In prolonged or in instrumental delivery, in cases where the whole hand must be introduced or otherwise injuries of a serious nature sustained, vaginal injections are always, but uterine injections rarely, indicated, because the conditions are different from those in which labor proceeded normally. In the former, we deal with open, raw and sometimes gangrenous surfaces, and have a patient more or less exhausted. In the latter, nothing, except that the patient has suffered a great deal of pain, which was perhaps even mitigated by the use of chloroform. There are no broken surfaces, indeed, nothing but what ought to be there. What do you think of putting pledgets of absorbent cotton steeped in a carbolized or other antiseptic solution, into the vulva, and the placing of an antiseptic cloth over the vulva, as a means of prophylaxis? It is my honest conviction that such practice as this is not the fruit of practical experience, nor was it invented by necessity. To-day, when one new measure or remedy succeeds another, when so many are ever ready to announce something new (?) and, being announced, as many, if not more, are ready to improve and add to the new discovery, the perplexity in which the practitioner is placed at times in consequence, is occasionally not only annoying to himself, but it casts a shadow upon the profession at large.

My limited time does not permit me to speak *in extenso* of the ill-effects of vaginal irrigations that have occurred after natural labor. Therefore in brief, only a few references:

Dr. John Cleveland¹ reported a case to the Cincinnati Obstetrical Society, in which death occurred twenty-four hours after the use of a vaginal warm water injection. This patient was apparently doing well, and the injection was employed simply from a sense of duty on the part of the doctor. Almost immediately after the injection was made a severe pain supervened, and could not be subdued even by repeated injections of morphia. The abdomen became tympanitic, the temperature rose until it was 104 in the evening and 108 the next morning. The patient died, notwithstanding all the efforts that were made to save her life.

Dr. G. Frank Lvdston² read an interesting paper May 5, 1884, before the Chicago Medical Society, on "Puerperal Septicæmia and the Prophylaxis of Puerperal Inflammations," in which he cites and reviews the records of the Charity and Maternity Hospitals of New York. "After comparing the different modes of treatment and their results, he clearly demonstrates that the mortality rate, as caused by septicæmia, is more than one-half less when vaginal injections were not allowed than when they were employed. Later on he states that he has seen the temperature rise and pelvic inflammation follow the use of frequent vaginal injections; and cases which may eventuate in puerperal septicæmia or lead to fatal issue would often do well and make perfect recovery if left alone, kept free and quiet from curious visitors. As for prophylactic intra uterine injections, he further says, the man who uses them will sooner or later come to grief in making too general use of this procedure. In speaking of his experience in the New York city hospitals, where the non-interference plan was practiced in obstetrics, the death-rate from septicæmia was at a minimum. Subsequently 'reform' was introduced in the way of prophylaxis and complicated manipulations, with the 'direct and immediate effect' of increasing the mortality rate, which became alarmingly high. Simultaneously, upon Ward's Island, there were present a large number of Russian-Jewish refugees who were physically filthy and mentally despondent. Upward of ninety of these women were delivered without death. There were numerous forceps deliveries, but there was absolute non-interference in the after-treatment. Here was a good opportunity to compare fancy mid-wifery results with the let-alone method."

Dr. J. K. Bartlett,³ in his admirable annual report of 1883, when Chairman of this Section, in speaking of antiseptis in private obstetrical practice, says: "None of these prophylactic measures seem necessary in cases of uncomplicated labor, and some of them are absolutely dangerous. Intra-uterine injections are especially so regarded, and the use of carbolic acid solution into the vagina have not always been harmless."

I admit that many times the fault may lie with the individual who makes these injections. But this charge should not be made general, for surely it does not require a very high degree of education and skill-

fulness to carry them out properly. Therefore the charge (made by those who apply antiseptic injections in every case) that the trouble, arising in certain cases, is due to this cause alone, is certainly not tenable and seems to be a poor excuse. The ground which I am taking is sufficiently supported by high medical authority, and justifies the conclusion at which I have arrived.

In conclusion, I wish to state that out of nearly 400 labor cases attended by me, the one just submitted to your consideration is the first that would come under the term, puerperal fever (if such it shall prove to be in your opinion). I have seen a number of cases of puerperal septicæmia, but none of them were under my care as physician in charge during labor. They occurred principally in the hands of midwives, and in a few cases in which I was called in consultation. In the early part of my professional life I invariably used antiseptic injections whenever I had the time to make them myself. My practice called me largely among the poorer class of people, who could not pay for a syringe or drugs, and, occasionally, even when able to supply these they obstinately refused to go to the expense. Speaking from experience and with a typical kind of good sense, they declared that "it was all nonsense, they had never heard of such a thing before." To my surprise all these cases, though frequently abnormal and complicated in character, did well, and, I must confess, some even better than those in which antiseptis was rigidly carried out.

Notwithstanding, according to precept, I insisted upon vaginal injections whenever and wherever it was possible. Suddenly, about three years ago, I observed for the first time the ill-effect from the use of a fountain syringe. Half an hour after the injection, though not the first one nor immediately after the termination of labor, pain supervened—and such pain! Whoever has seen a case of uterine colic will know what that means. One grain of morph. sulph. subcutaneously was necessary to subdue this patient's agony. In the course of the same year I had two other similar experiences. The last occurred in a case in which I took particular care that all should be done properly. Everything progressed favorably; the first injections were used on the fourth day after labor. The ill-effects followed as quickly as related in the first case, but the suffering was much more intense. The patient moaned piteously and with her hands firmly pressed upon the abdomen, she reeled from side to side, crying and begging for help in the most heart-rending tones.

Now, since we have as a result of carefully employed antiseptic injections such scenes of suffering and even fatal results, is it not uncalled for and wholly unjustifiable to resort to them in normal cases of labor?

ON TRACHOMA.¹

BY ADOLF ALT, M.D.,

OF ST. LOUIS.

This paper will not startle you by many new points, as it seems to me that at every such a gathering of men working in the same branch of the healing art, we should exchange our experiences in the healing of the more common affections, and that our time is better spent in such discussions than in relating some very interesting but rare cases.

Let us first recapitulate some of the histological points of the normal and trachomatous conjunctiva. The normal human conjunctiva is made up of typical adenoid tissue (and especially so in the part which is called the fornix), and of a fibrous and an epithelial layer. The surface of the conjunctiva shows numerous minute folds, elevations and indentations. The adenoid tissue and these folds (according to Ræhlmann) are formed in the second and, respectively, fifth month after birth. The adenoid tissue does not contain any lymph follicles, although this has been asserted by some authors. Yet it is full of larger lymphatic spaces and blood vessels.

The following is the condition of the trachomatous conjunctiva, as I have studied it on numerous pieces taken from the living subject: The adenoid tissue is thickly crowded with lymphatic cells. This cell infiltration is, however, unequal in density, and here and there in every microscopical section we find places where the cells are aggregated in larger numbers; this is what has been called the trachoma follicle. The trachoma follicle, then, is a roundish, oval or pear-shaped aggregation of lymphatic cells—a lymphoma, as we find it in other mucous membranes and in glandular tissues, as the liver, the kidneys, etc., in the shape of miliary lymphomata. The cells seem to be more numerous and more closely pressed together at the periphery of the follicle, and they are less densely packed in the central portions. The follicle has no connective tissue coat of its own, and is therefore not analogous to the lymph-follicles of the intestinal tract, but in its growth it presses the fibres of the conjunctival tissue aside, and the thus condensed conjunctival tissue has been mistaken for the coat of the follicle. In the central portions of the follicle we may sometimes see a net-work of thin, pale fibres, and the cells in these portions are often apparently larger than the more densely packed peripheral ones. Even in the peripheral portions a small amount of intercellular substance may be detected in very thin sections. It has been stated that the peripheral cells of the follicle are gradually transformed into spindle-cells and fibres, and that in this manner a continuous membrane enclosing the follicle might be formed. I cannot deny the possibility of such an occurrence, yet have failed thus far to see it in my specimens. Finally, the cells of the follicle may undergo a regressive metamorphosis, so that instead of the follicle we find a grumous mass of detritus, or they may be transformed into connective tissue, or be absorbed. The follicle is often found to

contain blood-vessels; sometimes they are wanting. Enlarged lymphatic canals are usually found in its neighborhood. The pressure of the follicle may cause the epithelial layer which covers it to undergo a fatty metamorphosis and to be cast off. In this manner a superficial ulceration may result, and then the contents of the follicle can easily and spontaneously be evacuated. In the process of healing of these ulcerations sometimes polypes, and usually small scars, are formed. The follicles, furthermore, may be so numerous as to press each other, and several of them may thus sometimes be found to have merged into one.

During the progress of this disease the adenoid tissue of the conjunctiva gradually loses its function and is destroyed. In microscopical sections of trachomatous conjunctiva epithelial formations are frequently seen in the depth of the tissue. These have been described as true glands newly formed within the conjunctiva, and their formation has been considered a characteristic symptom of trachoma. It seems, however, to be established beyond a doubt that we have not to deal with new-formed glands, but simply with the epithelial coat of the numerous indentations found even in the normal conjunctiva, the cells of which are perhaps stimulated to hypertrophy by the inflammatory process, and are displaced by the irregular swelling and infiltration of this membrane during the progress of the trachoma.

I may state here that the histological conditions are the same in cases of solitary follicles, in follicular catarrh, and in trachoma, κατ' ἐξοχήν, although differing in degree. As you know, Sattler, then of Giessen, had thought he had found the micro-organism to which the disease under consideration is due, yet he acknowledged later on that he had been mistaken, and the peccant coccus may, perhaps, yet be detected.

I do not wish to go any further into detailing all the mischief which may be done by this disease to the cornea and the lids (since these things are too well known), nor into the question of the ætiology of trachoma. From the histological conditions in this affection, what would be the rational treatment? Theoretically it would appear, that to adopt nature's own course in the healing would be the best method; that is, we should either bring about the *absorption* or the *evacuation* of the trachoma follicles.

Absorption of the follicles may undoubtedly be brought about by a stimulating treatment. To this are due the unquestionably excellent results of a careful and prolonged treatment with sulphate of copper, the yellow or red oxide of mercury, or similarly acting substances. The treatment with such substances, applied with a view to *stimulate*, not to *cauterise*, will assuredly, as far as the trachoma of the conjunctiva is concerned, give the best possible results, and it may lead to a perfect *restitutio ad integrum*, when the disease has not as yet led to more serious secondary affections. It would, therefore, seem that in all cases in which no secondary changes have as yet taken place, the application of the remedies just named would be the best method of treatment. Empirically this has been found to be so, and this method

¹ Read in the Section of Ophthalmology, Otology and Laryngology, at the Thirty-seventh Annual Meeting of the American Medical Association.

is to this day the most generally used method in the treatment of trachoma. To shorten the process of healing which, as we know only too well, is still a very tedious and prolonged one, I have of late practiced excision of the most prominent portion of the conjunctiva, and I must say with a very happy result. The pieces which I removed are not very large, and the resulting scar is hardly visible. Yet the duration of the healing process has in all cases been very materially shortened, and no harm has been done to the patient. No doubt the bleeding, and later on the formation of the scar, act beneficially on the remaining tissue. The results which I have seen are such that I have adopted this partial excision as a method for the future, and can earnestly recommend it.

If the case be so far progressed that it is no longer to be hoped that we can bring about the absorption of the follicles, or if the secondary changes are such that in order to save the function of the eye, etc., the trachoma must rapidly be got rid of, what would then be the most rational method? Surely, again, what we have found to be nature's own, namely, the evacuation of the follicles. This is accomplished by different methods. There are several quacks in this city who cure the eyes which the best oculists have been "fooling with" for many months, and even years, as the people say, and what is their method? They apply a very strong caustic (nitrate of silver), paste, and thus cause the sloughing off of the whole surface of the conjunctiva, giving the contents of the follicles a chance to escape all at once. If this procedure did not endanger the function of the eye more even than the disease itself, it would be beautiful. Yet, in our Poor-House you can see the bad results, if you cannot see them elsewhere. Scientific men will not resort to such measures, and, if they do, they will at least guard the eye as such against all harm, if that can possibly be accomplished.

Another and decidedly better method for evacuating the trachoma follicles is to prick each and every visible follicle with a needle or knife, and to squeeze out its contents, and this may be modified by applying a strong caustic (say chromic acid) to the interior of the follicle. Both procedures seem to be good, yet the numerous scars which must inevitably result from such numerous, if ever so minute, injuries are, it seems to me, of decided weight in the balance against them.

A short time ago the excision of the whole of the fornix has been highly recommended, and this method has then by others been amended in such a way as to remove the whole of the tarsal conjunctiva and the tarsal tissue. If the excision of the fornix is complete, the conjunctival sac must become more shortened than is even sometimes done by the disease itself, and the originator of this method (Schneller) states himself that some of his patients could not open their eyes as well as before. On theoretical grounds, then, I should think we might not only expect good, but also very disagreeable results from such an evacuation in bulk of the adenoid tissue of the conjunctiva. The method of excising the palpebral conjunctiva and the tarsal tissue, I think, does

not need any consideration, as long as there are better methods.

There has been a good deal of theorizing done with regard to the good effects which have been empirically found to result from the inoculation of blennorrhoeal discharge, and, in more recent times, to the good effects of the application of jequirity in trachoma. As you know, Sattler, who invented the trachoma coccus, explained the effect of jequirity by the action of a jequirity bacillus, also of his own invention, who actually was to eat up the trachoma parasite. The beneficial action of these two agents, pus and jequirity, in trachoma seems, however, to be due: *first*, to the alterative effect which the violent inflammation, caused by both agents, must have on the tissues affected; *secondly*, to the constriction to which the follicles are undoubtedly subjected during this violent inflammation; and *thirdly*, to the fact that the epithelial covering is, during this inflammation, destroyed, cast off, and the contents of the follicles are thus spontaneously evacuated. It is to be pitied that both agents have rather bad effects on the eye-ball, otherwise their usefulness would be very much greater. I have never made use of the inoculation with blennorrhoeal pus, and should not do so now, since we have jequirity. The latter I use, in the form of dry powder, dusted on to the places where I want it more especially to act. I am satisfied that, cautiously applied in this manner, its action is less violent and less dangerous than it is with the infusion.

Without trying to praise a remedy simply because it is new, and without being very enthusiastic concerning it, I may further state here that in the later stages of the trachomatous process iodol seems to act quite nicely. I have used it in the shape of an ointment with cosmoline and lanoline.

MEDICAL PROGRESS.

SOME HYPNOTICS.—DR. S. G. WEBBER, of Boston, says: Several drugs have been lately given to the profession with the claim that they are valuable hypnotics. I have had an opportunity of testing these in the cases of many patients in the Adams' Nervine Asylum.

Paraldehyde has been some years in use. It has advantages over chloral. The immediate subsequent effects are less unpleasant. It very rarely causes headache on the next day; sometimes patients have a sensation of fullness or pressure in the head for a few hours after waking. I gave it in one case where the patient had been taking chloral in large doses, not measuring the dose, and had been injuriously affected by the drug. The paraldehyde gave, in this instance, better and more prolonged rest; the patient partially recovered his mental powers and some measure of strength. The paraldehyde was continued several weeks in nightly doses of 40 minims. In this patient there was probably disseminated sclerosis, and it did not seem possible to do without some agent to produce sleep, at least so long as he was at home. The chief objection to paraldehyde is

its disagreeable odor and taste, and also the odor it imparts to the breath. I do not remember to have met any unpleasant symptoms arising from its use; but had never seen a case in which it has been used habitually for a long time. The dose is from 45 to 80 or 90 minims; 60 minims is the average dose. Occasionally a dose of 80 minims has failed to give the sleep which I have desired to obtain.

Urethan came into notice later than paraldehyde; it is much more pleasant to administer, having scarcely any taste or odor. When I first gave it the dose was too small, but by increasing it to 30 grains good results were generally obtained. Sometimes much larger doses are necessary. It is quite soluble; 15 grains will dissolve in 1 drachm of water. The after effects are generally unimportant. It has seemed once or twice to give rise to nausea the day after; but often the patient says the sleep has been very natural and refreshing. It is not so sure to produce sleep as paraldehyde.

Hydrobromate of hyoscin has the advantage of being almost tasteless; and the dose is small. I began with a dose of one hundred and twentieth of a grain, as recommended by the articles I had read; but soon found this too small, and increased to a sixtieth of a grain, using the following formula, giving 20 minims:

R. Hydrobromate hyoscin	gr. i.
Alcohol.....	℥iss.
M. Aquæ g. s. ut fl.....	℥xx.

In a few instances I have given 25 minims of this mixture. There is so little taste to this that it can be given in some simple drink, as gruel or beef tea, without the knowledge of the patient.

In one patient it produced discomfort in the head the next day, so that after two trials it was given up and urethan given instead. In other cases the sixtieth of a grain given for a week or more has produced no bad effects. In a few cases it has failed to produce sleep, and the sleep secured in other cases has not been of so long duration as that usually produced by paraldehyde, but subsequently in these same cases the latter drug has not proved more efficacious. On the whole, my experience with this drug is that it will act favorably with a large number of patients, that it is acceptable on account of its lack of taste and odor, and because of its small dose; the sleep obtained is very refreshing and natural; it is, however, rather more likely to leave unpleasant effects, and seems to lose its power by repetition sooner than either urethan or paraldehyde.

Hypnone has a strong odor of bitter almonds. One patient spoke of it as having "all the odors of Araby the blest." I have given it in capsules in dose of 5 to 8 drops (.07 to .13) or even more, the former dose is rather small for good results. It will produce very natural sleep, and the patient awakes refreshed. It is of much less value than the drugs already considered, and fails more frequently than the others in producing sleep. It may be conveniently substituted for the others when they have been taken some time consecutively.—*Boston Medical and Surgical Journal*, October 14, 1886.

SUBCUTANEOUS INJECTION OF SALT SOLUTION.—**DR. ALBERT H. TUTTLE** writes as follows from Vienna: I lately witnessed the subcutaneous injection of 50 ccm. of a salt solution into the body of a boy 7 years old, by Professor Monti, and believing it may be of interest to your readers and perhaps at some time useful, I send you this brief description of his method. The requisites are a piece of rubber tubing about six feet long, a large hypodermic needle and a graduated beaker containing a solution of salt. The salt solution is heated to 100 F., and then placed about four feet above the patient on a stool that rests on the top of a table. The hypodermic needle is attached to one end of the rubber tubing. The tubing is filled with water, and one end is inserted into the salt solution, then the needle end of the tube is lowered and the contents are allowed to run off until the stream becomes warm from the salt solution in the beaker. The needle is now inserted into the subcutaneous tissue while the stream is flowing. At this moment an assistant reads the level of the fluid in the beaker. This done, one can tell exactly by means of the scale on the beaker how much of the solution has been injected. The tissue is distended by the fluid forming a tumor which disappears in the course of an hour or two. In the case I saw the injection was made an inch and a half below the naval, and a half inch to the right of the median line. The swelling was an inch and a half in diameter and about half an inch in height. The whole time occupied in giving the injection and making the necessary preparations did not exceed twenty minutes. The method has been employed in the collapse of cholera infantum, and may further be found useful in some of those cases where intravenous injection has formerly been resorted to.—*Boston Medical and Surgical Journal*, October 14, 1886.

LATE OCULAR SYMPTOMS OF SYPHILIS AND THEIR TREATMENT.—**ABADIE** (*Annales d'oculist.*, May-June, 1886), again urges the advantages of his method of subcutaneous injections of mercuric bichloride in the late ocular lesions of acquired syphilis and constitutional syphilis. These lesions are characterized by their complex nature and the slowness of their evolution. Chorio-retinitis is frequently accompanied by chronic iritis, and even by parenchymatous keratitis. Many of these cases heal spontaneously without treatment, while others show a very disquieting tenacity, which resists all treatment until the hypodermic mercurial injections are employed. This latter method of treatment gives good results also in certain forms of chorio-retinitis limited to the region of the macula. In cases of isolated paralyses of the cranial nerves or twigs of nerves, without cerebral complications, the extreme rebelliousness of the trouble is successfully conquered by the hypodermic method of treatment. For this purpose Abadie employs a solution of mercuric bichloride, 1 part; sodium chloride, 2 parts; and distilled water, 100 parts. He injects on alternate days, 20 drops of the solution beneath the skin of the back, and makes gentle massage over the spot afterward.—*New York Medical Journal*, October 23, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

CHICAGO, ILLINOIS.

SATURDAY, NOVEMBER 13, 1886.

CASTRATION IN NERVOUS AND MENTAL
DISEASES.

Such is the title of a symposium, in the October number of the *American Journal of the Medical Sciences*, by SIR SPENCER WELLS, DR. ALFRED HEGAR, and DR. ROBERT BATTEY. We could only expect that each of the papers singly would be of interest; and as they appear together triple interest is given to the subject.

In some respects the contribution of Sir Spencer Wells may be looked upon as a moral polemic, or philippic, against the abuse of the operation, and on this point Dr. Battey also has something to say. In view of the nature of the operation, however, too much cannot be said against its abuse. If the duties of the surgeon often lead him near the line that separates the legal and justifiable from the illegal, he should on that account be all the more cautious of overstepping this line. There has always, we may presume, been such a fascination about a new operation as to give to most of those who could handle a knife, a case of acute *pruritus secandi*; certainly such is the case now. Sometimes it has almost seemed that a new operation has been invented for the purpose of coining a new Greek compound. Of late years the good old word "obstetrician" has been metamorphosed into "gynecologist" in too many instances, and therapeutic specialties have too often taken the place of broad principles. "Groping among details is an absorbing and paralyzing occupation, and soon the curve of a pessary or the lining of a speculum fills the field of vision, and great principles are lost sight of."

It is not until we read fifteen pages of the contri-

bution of Sir Spencer Wells that we come to know what he thinks (really) of oöphorectomy. While what he says, generally, of unnecessary operations on the reproductive organs of women is good, and has been so considered for several years, the result is really to obscure the discussion of the main question. He draws the following conclusions regarding castration for nervous diseases: 1. The operation of oöphorectomy, or removal of the normal ovaries, is one which may be advised in some cases of uterine fibroids, and in uncontrollable uterine hæmorrhages. 2. It is to be resorted to in certain malformations of the genital organs, deformities of the pelvis, and accidental obstructions of the vagina. 3. The right to use it is very limited in cases of ovarian dysmenorrhœa or neuralgia, and only when they have resisted all treatment, and life or reason is endangered. 4. In nearly all cases of nervous excitement and madness it is inadmissible. 5. It should never be done without the consent of a sane patient, to whom its consequences have been explained. 6. The excision of morbid ovaries and appendages should be distinguished from oöphorectomy, and ought not to be done without the authority of consultation, as in most other cases of abdominal section. 7. In nymphomania and mental diseases it is, to say the least, unjustifiable. It will be seen that Sir Spencer Wells does not take into account the removal of *diseased* ovaries for nervous disease (except perhaps in 7), and it is this particular point that his paper not only differs from those of Hegar and Battey, but is actually incomplete. He assumes throughout that normal ovaries are being removed, and it is against this operation that his polemic is directed. It is to be regretted that he did not discuss the question at issue more fully.

Dr. Battey opens his paper as follows: "Within my knowledge it has not been the practice of American surgeons to attempt the cure of mental and nervous disorders by the removal of healthy ovaries or of healthy tubes. The ovaries removed, and the tubes as well, have presented signs of disease—signs which are evident to the naked eye and palpable to the sense of touch. For the misconception upon this point still existing, my own ignorance of both the histology and pathology of the ovaries is largely responsible in that, during the early history of the operation, I removed ovaries which I erroneously supposed to be healthy, and gave to the operation the unfortunate and now obsolete name of 'normal ovariectomy.'" Thus, in a breath almost, are the first fifteen pages of Sir Spencer Wells' paper disposed of. Now let us look at Battey's results. The operations

under consideration, he tells us, have been done for the relief of mental and nervous disorders, which may be divided into three classes: oöphoro-mania, oöphoro-epilepsy, and oöphoralgia. He uses the first two terms instead of hystero-mania and hystero-epilepsy because his clinical experience teaches him that these disorders are dependent upon a nervous irritation proceeding from the ovaries and not from the uterus. "I say that my clinical experiences so teaches me, because (a) I find the disorders existing in cases where I recognize organic disease of the ovaries, and am not able to recognize any organic disease of the uterus; (b) in cases of uterine as well as ovarian disease, when the diseased ovaries are removed, the nervous disturbance disappears notwithstanding the fact that a displaced or diseased uterus may remain. . . . In general, epileptiform manifestations have ceased at once. Some of the cases have required for a time the tranquillizing effects of the bromides to ward off threatening symptoms, whilst others have needed nothing. My cases of mania have all been quite chronic and the improvement has been slow. In oöphoralgia, in a few instances, the cure has been immediate and permanent. In the majority it has been slow and gradual; and in others nothing has been gained for even two years after the operation. In a few of these cases the long-established opium habit has proved a complete bar to recovery." Of his cases which have had two or more years to test them 7 were cases of oöphoro-mania, with 1 cured, 4 improved; 9 cases of oöphoro-epilepsy, 9 cured; oöphoralgia 20, 13 cured, 3 improved, 4 not improved. The cases of oöphoro-epilepsy were cured promptly and completely.

Dr. Battey's results are thus seen to directly controvert the last of the conclusions drawn by Sir Spencer Wells. As the others relate to the excision of normal ovaries it is obvious that they cannot be discussed, except to say that they are almost foregone conclusions. But let us look at the array of authorities, quoted by Battey, which show that removal of *diseased* ovaries is justified in mental and nervous diseases. Dr. Wm. H. Byford says: In looking over my cases I find that all my patients on whom I have operated for nervous disorders were greatly benefited. Three years ago I did this operation for an aggravated form of nymphomania. The patient is now cured of her terrible malady. In a case of double oöphorectomy for the relief of prolonged invalidism attended by headache of indescribable severity, the operation was an entire success. This patient, four years before the operation, was insane for several months. It is now five years and the pa-

tient remains in good health. I entertain no question that the operation is entitled to a legitimate place in surgery for desperate nervous conditions. Dr. Mann, of Buffalo, reports two operations for oöphoralgia, done more than two years ago, both cures. Dr. Sutton says: I have observed in many cases that when marked nervousness existed, it either entirely disappeared or was greatly lessened after removal of the ovaries and tubes. Dr. Wm. T. Howard reports a case of hystero-epilepsy (oöphoro-epilepsy), operated on three years ago, now cured. Dr. H. P. C. Wilson says: In my hands the operation of castration in women for nervous and mental diseases has been most satisfactory; all the cases that I and my son, Dr. Robert T. Wilson, have operated on for the above conditions have either been much benefited or entirely cured. He mentions one case of hystero-epileptiform convulsions, of several years' standing, which was entirely cured. Dr. Goodell says: After the lapse of many years my cases of oöphorectomy for insanity, for hystero-mania, hystero-epilepsy, and pelvic neuralgia, show positive and permanent benefit. I can recall but two failures, and those were two cases out of eight of insanity or threatened insanity. The remainder, six in number, were cured. A ninth case, a dreadful one of hysteria, menorrhagia and dysmenorrhœa, had two attacks of insanity after removal of her ovaries. Dr. T. Gaillard Thomas says: For all nervous and mental disorders in women which are created or markedly aggravated by the process of ovulation I regard castration as a most valuable resource. His experience with the operation for purely nervous and mental disorders extends to five cases: A case of insanity (menstrual) cured, a case of hystero-epilepsy cured, a case of menstrual epilepsy cured, and two cases of epilepsy not improved. "Castration of the female for nervous diseases has, in my opinion, a brilliant future before it, and yet, I feel that in this and in other conditions it is now being greatly abused by resort to it in entirely inappropriate and unnecessary cases." All the writers quoted express the fear that the operation will be abused, and think its field limited.

We have but little space in which to speak of the admirable paper of Professor Hegar, in which he discusses the subject both scientifically and practically. "Castration is indicated in a psychosis evoked or maintained by pathological alterations of the sexual organs, and in a neurosis originating from the same source, as soon as this imperils life or hinders all occupation and all enjoyment of life. The indication is also present when that disease represents

only one causal factor in the genesis of the affection, without the removal of which a cure is not to be thought of. Of course, also, the remaining causes of suffering must be in this case accessible to treatment. Other milder methods of treatment must have been tried previously without success, or, as in the case of many small tumors of the ovaries and tubes, must from the outset give no promise of success. Castration must actually affect the cause which occasions or keeps up nervous irritation. The operation will thus be of use when a degenerated or dislocated ovary represents the irritative focus, or as soon as a greatly swollen and retroflected uterus presses on the sexual plexus and the organ is brought into a state of atrophy. Castration promises success when the bleeding and anæmia occasioned by a fibroma play an important part in the maintenance of a psychosis, so that a cure does not appear possible without getting rid of that evil; but castration is absolutely no universal remedy for any neurosis originating from a genital-organ disorder, or kept up by the same. The cessation of ovulation will avail nothing if the irritation starts from the nerves which are compressed in a shrunken cicatrix of the broad ligament, or elsewhere in a cicatrix of the pelvic connective tissue." Altogether, it may be said that no previous paper has appeared in which this subject has been so thoroughly and impartially discussed, in all its bearings, as in the contribution of Dr. Hegar.

THE DUTIES OF SECRETARIES OF SECTIONS.

In *THE JOURNAL* of October 30, DR. B. A. WATSON has called attention to some defects in the practical working of the Sections of the Association, and chiefly to the fact that the discussions on papers are not fully reported. It must be said that this charge is true. The discussions as sent with papers to this office are usually entirely valueless, and in not a single case for two years have they been at all full. It is of no earthly interest to anyone to know that a certain paper "was discussed by Drs. Brown, Jones, Smith, Johnson, and several others." There is no information to be gained by reading that "Dr. — asked a question about the dose of croton oil, and Dr. — answered it." It may be true that "Dr. —'s paper was ably discussed by several gentlemen." We must presuppose that all papers read before the Association are discussed by gentlemen when discussed at all, but it is for the readers of the discussions to say whether the discussions were able or not. Our curiosity is excited by reading in a Secretary's report that "The discussion was closed

by Dr. —," but our stock of information is not increased.

In regard to one point we must take issue with Dr. Watson: it is in many cases practicable to write out a discussion before going to the meeting of the Association. It is done in other scientific bodies. And should any matter come up which has not been embodied in the written discussion, it can be easily added to what has been written. And should no new point come up the discussion is ready to be handed over to the Secretary. To say the least, those who discuss papers should do all that they can to assist the Secretaries in making out a useful report of the Sectional meetings. If a paper is worth discussion it is worth while for those who discuss it to make a little self-sacrifice in having their remarks appear in proper form, and accurately.

The position of Secretary of a Section is a purely honorary one, but for all that he who accepts it should feel it a duty to do his work properly and carefully. It is regarded as an honor to be elected to such a position, but it should not be regarded as an honor which entails no duty or work on the recipient. No one should accept the position who is unwilling to do the work devolving upon him. It is entirely useless for a Secretary to report in full the business transactions of his Section to the Editor of *THE JOURNAL*. This properly belongs to the business of the Association, and as such should be sent to the Permanent Secretary to be incorporated in his report. *THE JOURNAL* does not publish separate reports of the Sectional meetings of the Association, and when they come to this office they are only so much waste paper. What is wanted of the Secretaries of Sections is an accurate and full report of the discussions on papers read in the Sections, giving simply the name of the author and the title of his paper. Abstracts of papers read in the Sections are of no value whatever, as the papers are published in full in *THE JOURNAL*. It will be noticed that in *THE JOURNAL* the discussions, such as are sent, are placed immediately after the papers. The reason for this is obvious: the papers are published at different times, not in a lump, and it would be annoying to have to refer back possibly eight or ten numbers to read the discussion on a certain paper.

There can be no doubt that the discussions in the Sections would be better if the authors of papers would spend a little more time on them, and send, at an early date, the main facts and conclusions to be drawn to the Chairman or Secretary of their Section, who could furnish them to such persons as would be likely to discuss the papers. Each person

who writes a paper should try to make an actual addition to our stock of *facts*. A speculative paper may be interesting enough at times, but as a rule it is only an encumbrance to medical literature.

THE INTERNATIONAL MEDICAL CONGRESS.

The following just and liberal sentiments, taken from the editorial department of the *St. Louis Courier of Medicine*, will be cordially approved by the profession in this country:

The success of the International Congress, which is to be held in Washington, D. C., next year, can no longer be questioned. Reports from physicians who have been abroad this last summer warrant the confident expectation that large delegations of eminent physicians from the various European countries are already laying their plans to attend the Congress. The differences which arose between some of the most prominent members of the profession in our own country, and which, for a time, threatened to render the meeting an entire failure, have been to some degree adjusted, and to some degree subordinated to a recognition of the paramount importance of the general interests of the profession at large over the personal dignity of the individual.

The officers who have been selected for carrying out the arrangements are men of ability and energy, who will spare no effort to make the occasion one of profitable enjoyment to the many guests who are expected from abroad, as well as to the much greater number from all over our own country who will crowd to the National capital for the sake of meeting and hearing the ablest representatives of medicine and surgery from beyond the ocean.

We anticipate very much of profit to our own country from the results of this meeting. It will bring the profession here into relations of personal friendship and intimacy with that of the old world, as a result of the visit to us of so many of their leaders, which would never be reached so long as the visiting was done solely by Americans. Americans have been honored guests at the meetings of the International Congress held in various European centres, and now the opportunity is afforded us to honor ourselves more highly, in doing honor, as becomes our Nation, to the representative men of the profession throughout Europe.

Let us all unite to make this meeting of the International Medical Congress the best possible success by burying all feelings of personal pique or slight, or even of injury, and showing to the world that the profession of the United States is heartily one in

welcoming our friends from abroad. Let our best men attend, and carry with them the evidence of their interest in papers giving the well-digested results of their experience. So shall we do the highest honor to our guests in treating them to the choicest results of our labors, and at the same time elevate the standard of professional work here.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF VIRGINIA.

Seventeenth Annual Session, held at Fredericksburg, Va., October 26, 27, and 28, 1886.

The State Medical Society of Virginia convened in the historical city of Fredericksburg October 26, at 8 P.M. The attendance was large, and representative of the profession of the State. In addition, Drs. Theophilus Parvin and Wm. S. Forbes, of Philadelphia, Pa., Archibald Atkinson and Frank Donaldson, Jr., of Baltimore, Md., Wm. T. Cheatham, of Henderson, N. C., J. Taber Johnson and Patrick J. Murphy, of Washington, D. C., and Thomas R. Evans, of Mt. Carbon, W. Va., were present as guests.

According to custom, the meeting of the first night was open to the public as well as to the profession. The Opera House was well filled with ladies and citizens at the hour of meeting, notwithstanding the very rainy weather.

After the PRESIDENT, DR. RAWLEY W. MARTIN, Chatham, Va., called the session to order, and after prayer by the Rev. Dr. James P. Smith, of the Presbyterian Church, and addresses of welcome by Mr. Mason, on the part of the citizens, and Dr. H. M. D. Martin, on the part of the local profession, DR. HUGH T. NELSON, of Charlottesville, Va., was introduced, and delivered the "Annual Address to the Public and Profession," his subject being

THE FALLACIES OF MODERN MEDICINE.

The committee to nominate applicants for Fellowship during this session presented sixty-three applications, each of which was approved.

The report of the Necrological committee, prepared by the Chairman, Honorary Fellow Dr. S. C. Gleaves, of Wytheville, Va., contained memoirs of the following named deceased fellows:

Honorary Fellow and ex-President Dr. A. M. Fauntleroy, of Staunton, Drs. Meade Kemper, of Norfolk, Thos. D. Stokes, of Danville, David Steel, of Petersburg, J. T. Spencer, of Farmville, Richard H. Cox, of West Point, and Jenifer Garnett, of Richmond.

WEDNESDAY, OCTOBER 27.—SECOND DAY.

MORNING SESSION.

The Society was called to order at 9:30 A.M. by the First Vice-President, Dr. John M. Apperson, of Town House, Va.

Honorary Fellow DR. JOHN HERBERT CLAIBORNE, of Petersburg, Va., presented a paper on

SCHOOL HYGIENE.

He said that he had seen an article in a recent popular monthly on *The Bodies of Our Children*, to which subject he would limit his remarks. This article had set him to thinking and inquiring how much had been done for the "souls" and "minds" of our children, and how little for their "bodies." The parent and the preacher, from pen and from pulpit, had given line upon line, precept upon precept, while the Sunday School, with pictures, charts and maps, and pretty books, had made the way so pleasant that it could no longer be called straight, nor its gates narrow. Indeed, so many asperities had been rasped down, so many rough places had been made plain, so many mountains brought down, so many valleys upraised, that the old Pilgrim of Bunyan would no longer recognize the road which he had trodden in so much pain and peril. And the public and the parents had given so much time and money to the "mind" that schools and colleges and universities covered every hill—and saying nothing of *private* schools—about one-third of the taxes assessed in this commonwealth were assessed for purposes of education. The "minds" were thoroughly looked after—were strained, even forced, as potatoes in a hot-bed—and boys and girls were expected to be "wise beyond what is written."

But the bodies—effeminate, emasculate, enervate—were left to struggle in pain and ignorance, with the great labors and trials of life, and, finally called on to do a man's work or a woman's work, without power, what was the result? Failure of the men, feeble and of impoverished strength to meet the great requirements of an age of energy and exaction; and for the women the shawl, the sofa, neuralgia, headache, backache, hysteria, the last that great demon of domestic life, scarcely less fruitful of unhappiness in the family than the husband's dram. For this he held the parent, no less than the teacher, responsible—the desire of the one and the requirement of the other that the minds of the young of both sexes should be filled, in a few years of school life, with all knowledge and all accomplishments.

The remedy lay in a little common sense consideration of the whole subject, that same common sense which sensible people apply to all other enterprises and objects of life. The parent must exact less, and the teacher be content with less. Again, mental and physical training must be conducted at the same time and in the same school. A regular time should be appropriated to play, as to study, and children should be taught to *play*, as they are taught to study. The play-room or gymnasium should be built when the school house is built, and the children should no more be turned loose to play and train themselves in the one, than they should be turned loose to study and educate themselves in the other; not only failure, but confusion, pandemonium, would prevail in both; and a teacher that can be made capable of teaching the mind of the young, can be made capable of training the body of the young.

One teacher may only be a teacher of the rudiments of the one, and one teacher may only be a teacher of the rudiments of the other, but skilled labor, skilled service may be acquired for both by proper compensation, and by proper training of teachers.

This subject was deemed of such great practical importance that a resolution was unanimously adopted urging upon the Superintendent of Public Instruction of Virginia, the suggestion that he should have thousands of copies of the paper struck off in pamphlet form, to be distributed to teachers and patrons of schools throughout the State.

DR. J. A. ANDERSON, of Elba, presented

A REPORT ON ADVANCES IN ANATOMY AND PHYSIOLOGY.

Taking up first the department of *Physiology*, he spoke of some recent observations relating to the process of digestion, noting Reichmann's conclusions regarding the digestion of milk. Then he summarized Löwenthal's theory of menstruation. Simanowsky's experiments on dogs, clearing up in a great measure the physiology of hepatic colic, were then dwelt upon. The views of A. Weiss, as to what becomes of the bile in the intestines, were mentioned. He then presented the latest observations relating to the connection between glycosuria and biliary obstructions. Schneiber's discovery as to how albuminuria can be experimentally produced in man, was detailed. The functions ascribed to the corpus striatum by Baginsky and Lehmann were recorded. Freund's demonstration that the coagulation of blood is hindered by the use of oil, was alluded to. After speaking of the recent views as to the origin of the fibrin ferment, Dr. Anderson passed on to *Advances in Anatomy*, mentioning first the use of the fossa at the lower end of the fibula. Then he described Gruber's extensor tendons of the fingers, and Walsham's crico-hyoid muscles.

The Secretary presented, by title, a paper by Honorary Fellow DR. J. M. TONER, of Washington, D.C., giving "*A Sketch of the Life of Dr. Gustavus Richard Brown, of Port Tobacco, Maryland, one of the Consulting Physicians during the Last Illness of General George Washington, at Mt. Vernon, Va., together with a Copy of his Will.*" This is the last of the sketches of the three physicians attending General Washington, which Dr. Toner has contributed to the "Transactions" of the Society in as many years, and which are of great historic value to Virginia, and especially to the profession of Virginia. These contributions are specially prized, as no one else could or would have been painstaking and liberal enough to collect and contribute the data Dr. Toner herein furnishes.

THE PRESIDENT, DR. RAWLEY W. MARTIN, of Chatham, then delivered the *Address of the President*, on

PRACTICAL HINTS ON HYGIENE.

He remarked that until a recent period the profession has been too much engrossed in finding cures for many diseases which are now better managed by taking the ounce of prevention. The profession is now everywhere aroused to the importance of preventive medicine. He urged physicians to teach

the people hygienic. Hygiene should be a part of the school curriculum.

The chief cause of malarial diseases is the want of proper drainage of our lands. The destruction of forests is always followed by increased sickness. Therefore the waste of timber should be prohibited by law. He urged the members to get their legislators to vote for an appropriation to sustain the State Board of Health.

Artificial feeding of infants is believed to be largely responsible for their increased mortality. The failure of American mothers to nurse their offspring is an anomaly to be found in no other country in the world.

Insanity is largely due to the violation of Nature's laws, and to the large consumption of alcoholic beverages. Their influence in shortening life may be gleaned from the following: A temperate man at the age of 20 may expect to live 44 years; if intemperate, 15.5 years.

The general discussion on

PUERPERAL SEPTICÆMIA

was opened by DR. L. ASHTON, of Falmouth. He defined puerperal septicæmia as an infectious disease, due to inoculation of the wounds which result from the separation of the decidua, and passage of the child through the parturient canal, as well as from infectious diseases, such as erysipelas and all zymotic forms. He described the disease as being a *metritis*, a *vaginitis*, a *peritonitis*, a *cellulitis*, and a *phlebitis*, and discussed fully the characteristic symptoms of each. He traced the history of the disease from the days of Hippocrates, giving the different views held by the leaders in medicine down to the present time, as to the nature of the disease, and showed that Semmelweis, of Vienna, in 1847 first taught that the disease was produced by the poison engendered by cadaveric decay, and that at this day all modern investigators acknowledged it to be due to a septic material which enters the circulation through solution of continuity in the generative tract or to some of the infectious diseases. He dwelt earnestly upon the importance of clearly diagnosing between puerperal septicæmia and pyæmia. Prevention was next considered, and he gave the views of Thomas, Garrigues, and others, and discussed fully the importance of absolute cleanliness on the part of the obstetrician, and the obstetric equipment, but entered an earnest protest against the folly and uselessness, in ordinary labors, of using the germicides, etc., as advised by Fancourt Barnes, Doléris, and many others, and contended that pure clean water that has been boiled, is all that is requisite in most cases.

In the treatment, he says, the first thing to do on rise of temperature indicating an attack of puerperal septicæmia, is to cleanse the vagina with a 2 or 3 per cent. solution of carbolic acid, or listerine (1-4), or corrosive sublimate (1-3000), every four to six hours. Much stress is laid upon the importance of intra-uterine injections in the successful treatment of the disease. Great caution is necessary in their use, and the intelligent physician should make them himself, using always a Chamberlain glass tube, or the

tube invented by Dr. Lyman, of New York, fitted to a Davidson's syringe. Opium to control pain and nervous shock, is highly spoken of, when given in sufficiently large doses. To reduce temperature, salicylic acid, or antipyrin preceding quinine, with the use of cold applied by means of the Skibber's cot, Townsend's rubber-tent coil, or sponging. Alcohol holds a high place in the treatment, as does digitalis. The dirt in all cases should receive particular attention as a means of restoring tissue waste.

The President requested DR. THEOPHILUS PARVIN, of Philadelphia, Pa., attending the session by invitation, to present his views on puerperal septicæmia.

DR. PARVIN began by stating that scarcely had he arrived in this City before he received two evidences of Virginia hospitality. First, as he stepped off the train, he was accosted by a citizen who so courteously insisted upon his breakfasting with him that he had to accept the invitation. Secondly, he had arrived in this hall only a few minutes before he was informed that the Society wanted him to make some remarks on this subject.

In the acceptance of this latter invitation, he was reminded of the anecdote told upon one of Virginia's brightest orators, the illustrious John Randolph, of Roanoke. Randolph used to say when he had finished a speech, that he always regretted what he had not said. As for himself, Dr. Parvin said that he feared that when he was done he would have to regret what he had said.

In the outset, he said that if he were called upon to give a definition of the term puerperal septicæmia, he would define it somewhat after this manner: Puerperal septicæmia is a febrile affection of woman in childbed, which is contagious and heterogenetic. He believes the disease is dependent on germs for the following reasons:

1. The smallest particle of infected matter conveyed from one puerperal woman to the vagino-uterine tract of another woman in childbed gives the disease.

2. We may assume this statement to be correct from what we know to be the effect of germicides in preventing the disease.

3. Analogy also helps us to this conclusion, as we know that many diseases are dependent upon the introduction of living germs into the system.

Some gentlemen say that germs are autogenetic. Whoever believes this must believe in spontaneous generation. Dr. Parvin believes in no such doctrine. We don't say that scarlet fever begins itself. The poison is conveyed from outside—from another case of scarlet fever. So we say of puerperal septicæmia. The disease of which we are speaking, and which kills the woman, is not born in her. It is brought to and deposited in her from a preceding case of puerperal septicæmia. He does not believe that scarlet fever, diphtheria, or erysipelas can produce puerperal septicæmia. In a word, these specific poisons of these diseases are not identical with that of puerperal septicæmia, but they may be associated in one case, and thus have the appearance of conveying these different diseases. But a dog cannot breed a cat, although they may associate with each other. He referred to

a fatal case of puerperal septicæmia in a mother who had nursed her child through an attack of scarlet fever, but when she was confined immediately afterwards, she had a nurse who had been with a case of puerperal septicæmia. The question has often been asked, Can a puerperal woman have puerperal septicæmia without having a wounded womb? He does not believe it. He has never seen a case unless there was a wounded uterine surface. Likewise the question has been asked, Don't retained membranes, clots, etc., become causes of puerperal septicæmia? I would answer, "no," provided they are kept aseptic. These decaying secundines simply furnish the suitable soil for the nourishment of the microbe. The poison itself always comes from without.

Dr. Ashton, in his elaborate and well prepared paper, spoke of diphtheria of the vagina as a form of puerperal fever. Dr. Parvin would remark that only a few authors of the present day admit that there is any such form. He does not think such a form really exists. Some authors have supposed that there was no puerperal septicæmia without a very high temperature. But he has seen cases where the temperature never rose over 101° or 102° F., and the pulse not more frequent than 100 per minute.

Dr. Parvin divides puerperal septicæmia clinically into two forms: (1) Lymphangitis, and (2) phlebitis.

Lymphangitis occurs early after the onset of septicæmia—by the second day—and the inflammation extends to other pelvic and abdominal tissues causing even puerperal peritonitis. In this form of septicæmia in the childbed woman, we may find that the patient had an ushering-in chill, but such an event is not necessary to its clinical history.

In the *phlebotic form*, we always find that the woman has repeat-chills. The milk-leg form is also the safest to the patient, as it indicates a localization and a limitation of the disease. The adhesive form of puerperal phlebitis is not of spontaneous origin.

Dr. Fordyce Barker and others have written much about the prevalence of malarial puerperal fever. In the fifty or more cases of puerperal woman seen by Dr. Parvin, he has seen only two cases of puerperal malarial fever. In this intermittent form of puerperal fever, the temperature rises from the normal or nearly normal standard suddenly and very high, and as suddenly falls to the nearly natural elevation.

As to the *treatment*, Dr. Parvin has tried many plans, but the result of his experiences has brought him to depend chiefly upon opium and whiskey. Nourishing food should be given throughout the disease. Antipyrin, quinine, etc., undoubtedly may do good for awhile in lowering the temperature, but they soon break down the tone of the stomach, and impair the digestive function. It is true he uses these agents sometimes to meet a specific and a purely temporary indication; but he certainly would not depend upon either of them for a continuous or prolonged treatment. In recommending the free use of alcohol in suitable cases, he would not be understood as saying that it is needed in the majority of instances. But when the temperature rises to 103° or 104°, its temporary administrations acts well. It induces

sleep, allays nervous agitation, and lessens the fever heat very ostensibly.

In summarizing his remarks after the narration of some sad experience many years ago, coming out of the views which had been taught him by the great Professors of the Philadelphia schools when he was a medical student in that city—that puerperal fever was autogenetic—he said: "Gentlemen, if there is one thing impressed upon my mind more than another, it is the conviction, as if written with fingers of fire upon my memory, that puerperal septicæmia is contagious."

DR. JOHN N. UPSHUR, of Richmond, reported a case of puerperal septicæmia which he thought gave a good example of the autogenetic origin of the affection, the source of contamination being the suppurating endometrium. The attack set in two weeks subsequent to confinement, after what seemed to be a perfect convalescence, the only symptom pointing to trouble being the character of the lochial discharge, it continuing *bright red too long*. The appearance of a foul smelling diarrhoea, as a critical discharge, was a point of interest. The death of a sister of this patient from septicæmia, she being three months advanced in pregnancy, who, from her condition, was more susceptible to contagion, and the probability that her attack was contracted from exposure to the foul air of her sister's chamber, incident to the alvine discharges, makes the supposition that the contagion entered her system through the lungs plausible, and gives an example of the heterogenetic origin of the disease. The prompt action of amyl nitrite, the large amount taken, and its long continuance when the patient was profoundly collapsed, and death seemed imminent, was also a point of interest.

Dr. Upshur stated it as his opinion that, while quinine and the salicylates are not curative in the treatment of puerperal septicæmia, yet they exert an antidotal influence on the poison circulating in the blood, and thus prove beneficial.

DR. CHAS. R. CULLEN, of Richmond, said that as soon as delivery is completed, the womb is left in a condition which makes it subject to infection from several diseases, as erysipelas, scarlet fever, sloughing sores, carbuncles, cancer, etc. The principal writers admit the clinical fact, but disagree as to the agents producing the infection—whether ptomaines or decomposing matter, or bacilli, or bacteria, or microbes. Dr. Barnes, of London, admitted that puerperal septicæmia might be propagated even by the breath of the physician or nurse, and says that the disease is more liable to occur in primiparal cases. Dr. Guérin, of Paris, confirms these statements. Dr. Cullen then referred to the histories of several reported epidemics, showing the great contagiousness—both from other cases of puerperal fever and from other diseases—and fatality of the disease, and quoted from foreign and domestic records to prove his point. The great English surgeon, Dr. Hunter, said that his first case of puerperal fever commenced from his handling an ordinary sloughing felon on a patient's finger, and soon afterwards attending a puerperal woman. From this case, a large number of fatal cases developed. He discontinued obstetrical practice, and got his

partner, who had not been in any of the infected cases, to attend six other cases of labor, and no puerperal disease resulted. He then resumed his obstetrical practice, when the disease reappeared in his cases, and he was compelled to discontinue obstetric attendance. Dr. Cullen gave other instances, leading to the deduction that surgeons should not attend labor cases—not that all surgeons would be conveyors of puerperal septicæmia, but the dangers are too great in that direction.

As to treatment, he advocated isolation of the patient, and disinfection of all persons and things to come in contact with her genitalia. Vaginal washes of weak solutions of corrosive sublimate, etc., should be used.

DR. B. B. TEMPLE, of Danville, said that no one in his city who comes in contact with a case of scarlet fever, diphtheria, erysipelas, and the like, was allowed, by professional opinion there, to attend a case of labor. He thinks, as a result of this prohibition, that puerperal septicæmia is very rare, if it occurs at all in his city.

DR. WM. S. FORBES, of Philadelphia, present by invitation, in response to a request for a statement of his views, apologized for not speaking on the subject because of feeling unwell. He would remark, however, that one thing had impressed him, and that was the special adaptability of woman to septicæmia. Septicæmia follows in those surgical cases especially where depletion has occurred. For instance, he has been struck with the frequency of its occurrence amongst "strikers" who have received wounds or injuries. Without work, they soon become unable to provide for their healthful sustenance and nourishment, and their physical organisms become depraved, thus laying themselves the more liable to such a disease.

DR. PATRICK J. MURPHY, of Washington, D. C., in response to an invitation to express his opinions, said he would limit his remarks to a few clinical facts which had been impressed upon him by his fifteen years' experience in the Columbia Lying-in Hospital, where he had met with all forms of the disease. He was rather inclined to accept the views of Dr. Parvin in regard to the matters of autogenesis and heterogenesis. Before antiseptics were introduced, puerperal fever was much more frequent in practice than it is now. He objects to the term "puerperal fever" as applicable to the disease under consideration—preferring that of *puerperal septicæmia*.

In regard to the treatment, the two important things were: first, prophylaxis; and second, curative agencies. By the prophylactic measures adopted, he has seen the death-rate reduced from 9 per cent. to 2 per cent. During the second stage of labor, when the os uteri is sufficiently dilated, he uses a hot 6 per cent. carbolyzed douche into the vagina. This measure takes the place of ergot in producing uterine contractions. When the child is born, if the placenta is not immediately expelled, he uses Credé's method, by using gentle friction backwards on the abdomen, and this soon brings on labor pains which expel the after-birth. He next cleanses the parts with simple sponge-baths, and then applies cotton to the vulva.

As to the curative treatment, he agrees with Dr. Parvin as to the value of opium and whisky, and as to the impropriety of depending on such agents as antipyrin, quinia, etc. In fact, he objects to the use of antipyrin in cases of puerperal septicæmia, while he thinks the administration of quinia in anything like heroic doses is to be condemned. He has found spirits of turpentine better than whisky, both for internal use and externally for stupes. If there be much pain, he resorts to suppositories of extract of Indian hemp. He has seen Warburg's tincture, Norwood's tincture of veratrum viride, etc., tried as antipyretics and fail. If the typhoid form of the disease sets in, he treats the case as he would one of typhoid fever. Instead of the cold water coil, he uses a flannel bandage over the abdomen, over which he pours alcohol, which rapidly evaporates. The cold water coil is too apt to produce shock.

AFTERNOON SESSION.

DR. JOHN S. APPERSON, of Town House, Va., read a paper on "Puerperal Septicæmia." The question which he thinks of paramount importance to decide is whether we shall accept the dicta that puerperal fever is identical with surgical septicæmia, and produced by the absorption of septic matter, "either originating within the generative organs of the patient herself, or coming from without," and regard every puerperal woman, by virtue of her physiological state, as supplying suitable culture-beds for the propagation and growth of pathogenous fungi. If so, then we might formulate the practical inquiry: To what extent are we justified in the local use of disinfectants, antiseptics, and potent germicides prior to, at the time of, and subsequent to labor?

Examination of the record of the 656 cases of labor in Dr. Apperson's practice, where no systematic use of any antiseptic has been applied, shows that only ten cases of metria in any form have occurred, and only one death. He could hardly expect a better result. He has seen many other labor cases, but is rarely called to a case of puerperal fever. Hence the conclusion, that pathogenic fungi are not so prevalent as might be inferred from the writings of authors on the subject. Cleanliness he specially insists on in the lying-in room.

DR. BEDFORD BROWN, of Alexandria, read a report of

SIX CASES OF PUERPERAL SEPTICÆMIA ILLUSTRATING THE RESULTS OF TREATMENT UNDER THE OLD AND THE NEW METHODS.

He believes veratrum viride peculiarly adapted to the treatment of the morbid changes in the circulatory system and the pyrexia. It acts as a nervous sedative and prevents heart labor and exhaustion. For the tympanites, 2 pints of infusion of flaxseed containing a drachm of oil of turpentine, 5 to 10 drops of carbolic acid and 1 ounce of Listerine, are thrown up the rectum into the colon twice daily. As to prevention, in no case where antiseptics have been properly used in labor has he met with puerperal septicæmia. His invariable custom is to cleanse

out the genital canals by carbolic soap, warm water, and borax. He believes ergot also is an important prophylactic, especially when the uterus is large, flabby and relaxed. Keep the uterus under its influence until all probability of infection has ceased.

DR. THOS. J. MOORE, of Richmond, first discussed the origin of puerperal fever. He regards the cause as identical with that of puerperal septicæmia, and they were therefore one and the same disease. The germ theory was fascinating to the investigating mind beyond conception. The French, German, English and American schools had all met upon common ground.

He then replied to the argument offered by Prof. Parvin, in which the latter had stated that it was impossible for scarlet fever, diphtheria, erysipelas, etc., to produce puerperal fever, as the peculiar microbe (or bacillus) would not give rise to a disease different from the special disease it was peculiar to. Dr. Moore said that he could not agree with the eminent Professor. In the first place, it was yet undetermined as to whether the three diseases above mentioned had a special microbe; secondly, all diseases producing puerperal fever from without had associated with their causative material the micrococcus of putrefactive decomposition; in other words, it was their secretions undergoing decomposition that gave rise to this common resultant—puerperal fever. Such was the case likewise with pyæmia and septicæmia. If the micrococci theory was not the proper one, then all of these diseases, through the process of retrograde metamorphosis, gave rise to some special animal poison that caused this disease, this process being fermentative in its nature. He accepted both author and heterogenesis. The poison, he believed, as a rule, entered through some abraded or torn surface through the lymphatics and the veins; sometimes it penetrated healthy mucous membranes, as demonstrated when females suffered an attack of this fever prior to parturition.

In regard to treatment, he believed much that was done during the act of parturition, meddlesome and harmful. He did not believe the female of the present day was so susceptible to pernicious impressions as many of the more enthusiastic would have us believe; he did not believe that any woman's life was imperiled where all the minutiae of details as laid down were not complied with. He gave his own experience in one of the largest lying-in hospitals in the United States, seventeen years ago, prior to the origin of this new school. Mere cleanliness of beds, wards and water-closets was observed, and for months they were without fever; in fact, could have remained indefinitely so. He had not the same dread of these microbes as many of the gentlemen of the present day; he believed in precautions, but not to the same extent as those who were on the *qui vive* of apprehension.

Prof. Parvin entered the hall as Dr. Moore ceased speaking, and Dr. Hunter McGuire arose and said that several Fellows speaking during Dr. Parvin's absence were unable to reconcile the statement made by that learned professor: that while he believed that scarlet fever, diphtheria and erysipelas were the

results of separate and distinct poisons, each one of which was able, by contagion, of reproducing its own disease and no other, any one of them might, under certain circumstances, generate puerperal septicæmia. How could scarlet fever, for instance, which was capable of producing scarlet fever *only*, under certain favorable circumstances produce septicæmia in the parturient woman?

DR. PARVIN replied that he could understand the ground for the seeming inconsistency as it occurs to Dr. Moore. In formulating his opinions as to contagiousness from another case of puerperal septicæmia being the sole cause of the disease, he would not have it understood that he states a fact, but a belief. The specific poison of the septicæmia is often *associated* with that of scarlet fever, diphtheria, erysipelas, etc.; and hence, in the production of puerperal septicæmia by contagion from such diseases, there is the appearance that the poison of the one disease is the same as that of the other. It is a fact of interest in this connection, that apparently the same micrococcus occurs in erysipelas as in puerperal septicæmia. It cannot be differentiated by the microscope, or other known means, but it can be by the effect produced.

He wished to add a few remarks to those he made this morning in regard to treatment. *Local treatment* is the most important. In the way of prophylaxis, first, the utmost care should be exercised, from the very threatening of labor to its full completion, that no infected person or thing be brought in contact with her genitalia. Do not make unnecessarily frequent or prolonged digital examinations *per vaginam*. He would much prefer that the accoucheur should keep his hands in his pockets, and leave the labor to Nature, than that he should keep his finger anything like continuously on the *os tinca*, or anywhere else about the vulvo-vaginal uterine tract. Let everything and anything that is to come in contact with the woman be perfectly clean and freed from any infectious germ. In the second place, under the head of local prophylaxis, he thinks well of the resort to vaginal douches as soon as labor is over; and, according to the indications in any given case, he uses vaginal injections of solutions of corrosive sublimate of the strength of 1 to 1000, or 2000, or 3000. If fever develops, he substitutes 3 per cent. solutions of carbolic acid. This solution he applies to the whole vaginal tract through Bozeman's tube, which tube he prefers to Molesworth's, or any other with which he is acquainted. If offensive matter oozes or is discharged from the womb, dilate the *os uteri*; and with the curette remove all remnants of after-birth, clots, or other offending matter. Sometimes he has been astonished at the large amount of discharge thus removed.

DR. B. B. TEMPLE, of Danville, Va., asked whether or not Dr. Parvin regards it safe for a physician attending a case of scarlet fever or erysipelas, etc., to go directly from such a patient to a woman in labor?

DR. PARVIN replied that a physician can communicate septicæmia to a puerperal woman unless thorough aseptic precautions be taken; for the germs of the one disease may be *associated* with the germs of

the other. Hence, he would repeat, let all attendants upon a puerperal woman be required to be thoroughly aseptic. Many years ago, in his practice, a man was wounded in the abdomen, and died. A professional friend of his, while making the post-mortem, wounded his finger, and died of "dissecting wound poison." Dr. Parvin attended him in his fatal illness. At the same time, he had several cases of labor on hand, and all of the patients that he delivered died of puerperal septicæmia.

DR. J. SPOTTSWOOD WELLFORD, of Richmond, Va., asked Dr. Parvin, in view of the facts he had mentioned, if it would not be scientifically more correct for him to say that the puerperal condition is necessary in order to produce the disease?

DR. PARVIN replied that perhaps that would be the best form of statement.

DR. HUNTER MCGUIRE, of Richmond, protested against the cross-fire of questions to which Dr. Parvin was subjected. The question under discussion, which was a debatable one, was so far unsettled; and it was scarcely fair to expect an answer to the direct and categorical questions to which his friend was being subjected. For himself, he thought there were many points which could only be determined by future observations; that it would require the combined experience of many observers to determine these mooted questions, and the personal observations of no one man would be sufficient.

He believed that a woman after child-birth was a good deal like a woman after a surgical operation—they were both liable to similar dangers. A very common danger in both is septic poison. This septic poison is the result of fermentative changes going on in dead matter only. This dead matter may be a piece of placenta, or extravasated blood. It is generally the latter. Fermentation taking place, we will suppose, in a mass of extravasated blood, produces inflammation and suppuration; and when a portion of this is absorbed, it produces constitutional symptoms which we call septic poison. Dr. McGuire does not believe that this clot should have access to the air in order to undergo these putrefactive changes, and produce blood poison. He had opened, as every other surgeon has, abscesses which had followed contusions, when extravasated blood had undergone fermentative change, and when air had had no possible access, and had let out, by incision, fetid pus, blood, and broken down tissue.

Many a woman has puerperal septicæmia which may be explained in this way. The contusion during child-birth is often severe. We find blood extravasated in large quantities in the parts about the uterus and vagina—sometimes a great thrombus in the vulva; it may be without breach of mucous or cutaneous membrane, and under these circumstances, if her general system is depraved, fermentative change may take place and end in septicæmia. He can readily see, too, how the introduction of the poison of scarlet fever, erysipelas, etc., would render the unhealthy inflammation and suppuration all the more likely to occur—not that these diseases set up a distinct and separate poison, but provoke into greater intensity any inflammation already impending.

He thought it was important to distinguish between the septic poison which he described, and the process of infection. He did not think from what he had heard to-day that this distinction was always made. The latter process involved the living tissue, not the dead matter; and micro-organisms, parasitic in character, are developed. The names of Pasteur and Lister would go down to history to the latest generation, the first for his discovery of micro-organisms, which the air, as a vehicle, conveys to wounds; and the latter for the changes he has wrought in practical surgery.

In midwifery he thought, as in surgery, cleanliness was the most important thing to observe. Get rid of the blood which, when dead and decomposing, was so dangerous. Dr. Parvin tells me that he will remove an ovarian tumor to-morrow, and I know that his greatest care will be to remove from the abdomen of the patient, as carefully as he can, every drop of blood which has escaped into it; and if this is impossible, to render aseptic any which is left, to prevent, if possible, its fermentation and putrefaction.

Other remarks on the subject were made by DRs. J. HERBERT CLAIBORNE, of Petersburg, WILLIAM C. DABNEY, of the University of Virginia, R. A. LEWIS, of Richmond, and others, going to show that other diseases than puerperal septicæmia (such as surgical septicæmia, diphtheria, erysipelas, etc., as well as retained membranes undergoing decomposition, etc.), might give rise to puerperal septicæmia.

DR. JOHN F. WINN, of Richmond, read a paper on
INTUBATION OF THE LARYNX IN DITHTERIA AND
MEMBRANOUS CROUP AS A SUBSTITUTE FOR
TRACHEOTOMY.

After considering the difficulties attending tracheotomy, and its high rate of mortality, he stated generally that the favorable results, so far, indicated that intubation would supersede tracheotomy in the conditions named. Mentioning the recent modifications in the tubes, he described the manner of their introduction, and followed with the statistics as far as could be obtained up to the time of reading his paper. These embraced the published reports of Dr. O'Dwyer's cases, in New York, Dr. Waxham's, in Chicago, and those of others. A recent letter from Dr. O'Dwyer reports fifty cases with recoveries—one in four. Dr. Waxham, in a private letter of October 23, 1886, reported thirteen new cases, with six recoveries, which, added to his published cases, make a total of ninety-six cases, with twenty-nine recoveries—30.20 per cent. One of these recently cured cases was an infant, aged nine months. Dr. Waxham says, in his letter to Dr. Winn: "I hope you will correct the impression that intubation is performed early. I have never known tracheotomy to be performed under more discouraging circumstances than has intubation, from the first to my last patient." Dr. Winn concluded his report by citing eleven propositions in favor of intubation over tracheotomy, and expresses the belief that we have every reason to regard O'Dwyer's method as a great advance in the treatment of diphtheria and croupous stenosis, and that we, as a profession, must not forget our indebted-

edness to Drs. O'Dwyer and Waxham for their labors in perfecting this operation.

DR. H. M. CLARKSON, of Hay Market, read a paper on

CHLOROFORM AND CHLORAL IN CHILD-BIRTH, recording many useful clinical experiences, and concluding with a statement of his conviction that the physician who now would withhold these agents to annul or lighten the throes of labor is either culpable of neglect of obvious duty, or else shows himself to be ignorant of facts with which he should be familiar.

(To be concluded.)

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Movements of the Heart and Intestines—Operations for Internal Obstructions—Krackowitz Prize—Building Fund for the Academy—Abscess of Brain from Suppurative Otitis—Cystic Tumor of Labium.

At the first November meeting of the Academy of Medicine, Dr. William Gilman Thompson exhibited a remarkable series of photographs illustrating the "Movements of the Heart and Intestines." Several years ago, he said, he had been much interested in reading the account of a series of photographs of horses taken while the animals were in motion, and this had suggested to him the practicability of securing similar views of the heart under various conditions. Carrying this idea out, he had been enabled to take photographs of the hearts of different kinds of animals while performing their movements naturally and under the influence of various stimuli. In his early experiments he employed an ordinary camera; but more recently he had devised a form of apparatus which rendered the work much easier as well as more accurate. The difficulty about the ordinary camera was, that only one view could be taken at a time, and then the plate had to be changed. By the aid of his improved apparatus, however, he was able to take no less than six successive views on the same plate in the space of one second; a feat in photography which he said had never before been achieved. The problem was to revolve the plate, which was circular, and stop it six times in the second; and this he had succeeded in accomplishing by means of an arrangement of cog-wheels turned by a handle. Each image was clear and distinct, without any blurring.

The animal whose heart was to be photographed was placed on a convenient platform, and anesthetized, and an incision having been made in the median line, the heart was exposed. A collar of celluloid was then slipped behind it in order to secure a light background, which was a matter of no little importance. The light used was strong sunlight and the animals experimented upon were cats, kittens, rats, pigs and pigeons. The results were very interesting, and the various changes in the form and position of the heart

were distinctly shown. The shape of the apex was found to be greatly affected by different drugs, and of the various stimuli employed, heat produced the strongest systole. Of the drugs, glonoin (either painted over the surface or used hypodermically), was active in effecting a strong systole, and chloral in producing an equally marked diastole. In photographing the movements of the intestines the same methods were employed. He had been able to demonstrate positively that two peristaltic waves sometimes occurred moving simultaneously in opposite directions; although the preponderance of motion was towards the anus.

In summing up his observations, Dr. Thompson alluded to the accuracy of the photographic method which he had devised, the rapidity and ease with which data for scientific conclusions could thus be accumulated, and the facility with which the action of various cardiac and intestinal stimuli could be illustrated before classes of students. In regard to the movements and form of the heart he spoke of the following points:

1. The long diameter may or may not shorten in systole; but it usually shortens from one-fifth to one-thirteenth.
2. The transverse diameter usually shortens at least one-fourth.
3. The apex does not in all cases cause the impulse-beat; and this very frequently is produced by the hardened anterior wall of the heart pressing against the thoracic walls. The form of the apex varies greatly under the influence of different drugs.
4. The contractile force of the right ventricle may out-last that of the left, and pathologically the two ventricles may contract independently.
5. The lumens of the ventricular cavities are capable of being entirely occluded by the circular fibres acting independently of the longitudinal and transverse; thereby demonstrating the immense contractile power in all the cardiac fibres.

On the same evening Dr. W. Gill Wylie reported two operations for intestinal obstruction. The first was in a case of total obstruction in a patient 50 years of age. On the 10th of October last he performed laparotomy, and it was found that the cause of the obstruction was a strong band of adhesions which held a loop of the ileum so firmly down that the lumen of the gut was completely destroyed. When the band was cut, however, the lumen was at once restored. The cause of the adhesions was peritonitis, which seems to have been set up by the passage of a uterine sound; the uterus and both broad ligaments being involved in a large fibroid. A point of interest in connection with this case was the existence of normal temperature and pulse, notwithstanding that such a grave local condition was present; the intestines in the vicinity of the obstruction being turned completely black. Dr. Wylie said that he was convinced that many cases of laparotomy were followed by more or less intestinal obstruction, which was generally mistaken for peritonitis. Until very lately it had been the universal practice to keep the bowels confined for five or six days after laparotomy, notwithstanding the occurrence of tympanites

and vomiting. He would not go so far as the well-known laparotomist who had declared that a brisk purge was the best treatment for peritonitis; but he felt sure that a turpentine or ox-gall enema was often of great service after abdominal section. He had adopted the plan, he said, of always opening the bowels after the first twenty-four hours, if there was any indication for it; and in all cases he did this at the end of three days, at all events. In the case in question, ten hours after the operation the patient had a copious liquid stool, and now, three weeks afterwards, the bowels were freer than they had been for ten years before. The other case was one of partial intestinal obstruction, and laparotomy was resorted to with an equally good result.

Dr. Wylie also related four other cases, in which he had performed laparotomy, which were not gynecological. One was a case of suppurative peritonitis, one of cancer of the liver, and two of tubercular peritonitis. In all but one an exploratory incision was made, and the diagnosis was not determined until after abdomen had been opened. In the two cases of tubercular peritonitis he left a drainage-tube in position as long as there was any fluid to come away, and he said that in Germany permanent drainage had also recently been resorted to in this affection with great relief to the patient. He then went on to remark that in a large number of cases of abdominal dropsy exploratory laparotomy was far less dangerous than tapping; and he contended that laparotomists in this country could never succeed in obtaining as good results as European operators as long as the mischievous practice of tapping continued in vogue. Patients with ovarian tumors, on account of the temporary relief afforded them by tapping, are very apt, he said, to defer applying to competent operators for their removal until a stage of exhaustion had been reached which rendered the chances of recovery very meagre.

On this occasion also the President, Dr. A. Jacobi, as Chairman of the Committee upon the Ernst Krackowitzer Prize Fund, the accumulated interest of which is available every third year as an award for an original essay, announced that the first subject selected was "New Observations on Osteo-Myelitis," and that competing essays should be sent in on or before the first day of January, 1889. The Committee of Award will consist of the Presidents of the New York Academy of Medicine, of the Bellevue Hospital Medical College, of the Medical Department of the University of the City of New York, and of the College of Physicians and Surgeons, unless the Academy should otherwise direct.

By an amendment to the by-laws adopted at this meeting a building fund for the Academy was established, and the amount which will shortly be available for this purpose from recent bequests and donations, including the munificent gift of \$25,000 from Mrs. Anna Woerishoffer, is about \$100,000.

At the first autumn meeting of the New York County Medical Association, Dr. F. Van Fleet presented the specimens from, and made some remarks upon, a case of "Abscess of the Brain from Suppurative Otitis." The lesson which the case taught was,

that if the ear trouble had been properly attended to in the beginning, the abscess (which was located in the left hemisphere of the cerebellum), would probably not have developed, and the child's life thus been needlessly sacrificed.

Dr. J. W. S. Gouley then exhibited a "Cystic Tumor of the Left Labium Majus" removed from a patient 30 years of age. It had distended the entire labium, and appeared to be a hypertrophied and dropical vulvo-vaginal gland. Much skill was shown by Dr. Gouley in the careful dissection of the entire growth, which extended for about an inch under the ramus of the ischium, and in the removal of which it was necessary to divide several branches of the pubic artery.

P. B. P.

BOOK REVIEWS.

A SYSTEM OF PRACTICAL MEDICINE. By American Authors. Edited by WILLIAM PEPPER, M.D., LL.D., etc. Assisted by LOUIS STARR, M.D., etc. Volume V, Diseases of the Nervous System. 8vo., pp. 1326. Philadelphia: Lea Brothers & Co. 1886.

With this volume is concluded a task which reflects credit on the Editor, his Assistant, the contributors, and on the publishers of the System of American Medicine, as it has been called. The plan of the work, as originally announced in the prospectus about five years ago, has been strictly adhered to, though some of the most able contributors have passed away in that time. The whole number of articles is 185, by 99 authors, and covering, with the copious indices, about 5600 pages. As a whole the work is one of which Americans may well be proud; subjects have been treated in a practical manner, and in one representative of the American School of Medicine.

The fifth and last volume, on Diseases of the Nervous System, opens with an exhaustive article on the "General Semiology of Diseases of the Nervous System; Data of Diagnosis," by Dr. E. C. Seguin, who is also the author of the second article on "The Localization of Lesions in the Nervous System," the two articles covering 80 pages. One could not, perhaps, find a better introduction to diseases of the nervous system than these two articles. To the great majority of general practitioners diseases of the nervous system constitute a bugbear of medicine; or they may be looked upon as a great ocean on which the practitioner and his patient get afloat without chart or compass. Within five pages Dr. Seguin has admirably embodied the principles of diagnosis in nervous disease. In 105 pages Dr. Charles F. Folsom, of Boston, deals with "Mental Diseases." Dr. Charles K. Mills contributes the articles on "Hysteria," "Hystero-epilepsy," "Catalepsy," and "Ecstasy," and "Progressive Unilateral Facial Atrophy." Of these the first are more particularly interesting to the general practitioner, and are not only interestingly written, but are all that could be desired as thorough discussions of these subjects. "Neurasthenia" covers only nine pages, and we could wish that Dr. H. C. Wood had made more of

it; but on reading it one can scarcely see how the subject could have been presented in a more terse or able manner. Dr. Wood also contributes the articles on "Acute Affections produced by exposure to Heat," and on "Syphilitic Affections of the Nerve-Centres." Dr. Wood has done more to enlighten us on the subject of the effects of heat on the system than any other man; and many practitioners will remember with pleasure his writings on the subject of syphilis of the nervous system.

Dr. Henry M. Lyman contributes the article on "Sleep and its Disorders." The appearance of an admirable little book on "Insomnia" about a year and a half ago, from the pen of Dr. Lyman, testified to his ability to write well on this subject. Dr. Wharton Sinkler, of Philadelphia, is the author of the following articles: "Headache," "Tremor," "Chorea," "Athetosis," and "Paralysis Agitans." In 13 pages Dr. S. Weir Mitchell gives a most excellent summary of what is known of vertigo. Dr. Allen McLane Hamilton writes the articles on "Local Convulsive Disorders," and "Epilepsy." Dr. Morris J. Lewis, of Philadelphia, contributes the articles on "The Neural Disorders of Writers and Artisans." We are glad that under the prophylactic treatment of writer's cramp mention is made of the type-writer. The use of this machine by writers is not only an efficient preventive against writer's cramp, and the neural disorders of writers, but is a direct prophylactic measure against certain neural (?) disorders of editors caused by reading illegible manuscripts. Of course over-use of this instrument might cause the same trouble as that seen in piano players; but it should be remembered that this machine does about three times the work of the pen in the same time, and with not half so much fatigue to the whole body or any part of it. The articles on "Tetanus" is by Dr. P. S. Conner. Dr. Edward P. Davis writes of the "Disorders of Speech." Dr. James C. Wilson contributes the articles on "Alcoholism," "The Opium Habit and Kindred Affections," and "Chronic Lead-Poisoning." These three articles are worthy of a more extended notice than we can possibly give.

Dr. Francis Minot, of Boston, contributes the articles on "Diseases of the Membranes of the Brain and Spinal Cord," "Tubercular Meningitis," "Chronic Hydrocephalus," and "Congestion, Inflammation, and Hæmorrhage of the Membranes of the Spinal Cord," the last of which probably contains more that is actually new to the general practitioner. The article on "Spina Bifida," by Dr. John Ashhurst, is written in his usually clear and terse style. Dr. Spitzka has well sustained his reputation in his articles on "Anæmia and Hyperæmia of the Brain and Spinal Cord," and "Chronic Inflammatory and Degenerative Affections of the Spinal Cord." Dr. William Hunt, of Philadelphia, contributes the article on "Concussion of the Brain and Spinal Cord," and it is the only unsatisfactory article in the volume. In an exhaustive article Dr. Robert T. Edes treats of "Intracranial Hæmorrhage and Occlusion of the Cerebral Vessels, Apoplexy, Softening of the Brain, Cerebral Paralysis." Dr. H. D. Schmidt, contributes articles on "Atrophy and Hypertrophy of the Brain,"

"Disease of One Lateral Half of the Spinal Cord," and "Progressive Labio-glosso-laryngeal Paralysis." With Dr. James Hendrie Lloyd, Dr. Mills again contributes two articles, on "Tumors of the Brain and its Envelopes," and "Tumors of the Spinal Cord and its Envelopes." In the first is a table of one hundred cases of brain tumor, and in the second a table of fifty cases of tumor of the spinal cord. The exhaustive paper on "Infantile Spinal Paralysis" is from the pen of Dr. Mary Putnam Jacobi. Dr. Francis T. Miles, of Baltimore, contributes an interesting article on "Diseases of the Peripheral Nerves." In his article on "Neuralgia" we are glad to note the value which Dr. James J. Putnam gives to large doses of quinine, especially when the element of periodicity can be noticed. The concluding article is by Dr. M. Allen Starr, on "Vaso-motor and Trophic Neuroses," this rather obscure subject being handled in a satisfactory manner, considering the little that is actually known.

ILLUSTRATIONS OF UNCONSCIOUS MEMORY IN DISEASE, including a Theory of Alternatives. By CHARLES CREIGHTON, M.D., 8vo., pp. xv—212. New York: J. H. Vail & Co. 1886.

The typography and binding of this book are good. There seems to be no good reason, however, why they should have been applied to this particular book, which has nothing else to recommend it. What little of good there is in it may be much more conveniently found in other works. Its absurdities sometimes rise to the ridiculous, and thus become amusing.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

HEALTH IN MICHIGAN FOR OCTOBER, 1886.—For the month of October, 1886, compared with the preceding month the reports indicate that diphtheria, bronchitis, and scarlet fever increased, and that diarrhoea, dysentery, cholera morbus, cholera infantum, decreased in prevalence.

Compared with the preceding month, the tempera-

ture in the month of October, 1886, was considerably lower, the absolute and the relative humidity, and the day and night ozone were less.

Compared with the average for the month of October, in the years 1879-1886, cholera infantum was more prevalent, and intermittent fever, remittent fever, typho-malarial fever, pneumonia, consumption of lungs, and bronchitis were less prevalent in October, 1886.

For the month of October, 1886, compared with the average of corresponding months for the eight years 1879-1886, the temperature was about the same, the absolute humidity was slightly lower, the relative humidity was the same, and the day and the night ozone were more.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of October, 1886, at sixty-three places, scarlet fever at thirty-eight places, typhoid fever at forty-three places, measles at six places, and small-pox at one place.

Reports from all sources show diphtheria reported at six places less, scarlet fever at eight places more, typhoid fever at seven places less, measles at five places less, and small-pox at two places less in the month of October, 1886, than in the preceding month.

MEDICAL ASSOCIATION OF CENTRAL NEW YORK.—The nineteenth semi-annual meeting of this Association will be held at Rochester, on Tuesday, Nov. 16, at 10 o'clock A.M., under the Presidency of Dr. J. P. Creveling. All members of the county societies in jurisdiction are invited to be present, and participate in the work.

The following proposed amendment to Article 2 of the constitution, offered by Dr. Kendall at the last semi-annual meeting will come up for action:

Article 2.—The Association shall hold an annual meeting on the third Tuesday of May, which shall be held in Rochester and Syracuse on alternate years.

The officers of the Society shall have power to call a special meeting either at Rochester or Syracuse, at any time should circumstances demand such meeting.

The following papers are promised:

Details of Gynecological Treatment, by H. W. Streeter, M.D., Rochester; *Scarlet Fever and its Treatment*, by Wm. B. Alley, M.D., Nunda; *Four Cases of Lapero-Hysterectomy*, Ely Van de Warker, M.D., Syracuse; *Nephro Lithotomy*, W. S. Cheeseman, M.D., Auburn; *Tinnitus Aurium in General Practice*, M. A. Veeder, M.D., Lyons; *Pregnancy Nephritis*, E. R. Armstrong, M.D., Holley; *The Dangers Attending the Prolonged Retention of the Tracheotomy Tube*, J. O. Roe, M.D., Rochester.

J. N. ARNOLD, *Secretary*.

INTER-STATE NOTIFICATION IN INFECTIOUS AND CONTAGIOUS DISEASES.—In addition to the resolutions presented by the National Conference of State Boards of Health and adopted by the American Public Health Association, the following from the Advisory Council of the Association were also adopted.

WHEREAS, it is necessary for the protection and preservation of the public health that prompt infor-

mation should be published of the existence of cholera, yellow fever and small-pox.

1. *Resolved*, That the American Public Health Association believes it to be the duty of each State and provincial board of health within whose jurisdiction one of these diseases shall appear, to give immediately notice of the existence of the same to neighboring State and provincial boards of health, and to the boards of towns and cities in neighboring States and provinces which have no central board. In such States and provinces this duty of notification lies upon the local boards.

2. *Resolved*, That it is the sense of this Association, that whenever rumors of the existence of pestilential disease in a State or province prevail, and, upon application to the health authorities of said State or province, information respecting the truth of the rumor is refused, the health officials of another State or province are justified in entering the before mentioned State or province for the purpose of investigating and establishing the truth or falsity of such rumor.

In conducting the investigation, every reasonable effort should be made to cooperate with the health authorities of the locality.

3. *Resolved*, That a case which so nearly resembles one of the specified diseases as to raise a reasonable suspicion of its character, or a case in which concealment is attempted, ought to be reported as a suspected case, in the same manner as if the diagnosis were certain.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 30, 1886, TO NOVEMBER 6, 1886.

Major B. A. Clements, Surgeon, died Nov. 1, 1886, at Ft. Leavenworth, Kansas.
Major J. V. D. Middleton, Surgeon, ordered from Dept. Mo. to David's Island, New York Harbor.
Major A. A. Woodhull, Surgeon, ordered from David's Island, New York Harbor, to Dept. Mo.
Major J. W. Williams, Surgeon, ordered from Dept. Col. to Dept. East.
Capt. J. K. Corson, Asst. Surgeon, ordered from Jefferson Bks., Mo., to Dept. Col., upon expiration of present leave of absence.
Capt. H. S. Turrill, Asst. Surgeon, ordered from Dept. Platte to Dept. Col.
First Lieut. Benj. Muntlay, Asst. Surgeon, ordered from Dept. Col. to Jefferson Bks., Mo. (S. O. 252, A. G. O., Oct. 29, 1886.)
First Lieut. Wm. O. Owen, Jr., Asst. Surgeon, relieved from duty at Ft. Schuyler, N. Y. H., and ordered for duty as Post Surgeon, Plattsburg Bks., N. Y. (S. O. 170, Div. Atlantic, Oct. 29, 1886.)
First Lieut. Guy L. Edie, Asst. Surgeon, ordered from Ft. McIntosh, Texas, to Post of San Antonio, Tex. (S. O. 152, Dept. Texas, Oct. 27, 1886.)
First Lieut. H. S. T. Harris, Asst. Surgeon, ordered from Post of San Antonio, Tex., to Ft. Clark, Tex. (S. O. 152, Dept. Tex., Oct. 27, 1886.)

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING NOVEMBER 6, 1886.

Neilson, J. L., Surgeon U. S. N., ordered to the receiving ship "New Hampshire."
Drennan, M. C., Surgeon U. S. N., detached from receiving ship "New Hampshire" and granted one year's leave.

THE TREATMENT OF ANAL FISTULA ASSOCIATED WITH PHTHISIS.¹

BY E. E. GLOVER, M.D.,

OF TERRE HAUTE, IND.

The surgeon who operates in the phthical subject for fistula *in ano*, is almost certain to be placed in an embarrassing and false position if his patient makes a slow recovery. Excellent practitioners will often believe that there has been meddlesome interference, and with apparent justice, since authors in treating of fistula in conjunction with phthisis have generally taught that operative interference is unwise, as certainly resulting in injury to, or often hastening the death of the patient. This opinion has been strengthened by the fact that this has been held as an axiom of both professional and popular belief from an early day, and is probably now held by the majority of physicians. While a firm adherent to the belief in the value of operative interference in proper cases, it has been my intention to examine this subject and to impartially state the conditions of the present belief and practice of those of greatest experience; believing that by such a course I can better carry conviction than by a mere statement of personal opinion and experience. To this end I addressed letters of inquiry to members of the profession, and have been favored with a response so general, so widely distributed, and from many of such professional eminence, that it is but just to say that it reflects the views held at present by the representative men of the profession in the United States. In only one instance do I give the opinions of a foreign surgeon. Mr. Allingham, the distinguished rectal surgeon of St. Mark's Hospital, London, has given his views, and being of more recent date than his published writings, I do not feel that they should be suppressed.

The exact number of cases reported cannot be given, many having kept no notes, but can be safely placed at above 2000.

Question 1—Were you satisfied with the results in these cases? This is answered in the affirmative by D. Hayes Agnew, John Ashhurst, Jr., John H. Brinton, J. Solis-Cohen and S. W. Gross, Philadelphia; Robert Battey, Rome, Ga.; R. B. Bontecou, Troy,

N. Y.; R. Beverly Cole and Levi C. Lane, San Francisco; George J. Cook and Joseph Eastman, Indianapolis, Ind.; Edward Borck, Geo. J. Engelmann, E. H. Gregory and T. F. Prewitt, St. Louis; Frank H. Hamilton, Charles B. Kelsey, Louis A. Sayre and J. Williston Wright, New York; Moses Gunn and Alfred S. Houghton, Chicago; Henry O. Marcy, Boston; C. H. Mastin, Mobile, Ala.; Jos. M. Mathews, Louisville, Ky.; Richard C. Moore, Omaha, Neb.; A. M. Owen, Evansville, Ind.; N. Senn, Milwaukee, Wis.; J. N. Taylor, Corinth, Miss.; Theodore R. Varich, Jersey City, N. J.; James T. Whittaker, Cincinnati, O.; J. S. Wight, Brooklyn, N. Y.

Edmund Andrews, Chicago, Hunter McGuire, Richmond, Va., W. F. Peck, Davenport, Ia., Thaddeus R. Reamy, Cincinnati, O., and J. C. Wilson, Philadelphia, answer, yes, as a rule. Borck: yes, and so were the patients. Varick: In every case benefit has resulted. Allingham: I have operated in many hundreds of cases with good results, due precautions being observed as to bad weather, constant cough, or far advanced disease. Sayre: I have operated on a very large number of cases who were far advanced in phthisis. In every instance the operation proved beneficial. Owen: I have been so pleased with the results of the operation, that I have much to say in its favor, and nothing against it. Cook: The reasons given for opinions in opposition to operating, are various and contradictory. Alex. Y. P. Garnett, of Washington: In the majority of those operated upon the result has been satisfactory, by the removal of a painful and suppurating ulcer, so situated as to render locomotion painful, and the sitting position uncomfortable. Brinton: I have not been dissatisfied; I believe the operation proper. Samuel Logan, of New Orleans, and J. Williston Wright: Yes, as I have not operated indiscriminately. Ashhurst: I have never seen any particular harm result from the operation. Engelmann: Perfectly so for the time being; anal trouble completely relieved, but rapid fatal termination of the disease followed. Charles Denison, Denver, Col.: I have never operated, but I have not been at all satisfied with the results in the hands of others. B. F. Swafford, Terre Haute, Ind., answers no.

Question 2.—Excepting where the cough is constant or where the pulmonary disease is either rapidly advancing or far advanced, do you think it advisable to operate in this class of cases? This is answered, I do, by Agnew, Allingham, Andrews, Brinton, Wm. Brodie, Detroit, Mich., Borck, Bontecou, Solis-Cohen,

¹ Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

Cole, Cook, Francis Delafield, New York, Eastman, Engelmann, Gunn, Hamilton, E. Fletcher Ingals, Chicago, Lane, D. A. Linthicum, Helena, Ark., McGuire, Mathews, Moore, Owen, Prewitt, Peck, Reamy, Sayre, T. G. Richardson, New Orleans, and John Roberts, Philadelphia. Wight, Wilson, Varick, and Taylor: Operate early and freely. Agnew: Always cure the fistula if you can. The only question I propose to myself in operating for fistula in consumptive cases, is the following: Are the reparative powers of the patient equal to the work of healing the wound? Believing as I do that such sores have no safety-valve or derivative effect-office by which disease is attracted from the pulmonary organs, I have no hesitation in recommending that they be cured as quickly as possible. Cook: The only question to me is, the nutrition of the patient. Gunn: Yes, my experience teaches me that the cure of a fistula is not contraindicated in patients with a predisposition to, or with actually present consumption, in its earlier stages, if the proper means are taken to combat such predisposition or disease. Marcy: I believe the rationale of the older views is untenable, and because a man is afflicted with one disease to refuse to cure him of another is as irrational as it is cruel. Delafield: My own belief is, that two diseases are worse than one. Wright: Yes, on the ground that phthisis alone is better than phthisis and fistula combined. Solis Cohen: The operation is indicated on the general principle of relieving any source of irritation amenable to interference. I have not met with any unfavorable results. Kelsey: I believe it to be a safe rule to operate upon phthisical patients as upon others, being led by the idea that one exhaustive disease is better than two. No cautious practitioner would think of operating in either rapidly advancing or far advanced lung trouble. Cook: I have never yet had occasion to regret an operation, but have seen very great benefits result from checking the discharge. Ingals and Wright: Yes, the patient is more comfortable. Brodie: I can see no objection to operating if the patient has phthisis. Gregory: If the fistula give much discomfort I operate. I always operate when the disease annoys the patient. I should treat as under ordinary circumstances. Ashhurst: I do not operate unless the distress and annoyance from the local affection are greater than from the constitutional condition. Senn and Whittaker: If the disease is attendant with pain and discomfort.

Dr. Andrews says: If the irritation and discharge be slight, and the patient is liable to die in a year from phthisis, there is no very strong motive to submit to an operation. There is no ground on which one can strongly urge an operation to a phthisical patient. Battey: If the patient is suffering locally, yes—if not—no. Logan: Yes, but not where fistulous sinuses are very numerous or extensive, especially if the patient be weak. Garnett: I would not advise surgical interference in the early or incipient stages of phthisis, unless the local trouble occasion great inconvenience and pain, the chief object of the operation being to remedy these. Gross: My rule of practice has been to operate if the lung symptoms

were slight, and the fistula gives rise to much annoyance or local distress. Allingham: I consider recklessly operating very harmful, the wounds will generally heal, but the low reparative power makes healing a lengthy process; breaking down of the parts often takes place. The cough I consider very harmful, as this occurs in or during other conditions not phthisical. Matthews: It must be born in mind that there is a vast difference in fistulæ. Some may exist for years even in consumption, and cause but little distress, others are progressive and destructive, and if left alone will do incalculable harm in a very short time. Again, a very small sinus, if situated in proximity to the sphincter, will cause great pain that can only be relieved by an operation. Marcy: I have for years advocated and performed operations for the cure of fistula in consumptives. Devitalization by disease renders one a poor subject for surgical repair. Nevertheless, I have, as a rule, seen tuberculous subjects operated on do well and improve generally after being cured of another and a serious infirmity; locally a cause of suffering and a drain upon the health. Denison, Roberts, and Swafford, answer, I think not.

Question 3. Do you think that you would operate in cold or damp weather, when the patient must be confined to his room? Andrews, Brinton, Solis-Cohen, Eastmann, Houghton, Owen, Roberts, Swafford, Senn, Varich, Whittaker and Wilson answer: I would operate at any time. Bontecou and Gregory: Should not be very particular as to the time. Garnett: The weather would not enter into consideration with me as an important factor, except that of extreme heat. Andrews: Yes, better confine him for a few days anyhow. Gregory and Reamy: Yes, if the case demanded immediate relief. Mastin and Wright: I would prefer to wait for good weather, in order to avoid the dangers incident to confinement in such cases. Cole and Cook: In winter I would prefer to wait until spring. Borck, Cohen, Linthicum, McGuire, Peck, Prewitt, Taylor and Wight: I would prefer clear dry weather. Mathews: If it was a progressive one and caused great pain and inconvenience, I would operate with this disadvantage present. Roberts: I think not. Logan: Not as a rule. Allingham, Battey and Engelmann: No, I would not.

Question 4. Will the wounds heal in nearly every case? If not, why? From low reparative power, because of the concussion from coughing or what reason? Andrews, Allingham, Battey, Bontecou, Borck, Brinton, Cole, Cook, Eastman, Engelmann, Gregory, Garnett, Hamilton, Houghton, Ingals, Mathews, Mastin, McGuire, Moore Owen, Prewitt, Peck, Reamy, Sayre, Senn, Taylor, Varich, Whittaker, Wilson and Wight, answer, yes. Battey and Sayre: Yes, it has never failed me. Bontecou and Logan: Unless the patient is reduced too low. Engelmann: They seem to heal as well as in other cases, especially if the operation is done antiseptically. Senn: Yes, if the operation is thoroughly done. Owen: I have had several cases where the cough was so constant that sleep was not known without opiates, that were relieved by the operation. Kelsey: Cough

when violent and frequent is a decided contra-indication, interfering as it does, very certainly with the healing of the wound. Ingals: Yes, when done early in the disease. McGuire: The wound is healed kindly unless the disease is advanced and the powers of life low. Allingham: They heal slowly, but generally heal in my cases. Hamilton: They heal slowly. The fact is, there is some danger that they may never be made to heal. Cook: I think that there is but one question to decide in order to determine the propriety of an operation; that is the question of nutrition. If the nutrition is good it will, and the operation will be a benefit to the patient not only as to the local distress, but also as to the general health. Garnett: The wounds in all the cases, that have come under my observation have healed but one. Where the disease is far advanced and a cacoplastic condition of the fluids exist, one may reasonably expect the reparative process to be imperfect and difficult. Gross: A failure to heal depends first upon the low reparative power, and secondly upon the fact that the tissue lining the fistulous tract is tuberculous. Linthicum and Reamy: If retarded, I think first, because of the impaired vitality, but oftener from concussion of coughing. Mastin: I always try to allay the cough before operating. Andrews: Sometimes will not heal in consequence of tubercles about the rectum slowly ulcerating away. Ashurst: The wound is apt not to heal. Denison: The wounds will not heal readily. Kelsey: The sphincters should be interfered with as little as possible, as they are apt to be weak at the best. Allingham: The muscles should not be divided; they almost never want it. Andrews, Cook, Engelmann, Garnett, Gregory, Logan, Mastin, Sayre and Taylor, answer that they do not often fail to unite.

Question 5.—That the suppression of the discharge is positively beneficial? Is answered I do, or yes, by Brodie, Bontecou, Brinton, Solis-Cohen, Cole, Cook, Eastman, Houghton, Logan, Mathews, McGuire, Owen, Prewitt, Senn, Taylor, Varick, Whittaker, Wilson and Wight. Brodie, Varick and Wilson would operate on the general principle that they would close another drain on the constitution and thereby save strength. Reamy: I believe so. Roberts: Don't know that it has any effect. Sayre: I am positive of the fact. Wright: Indirectly, yes, by relieving the system of one source of irritation and exhaustion. Hamilton: The purulent discharges in these cases are often excessive and exhausting, and the continuance of the fistula provokes intestinal irritations causing tenesmus and diarrhoea. Peck: Yes, in favorable cases. Gregory: I suppose it advantageous. Mastin: Not beyond the local comfort of the patient. Linthicum: In advanced cases I think not. Borck: As far as comfort concerns. Allingham and Swafford: I cannot say this. Andrews: The discharge is usually too small to have a perceptible effect, but suppression of large discharges is beneficial. Battey: Doubtful. Garnett: The discharge, unless excessive or profuse, should in no case be arrested after the disease is fully established, unless precaution be taken beforehand of establish-

ing a seton or issue in the arm or some other eligible point, as a substitute for the conservative irritation exerted by the suppurating fistula. This plan I have invariably adopted. Blisters, setons and issues demonstrate in our daily practice this compensative sympathy which binds the intricate parts of the human system enabling each to coöperate, under certain conditions, in conserving the whole and maintaining its integrity. Hamilton: If there is any probability that the fistula has served a useful purpose as a derivative, it is much better to place an issue in the arm or in some other part of the body, rather than permit the continuance of the fistula. Linthicum: I would make an issue somewhere in the neighborhood of the diseased lung, keeping it open at least until the wound healed, in order to prevent a sudden termination from the fistula to the lung. Reamy: Modern views as to etiology and pathology of phthisis render the old views of benefit from counter irritation impossible. On the contrary, it can only exhaust strength, and hasten the fatal issue. Sayre: The suppression of the discharge will never increase the pulmonary trouble if you put an issue in the arm or some other part of the body, in cases in which it is necessary. Cook: When phthisis becomes worse after an operation, I believe it is not checking the discharge which causes it, but generally is an improper or careless treatment of the patient before, during, or after the operation. One who has phthisis is very sensitive to changes which others would not notice. It is strict attention to the details of treatment, both general and local, that brings success in these cases. Kelsey: Only once has it happened to me to see the cure of fistula followed by a marked increase of the lung trouble; and even in such a case the relation between the cause and effect cannot be established. Engelmann: I have seen it apparently increase the pulmonary trouble. Denison and Rochester: Have seen injurious and even fatal results follow the suppression of the discharge, but in the hands of others.

Question 6.—That the operation tends to retard or arrest the progress of the disease and to prolong the life of the patient? Battey, Bontecou, Brodie, Solis-Cohen, Cook, Eastman, Houghton, Kelsey, Linthicum, Mathews, McGuire, Moore, Owen, Prewitt, Reamy, Roberts, Sayre, Senn, Taylor, Varick, Wight and Wright answer, I do. Sayre: I am certain it does. Hamilton: It often does. Peck: Yes, in favorable cases. Moore: Have undoubtedly seen life prolonged by the operation. Wight: Retards as a rule. Mathews: I do, for the reason that if a good result is obtained, a great drainage is stopped, and also that nervous irritation ceases. Battey: Yes, as the patient is thereby enabled to take air and exercise. Agnew and Allingham: Retards if proper precautions are taken. Hamilton: It has happened to me in several instances to witness a marked improvement in the general condition of tuberculous patients when a cure of the fistula has been effected. Garnett: I do not believe that the operation exerts any influence in regard to arresting the disease, unless the discharge be excessive. In that event the arrest of it could negatively check the progress of the dis-

ease. Cole: It may retard but not arrest the disease. Reamy: Yes, I am of the opinion that any suppurating point, as a fistula in ano, may serve to drain away the vitality of the patient, as well as act as a nidus of distribution for the bacilli of tuberculosis. Senn: Yes, but not in all cases. Mastin: Indirectly, by removing a source of annoyance which lessens the powers of resistance by lowering the vital forces. McGuire: Tends to retard the progress of the disease, as prolonged suppuration provokes tubercular disease. Brinton and Sayre: I think it retards the disease, inasmuch as it improves the general health by removing one source of drain, and places the patient in a better condition to arrest the main disease, phthisis. Logan, Prewitt and Wilson: To the extent that it removes one cause of general debility. Whittaker: The fistula in this case falls among the local expressions of tuberculosis, every one of which should be treated and cured if possible. Gross: In confirmed cases of tuberculosis of the lungs the fistula rarely heals unless the entire tuberculous granulative tissue be thoroughly removed by the knife or spoon. Senn: I consider the local trouble tubercular in such cases, and would urge thorough removal of granulations with sharp spoon and actual cautery, and to always use Paquelin's cautery in place of the knife. In all cases except where the pulmonary disease is far advanced and the patient debilitated, I would operate, believing that operation adds to length of life and comfort of patient. McGuire: The organized matter lining the fistula should be cleanly cut away and the wound closed when it is practicable, with sutures, and union by the first intention obtained if possible. It can often be done. Gunn: The cure of the fistula is one of the means to be resorted to as an aid to such cure. If associated with proper means to combat the predisposition or disease, the cure of the fistula enhances the prospect of a cure of the consumptive patient. Owen: I regard it as a valuable preventative means. Richardson: Patients seem to improve after the closure. Roberts: Retards so far as it relieves the source of discomfort. Wright: Only in an indirect manner, viz: by relieving patients of one source of much distress or annoyance. Borck, Gregory, Swafford and Wilson: Cannot say. Bontecou: I do not think the operation has any influence on the pulmonary disease, except making the patient more comfortable. Whittaker: No effect upon it. Andrews: There is no substantial proof of it. Theoretically one would expect it to do so slightly. Engelmann, Ingals, Mastin, Peck, Roberts, Senn, and Taylor: I think not; or no. Denison and Richardson: No; life is shortened.

The answers seem to indicate that phthisical patients are less predisposed to fistula than is commonly believed. With reference to rapidly advancing cases or in the advanced stages of phthisis the general opinion is, that interference is unwise and that the life of the patient is often actually shortened. This is expressly stated by Allingham, Ashhurst, Cole, Kelsey, Linthicum, Marcy, Mastin, Prewitt, Swafford, Varick, Wight, and others. Senn, while recognizing this, says he would operate if the local

trouble gave rise to much discomfort and suffering.

Under the head of general remarks Roberts says: I am inclined to think that the refusal to operate is founded upon unproven tradition. Marcy: I am very glad that you are seriously discussing the subject, since the great mass follow rules of dictation rather than independent reason. Brinton: I think that the surgeon should try and weigh probable ill and favorable results, and in proper cases give the patient the best chance. Sayre: My rule is to operate on all cases as soon as the trouble is discovered. The longer the operation is delayed the worse it will be for the patient. I would suggest to dry up all exhausting discharges, and remove all sources of constitutional irritation, so as to improve the general health in all phthisical patients.

Cook: As anal fistula is only a tubular ulcer, differing in no respect as to the discharge from it, and the effect of this on the system, from an ulcer on any superficial part with a like extent of surface, I cannot understand why it should be viewed with superstition. We do not find physicians refusing to attempt to heal any other drain or discharge from the body. Houghton: I regard all rectal trouble located on or near one of the sphincters as operating reflexly through the sympathetic system, in a most injurious and often in a varied manner similar to cervical and urethral reflex irritants. This seems to me sufficient reason for their removal. Denison: The fistula will heal or the discharge lessen in a cool, dry and elevated climate, such as is known to arrest pulmonary phthisis. Under proper treatment of the lung disease the fistula heals itself, as in two patients of my own.

General Summary.—Operative interference is advised and practiced with benefit to the patient excepting, 1st, where the cough is constant, unless this be first allayed; 2d, where the pulmonary disease is either rapidly advancing, or is far advanced; 3d, where the reparative powers of the patient are so low that they evidently are unequal to the task of healing the wound.

Although it is proper to operate during any season, preference should be given to pleasant weather, such as will allow the patient to be in the open air.

Where the tissue surrounding the fistulous tract is supposed to be tubercular, some advise its removal by the knife or sharp spoon.

The wounds heal in nearly every case in which an operation is justifiable. There should be as little interference with the sphincter muscles as possible.

The suppression of the discharge is thought to be positively beneficial.

It is recommended by some that where the discharge is supposed to have a beneficial derivative effect, that a seton be inserted in the arm or other eligible part, before operating on the fistula.

It is believed that a successful operation tends to retard the progress of the disease, and to prolong the life of the patient.

There are many cases in which this question presents itself as a subject of vital importance, and one upon which all the experience of the profession should be thrown, that the disputed points may be cleared

up and the method of treatment placed upon a clearly defined basis. I believe that the matter contained in this paper, and the conclusions deduced therefrom, may contribute to this end.

DR. JOHN B. JOHNSON, of St. Louis, in discussing the paper, said that he had in mind a number of cases where the tubercular process was hastened or aggravated by the cure of the fistula in ano, and that the tuberculosis was not a local disease, but affected the follicles of the mucous surface of the digestive tract. He considered operation not justifiable in advanced phthisis.

DR. J. McF. GASTON, of Atlanta, thought there was no doubt about the salutary effect of operative treatment.

SOME OF THE COMPLICATIONS OF STRANGULATED HERNIA.¹

BY R. HARVEY REED, M.D.,

OF MANSFIELD, OHIO.

I will not presume on the intelligence of the members of this Association by unnecessarily occupying time in giving the history, anatomy, or even a description of this comparatively common operation, which is doubtless familiar to us all. There are few cities in America at this time, that have not one or more surgeons who can show a record of successful operations for strangulated hernia, and who are perfectly familiar with every step in this important operation. Hence I shall confine myself to a report of some of those complications which may arise in the path of any surgeon who seeks to relieve his patients of this dreaded malady by operative interference, as illustrated by a few cases that have come under my notice.

C. S., æt. 30, a vigorous, strong, muscular stone-mason. I was called in consultation with a physician of one of our neighboring towns on April 16, 1885, and found that about nine years previous to this attack, a hydrocele had made its appearance on the right side, which had subsequently been tapped and temporarily relieved. About the time the hydrocele made its appearance the right testicle was observed to be enlarging; this continued for some time, until it became more than twice its natural size, and remained so from that time on. On examination, it was found to be hard and of a fibrous character, was not painful, was adherent to the surrounding structures, and was to a great extent immovable, either voluntarily or otherwise. On further examination, he was found to have a large hydrocele on the right side, and a strangulated complete inguinal hernia.

Neither the patient or the attending physician had any knowledge of the existence of a hernia prior to his present illness, nor, in fact, then, until he commenced stercoraceous vomiting some ten or twelve hours before. After a fruitless attempt at reducing the hernia, I tapped the hydrocele and drew off over a pint of water, after which the hernia was reduced

by taxis, dressed with a spica of the groin, and the patient was given an anodyne, and rest in the recumbent position enjoined.

Very much to our surprise, we were informed the next day that the patient was no better, but, on the contrary, was still vomiting fecal matter, and gradually getting worse, owing to which they desired me to come and see him. Being so engaged as to make such a visit impossible at the time, I requested my friend, Dr. J. Harvey Craig, to go in my place. He found the hernia down, returned it without much trouble, and dressed it as before.

On the third day the same message was repeated, and we were again requested to visit him. By this time the case had become unusually interesting, and, in company with Drs. J. W. and J. Harvey Craig, I again visited the patient and held a consultation with his attending physician, only to find the same apparent condition as had previously been existing. We again reduced the hernia, and advised the attending physician to be vigilant in keeping it reduced, by carefully watching the compress and bandages, in the belief that that would give him the desired relief. Such was not the case; for the vomiting did not abate in the least, and on the fourth day the same message was repeated as before. Accompanied by Drs. Craig, Sr. and Jr., I again visited the patient and found the hernia protruding as before, which, owing to his incessant vomiting and straining, made it almost impossible to keep reduced. After a careful examination, it was agreed that some concealed difficulty of the bowel existed, and that an operation to discover and relieve it was in order.

Dr. J. W. Craig being the senior surgeon, performed the operation. The incision was made along the line of the inguinal canal, from Poupart's ligament to the internal ring, and the parts carefully dissected up until the inguinal canal was exposed, but no strangulation was found. The finger could be easily passed into the abdominal cavity through the internal ring, but no constriction could be found; the opening was enlarged sufficiently to admit of a careful examination of the condition of the small intestines, which were found normal. On further examination, however, it was discovered that the ascending colon had been dragged down further than usual, until the lower end of the vermiform appendix had escaped through the opening of the femoral ring and become strangulated at a point where it passed Gimbernot's ligament. When released it was found to be swollen to the size of a man's thumb, and very much discolored; so much so as to raise the question as to the propriety of removing it. But the gradual return of its natural color soon settled that question, and it was replaced in the abdominal cavity, and the wound carefully cleansed and closed. The operation was conducted and the wound dressed under antiseptic principles. The wound healed rapidly, and the patient made a perfect recovery without a single bad symptom, and returned to his usual occupation feeling as well as ever, excepting as to the hydrocele and the enlarged testicle. The former having been tapped twice since the operation, the last time being since the preparation of this report had been begun.

¹ Read in the Section on Surgery at the Thirtieth Annual Meeting of the American Medical Association.

It will be observed, the complications in this case were: 1, a hydrocele; 2, an enlarged and adherent testicle; 3, an obscure femoral hernia, consisting in the escape of the vermiform appendix with strangulation of the same, accompanied with all the symptoms of complete obstruction of the bowel, which, not being observable externally, was rendered doubly obscure by the existence of a complete inguinal hernia, which was supposed to be the source of all the trouble. Having had the continued symptoms of strangulation for four days, notwithstanding the inguinal hernia was reducible, and no other tumor was visible, we were confident of the existence of an obstruction of some character existing in the bowel, and felt that we were justified in laying open the inguinal canal and searching for the obstruction and removing it if possible.

In vol. i, page 490, Professor Agnew says in his "Surgery": "Should symptoms of strangulation be present without any visible tumor, and there be grounds to suspect the existence of a concealed, or an incomplete inguinal hernia, the surgeon should have no hesitation in laying open the canal in order to verify or to disprove its existence."

It was my fortune to witness an operation, by our honorable chairman, for strangulated hernia, on March 30, 1885, in the Milwaukee Hospital, a full report of which Dr. Senn has kindly furnished me for this paper:

Mr. W., æt. 35, a business man, had an old inguinal hernia which had been repeatedly strangulated, and reduced by various surgeons. For twelve years the omentum has been adherent to the entire surface of the sac. The patient was etherized, and the parts cleansed with a 5 per cent. solution of carbolic acid. A vertical incision was made, extending the length of the tumor and down to the sac, which was opened, exposing the omentum. The omentum being torn from the adherent surfaces, which included the right spermatic cord, necessitated the removal of the right testicle. After the cord was tied and cut, the omentum was ligated with a catgut ligature, which was passed through the tissue, then cut, making a double ligature transfixing the stump. The omentum was then cut off, the stump sutured with catgut to the edges of the internal ring, and the hernial sac dissected out. The parts were trimmed off, leaving enough to cover the stump, and sewed together with fine catgut. The external wound was then closed by sutures, a drainage-tube introduced into the scrotum, a full Lister dressing applied, and the patient kept at rest in bed. With the exception of a slight pain in the cord, a small rise of temperature for the two following days, the patient experienced no discomfort, and was discharged from the hospital on the 20th of April, just three weeks after the operation, perfectly well.

In this interesting case, it will be observed, there was both escape of the omentum and intestine, with marked adhesions of the former, involving the cord and necessitating the removal of the testicle, and protruding parts of the omentum, producing complications of a complex character.

In 1878 I was called, in company with a colleague,

to operate a young man who had a congenital scrotal hernia, which had become strangulated. The young man was about 21 years of age. Previous to this had enjoyed good health, and, with the exception of a congenital hernia for which he had never worn a truss, was a strong, muscular fellow, and used to "roughing it." The ordinary operation for strangulated hernia was performed, the patient making the usual progress in his recovery, with but slight trouble. But, notwithstanding our repeated instructions as to care and diet, he had several relapses after convalescence had set in, by eating bologna sausages, pretzels and cheese, drinking beer, and finally attempting to wheel brick on a wheelbarrow, before the external wound had closed entirely, and without any other support than that afforded by the compress and bandages, which resulted in tearing open the external wound for an inch or more, and in producing a small perforation of the protruding small intestine, with a discharge of the contents of the bowel externally. I dressed the wound, by thoroughly cleansing it with iodized water, closed the wound of the intestine with a fine silk suture, and after carefully replacing the bowel in the abdominal cavity, closed the external wound with interrupted sutures, and allowed it to heal by granulations; meanwhile keeping it cleansed with iodized water, well drained, enforcing quiet and a rigid diet on the part of the patient. He made a rapid and complete recovery without any further bad symptoms. In this case, the only complication arising in the case came on during convalescence, and was the result of carelessness on the part of the patient and friends.

Similar complications may occur in a country practice, where the surgeon has not the advantage of hospital nurses, and often the inconvenience of poverty to contend with, combined with ignorant and careless nurses, who either fail to realize or neglect to heed the surgeon's advice. While the operation for ordinary strangulated hernia is comparatively a common one, and when performed under ordinary circumstances, before it is too late, the prognosis may be considered quite favorable, yet the chances of complication are always possible, and when they do occur, the urgencies of the moment are generally great and more or less perplexing.

PEMPHIGUS CONJUNCTIVÆ.¹

BY WILLIAM DICKINSON, M.D.,

OF ST. LOUIS, MO.

Mr. White Cooper recorded the first case in England in Vol. I of the "Royal London Ophthalmic Hospital Reports." At that time about twenty cases only had been recorded by Continental writers. Mr. Lang, of London, has recently reported two cases, which are briefly recorded in the *Ophthalmic Review*, December, 1885. Stelwag, in 1870, von Graefe, in 1878, and Steffan, recognized this affection, and have written on the subject. Dr. James A. Campbell, of

¹ Read in the Section on Ophthalmology, Otology and Laryngology at the Thirty-Seventh Annual Meeting of the American Medical Association.

this city (St. Louis), met with a case of pemphigus conjunctivæ, of which he published an account in a monograph in 1878.

On account of the rarity of this affection I am induced to report the following case, it being the first that has occurred in my practice, now embracing a period of thirty-five years.

Case.—Mrs. A. B., of *petite* figure and generally enjoying good health, applied to me in 1880 for glasses to enable her to read readily. She was then quite presbyopic, being 56 years of age, and required convex glasses $\frac{1}{2}$. There was at that time also a minute circumscribed opacity at the centre of the anterior capsule of the lens of the right eye.

In June, 1885, she applied to me for treatment of the present affection, and gave the following history, viz: "I am a widow, the mother of several children; a teacher for forty years; have never had any affection of the skin, either general or local; have experienced much sorrow by the loss by death of children and from other causes. In 1883, when in the country, both eyes became severely inflamed, and were treated by a discreet physician of the place; after treatment of five or six weeks they recovered to a good degree, but still they have troubled me very much ever since, not being able to bear strong light, and eyes often filling with water, especially during the last year. In February of the present year (1885) my eyes became much worse, more red, inflamed and watery. My family physician gave me drops to use. The left eye became first affected, and the disease seemed to locate at the inner corner, presenting a large red spot, and causing severe pain. Water blisters at the same time appeared on both upper lids. Applied flax-seed poultices. After a time the severe pain subsided, but the redness at the inner corner remained. In April (1885) I consulted an oculist in this city (St. Louis) for this affection, having at that time large water blisters on both upper lids and also on the edges. He let the water out and gave me a white salve to apply. Ordinary light was then troublesome, rendering it impossible for me to look upwards. I remained under his treatment for two months, during which time there were several alternations of water blisters occurring on the upper lids, and recoveries. The redness at inner corner of left eye somewhat disappeared, it assuming a whitish color. I do not know whether the doctor knew what was the real matter with my eyes, at any rate he did not tell me, but repeatedly assured me that I should get well. At this time the lower lids began to turn in, and the lashes to rub and irritate the eyes. The eyes then watered more than before." At the instance of a mutual friend she at this time consulted me, presenting herself first about June 25.

Present appearances.—Both upper lids drooped; a very considerable degree of photophobia and lachrymation were present; also entropion of the lower lids to some extent, and consequently trichiasis. Not only the inverted normal cilia thus irritated the globe, but also numerous fine cilia which had abnormally developed along the inner margin of the lids. The vessels of the entire sub-conjunctival tissue were

highly congested. A large and wide fibrous band of whitish color, evidently cicatricial in character, was seen at the globe at the inner canthus, resembling a broad pterygium, and extending nearly to the margin of the cornea. It had all the physical characters of a cicatrix, seen as a sequela caused by some powerful escharotic. She stated, however, that nothing of the kind had ever come in contact with the eye. The punctum and canaliculus of the left lower lid were contracted; this condition was much relieved by the introduction and passage of Bowman's probes.

Having contemplated a visit into the country, immediately after this first visit she left the city. She returned, however, much sooner than she had intended, on account of the progressive pemphigus, and again came under my observation in August. The general condition of the eyes was unchanged, except as intimated, aggravated in degree, *i. e.*, entropion, trichiasis, and their consequences, photophobia and lachrymation were much increased. For the correction of these irritating causes, on August 18 I removed an oval piece of the integument from the right lower lid, this being more inverted than the other. For a time this mode of rectification proved entirely effectual, the cilia assuming their normal position. Progressive contraction of the palpebral and the ocular conjunctivæ, however, nullified the advantages gained, but as a supplemental operation I removed small portions of the integument, oval in shape, the long diameter being vertical, and then by a firm suture approximated the opposite extremities. By this device the desired object was attained, which benefit remained only a short time, on account of the progressive contraction of the conjunctivæ alluded to. In the early part of the treatment I removed the cilia by evulsion, but in November I employed electrolysis for the destruction of the bulbs which secreted them.

About this time large blebs for the first time developed simultaneously on the integument of the upper lids. In no other locality on the skin did pemphigus appear. About December 1 a small vesicle invaded the conjunctiva of the right globe on the upper and inner aspect, and near the cornea, which soon assumed the character of an ulcer; this, by the use of the usual agents, healed kindly. Soon after this a large bleb appeared in the lower fornix of the left eye; after a few days this also healed, but left behind its peculiar sequel, cicatricial tissue. Afterwards there occurred a bleb on the conjunctiva of the R. E., which, passing through the usual stages, finally healed. In January a bleb developed on conjunctiva of left globe above the cornea, and simultaneously a small one on the ciliary border of the same lid. A few days before this date, however, she complained of great soreness of the throat and painful deglutition. Upon examination I found an aphthous looking spot, which may have been of the same nature as the general affection under consideration. This, however, quickly healed by the application of a five grain solution of arg. nit. On February 20, 1886, another bleb developed in the left eye, and simultaneously a small one on the margin of the left upper lid. Electrolysis was continued, whenever

the regenerated cilia had matured sufficiently to irritate the globes. This always afforded temporary relief. By means of galvanism I also endeavored to induce a more healthy degree of enervation and nutrition; one rephophore being placed upon the closed lid, the other being applied to the nucha, or over the site of the sympathetic ganglia in the neck, or held in the hand; and later I applied the one rephophore directly to the conjunctiva, having first rendered the membrane insensible by cocaine, hoping thereby to overcome the persistent tendency to the formation of vesicles. The results were, however, not very encouraging. Eserine was also employed for the diminution of existing congestion, but with no appreciable benefit.

On March 1 a large bleb formed on the upper and temporal aspect of the left globe; this extended to and invaded the edge of the cornea, and simultaneously one appeared in a symmetrical location on the right globe.

At this date the patient ceased attendance for reasons unknown; her present condition therefore can only be conjectured. The cornea not having been directly involved, vision was only indirectly impaired, except from the circumscribed opacity in right lens, as mentioned. The entire lens had become cataractous to some degree as also that of the left, but from senile causes. Strict diet and tonics of quinine and iron were exhibited throughout the period of treatment, and during the last three months arsenic was added. A collyrium also of boracic acid was used; and to the sites of the epithelial abrasions were applied mild solutions of arg. nit. and an ointment of the amorphous oxide of mercury.

"OPIUM ANTIDOTES," AND THEIR VENDORS.

BY J. B. MATTISON, M.D.,

OF BROOKLYN, N. Y.

If aught were asked for as to further proof of the widespread extent of opium addiction in this country, it could easily be given by citing the number of individuals engaged in vending the various nostrums, each of which, it is asserted, has the only true claim to merit as the one genuine, sovereign cure for this phase of human ill.

It is now about seventeen years since an illiterate bricklayer in a Western city—who made some pretensions to the healing art by virtue of a small stock of herbs stored in a little back apartment—was struck with the shrewd idea that in this peculiar field lay a mine which, perchance, might be worked to no little pecuniary profit. Acting on this impulse, the opiate mixture was compounded, advertising circulars vaunting the nostrum made their appearance, the aid of the press was secured, and business began. It grew apace, and the coffers of its enterprising projector expanded as the circle of his deluded victims widened, in their costly but luckless efforts for relief. It was not to be expected that this genius would long be permitted to enjoy a monopoly of such a stroke of fortune, and so, ere many moons

had waned, claimants for like honors put in an appearance—the rivalry between them being measured by extent of their pecuniary resources and fertility of advertising device. It proved a fatal attraction to more than one who had begun a legitimate medical career, and had taken obligations, binding as an oath could make them, to do right by their suffering fellows; but who ignored both personal and professional pledges in their greed for gold, and betook themselves to the camp of the common charlatan.

The reason is soon told. In every walk of professional life can be found those who, forgetful of duty, prove faithless to the right. Again, it seems an easy task to secure the aid of some portion of the press, both secular and religious, in furthering schemes of this sort; and, in one case of this kind, several medical journals, misled by the previous good repute of an individual who had allied himself with this disreputable band, placed their pages at command of a small fraternity engaged in furthering his scheme. To their credit be it said, however, that on being made aware of the situation, they promptly refused further publicity and, with two or three exceptions, editorially avowed their unintentional complicity, and thus freed themselves from the stain that threatened to smirch their journalistic apparel.

Another reason—and this, probably, the strongest—is the peculiar nature of this disorder, which impels its subjects to court privacy, and in every way secure themselves from public gaze. This feeling, which is largely the outcome of that mistaken opinion held by the laity—and, strange to say, some in the profession as well—that those who, by force of necessity quite beyond control, have become victims to opium, are simply the slaves of a vicious indulgence, deserving censure rather than charity: this feeling, we say, is the main cause of that desire for secrecy on the part of the patient so essential to the charlatan in this special field, and of which he cunningly takes advantage to his own financial good. In hope of escape, the habitué often spends much of both time and treasure to no purpose; and after months—or years, it may be—realizing it futile, he abandons further effort and berates himself for his folly; yet finds some consolation in the thought that no one else is aware of the course he has been pursuing. Proof of this fact is not needed, yet it may be noted one of these nostrum circulars is before the writer in which, among several asserted claims to special merit, is "absolute secrecy, even from nearest and dearest friends or relatives!"

It really is surprising that men of more than average intelligence, some of our own fraternity—again and again we have known such—will consign themselves to such keeping. Case after case has been under our care in which months and years of time, and hundreds of dollars had been expended on these nostrums without good. In many instances, doubtless, ignorance as to the make-up of these mixtures leads to their purchase, yet it would seem that every well-educated physician should be aware of their nature. Such, however, is not the fact; and so, with the hope that the reports given in this paper may be accorded as wide publicity as their value demands,

let it here suffice to say that, while great advance has been made in the knowledge of drugs and their uses, no agent has yet been discovered that will fully take the place of opium when once the system has become habituated to its use, and any individual making an assertion to the contrary may be safely set down as a knave or a fool.

Some time ago, the writer was requested by the editor of a well-known journal to prepare this exposé, and not long after, a letter was received from the gentleman who has made the main report here given, stating that he had been instructed by his State Board of Health to examine as many specimens of "opium antidotes" as could be secured, and asking my aid in making the list as large as possible. The result is appended, making, it is thought, the most extensive yet presented, and one which should suffice to convince every reader, who may have had any doubt, as to the true nature of these nostrums, and the "ways that are dark" of their vendors.

Before giving details, it may be of interest to note the *modus operandi* of these individuals. In every instance, an accurate statement as to the daily or weekly amount of opium or its equivalent used, is an absolute essential in their so-called treatment. As one says: "Be especially careful to determine accurately *how much* of the drug you use in twenty-four hours, or in every seven days, if preferred." The time of taking, "at what hours," is another point desired, and these being given, it is quite easy to prepare the mixture of such opiate strength as will give a certain amount of the habitual narcotic in each prescribed dose—this amount being exactly that of the previous taking. This done, the habitué is simply continuing his addiction under a new name, and care having been taken that the opiate shall be quite enough for his need, he trudges along, hugging the delusive hope that, in no very long time, he will reach his wished-for goal. The initial amount of the nostrum supplied is intended for one month's using. Then, the patient having become accustomed, it is supposed, to this new order of things, another supply is given for a similar period, differing from the first only in that the amount of opium is lessened with each succeeding month, and so the play goes on, until the patient, failing in his effort, becomes distrustful and betakes himself to some other specimen of the same genus, or else abandons the whole affair. The price per month of the nostrum depends mainly, of course, on the amount of opium it contains. Supposing an habitué to be taking one grain of morphia daily, it ranges from two and one-half to twenty dollars. Patients are urged to procure a "full course," several months' supply, in the outset, the reward for which is a more or less generous (?) reduction in the cost of the nostrum, and—though this is not very explicitly stated—a larger stock of shekels to the credit of the vendor.

The mock honesty of some of these charlatans is amusing. One writes: "I do not advertise or send out circulars, as there are hundreds of quacks who are doing such low and mean work, I have become disgusted!" Another—Stephens—says: "I am aware that there are heartless impostors, destitute alike of

position and principle, who are constantly endeavoring to entrap and victimize the anxious, and perhaps too credulous sufferer. The cunningly devised spurious recommendations of these swindlers are well calculated to deceive the unwary. *You will most certainly be swindled by trusting to their representations!*" Still another—Kane—speaking of the so-called "treatment" which he in common with others adopts, says, with an outburst of indignant virtue, it is "practised so shamelessly and heartlessly by charlatans in various Western and Southern States. It is very rarely successful." And again: "Another matter in this connection needs attention, viz.: the lying pretensions of a few charlatans who, by specious advertisements and deceitful lies, induce the victims to these habits to buy their medicines or come under their care for treatment. These sharpers are utterly without conscience, and do not scruple to prey upon and undermine the health of their victims in order to gain a few dollars!" and elsewhere he bewailingly remarks: "As I have before said, I cannot sufficiently deplore the action of those unscrupulous men who prey upon victims of the habit under the guise of physicians. These quacks are utterly without conscience, without a jot or tittle of honesty or honor, and go on bleeding their patients pecuniarily, from day to day, while deluding them with lying assertions and holding out false hopes!"

Some of these nostrums are nothing but disguised solutions of morphia. Several years ago, the writer read a paper on this topic before the Kings County Medical Society, and among the specimens presented one analysis, made by a competent chemist, resulted.

Water	28.66.
Glycerine	66.89.
Morphia	4.45.
	100.00.

The coloring was aniline. Others may contain quinine, strychnine, cannabis, atropia, hyoscyamia or other ingredient; but be the mixture what it may, the prospect of failure is vastly greater than that of success. For obvious reasons, no record of this appears in the array of reputed proof put forth by these pretenders. That is not in keeping with their assertions. The vast volume of failures is a sealed book of blasted hopes and vain endeavor. Through the kindness of Dr. Samuel W. Abbott, Health Officer and Secretary of the Massachusetts State Board of Health, whose courtesy is herewith admitted, the writer quotes from the last—1886—official report of that gentleman as follows: "One of the most evident proofs of an increase in the consumption of opium is the existence and growth of a considerable number of so-called 'cures' or 'antidotes' for the opium habit. These preparations are advertised broadcast in the public prints, and occasionally in professional journals, which should serve a better purpose. If these so-called cures were of a similar composition to the great mass of empirical remedies, but little harm would result from their use. This is not the case, however, with the preparations in question. With but one exception, the active ingredient in the so-called cures examined by the analyst proved to be

opium itself in one or another of its varied forms. The preparations of this character enumerated in the analyst's report were obtained, in all instances, either directly from the proprietors or from their authorized agents, and were accompanied with their published circulars.

"The purchaser of such preparations thus becomes the victim of a cruel fraud, under the supposition that he is obtaining a remedy or antidote, the article which he receives being simply the enemy in disguise against which he is bending his energies to obtain relief. This shameful practice deserves nothing but the severest condemnation. To the credit of Massachusetts, but few, if any, of these preparations are made within its limits.

"There is one notable exception to the above statement as to the presence of opium in these 'cures,' and that is the chloride of gold cure, a preparation sold at an exorbitant price, doubtless in consequence of its alleged precious component. Reference to the analyst's statement, however, shows that this article contains not even a trace of that precious metal. Further comment upon this fraud is needless.

"The circulars referred to as accompanying the 'cures' are omitted from this report. It is sufficient to say that their style is remarkably similar in their methods of securing and fleecing their victims, each one accusing the others of fraud, and publishing as endorsements the names of many prominent persons in various parts of the country. We have sufficient proof that in many instances such names were published without the least shadow of authority."

The nostrum samples we secured were examined by Dr. B. F. Davenport, State Analyst of the Massachusetts Board, and his report is appended:

"S. W. ABBOTT, M.D., HEALTH OFFICER:

"*Dear Sir* :—I have to report upon twenty samples of so-called opium cures which have been obtained from their proprietors. They have all been tested for the presence of morphine, and they have all responded to the usual reaction therefor, except the 'Keeley's Double Chloride of Gold Cure.' This one, however, gave no reaction for the presence of even a trace of gold therein.

"The 'cures' were all uniformly obtained as for one who had acquired the habit of taking the, for an opium-eater, very moderate quantity of only one grain of morphine per day. It was expected, as proved to be the case, that the 'cures' for even such a mild case would contain enough morphine to furnish unmistakable evidence of its presence, if they contained any at all. The twenty varieties of 'cures' were as follows:

"S. B. Collins, La Porte, Ind.; Mrs. J. A. Drollinger, La Porte, Ind.; W. B. Squire, Worthington, Ind.; P. B. Bowser, Logansport, Ind.; J. C. Beck, Cincinnati, Ohio; J. L. Stephens, Lebanon, Ohio; H. L. Baker, Toledo, Ohio; J. S. Carleton, Chicago, Ill.; L. Meeker, Chicago, Ill.; Wm. T. Phelon, Chicago, Ill.; L. E. Keely, Dwight, Ill.; H. H. Kane, New York City; Chas. C. Beers, New York City; Salvo Remedy Co., New York City; F. E. Marsh,

THE MEDICAL SERVICE OF THE U. S. PENSION BUREAU.¹

BY P. S. CONNER, A.M., M.D.,

OF CINCINNATI, OHIO.

Professionally we come in official relation with the general Government in the inspection of recruits for the army and navy, the medical care of soldiers, sailors and boatmen, and the examination of applicants for pension, original and increase. The medical corps of the army and that of the navy can be entered only through rigid examination. The merchant sailors and river boatmen are cared for in the Marine Hospital service, by those who have passed an examination yearly becoming more severe. Neither chief nor subordinate in the war, the navy, or the treasury departments has aught to do with the selection of medical officers, and in none of the competitive examinations is regard had to political affiliations or party interests. The result is the existence of bodies of medical men capable, learned, honorable and honored.

The examining surgeons of the Pension Bureau, now numbering twenty three hundred, are the appointees of the Commissioner of Pensions, selected from the local practitioners because of personal friendship, of influential recommendations, or for political reasons; holding office only so long as may be agreeable to the appointing power. A few of the reviewing examiners at Washington owe their positions to having successfully passed competitive examinations; but their tenure of office is an uncertain one, and some of those best qualified have been removed upon the occurrence of a change of administration. The medical positions under the Pension Bureau, therefore, are among the offices which are of the party spoils, belonging to the victors, to be given to those whom it is thought best, for political reasons, to secure and to reward. Good men have often, incompetent men not seldom, been selected. The duties of an examining surgeon are peculiar. Pensions are granted for injuries and diseases received or contracted in the military and naval service, and in the line of duty. The present physical condition is, therefore, first to be determined. Is the applicant sound or unsound? And, if unsound, is the disability that for which pension is claimed? Subjective symptoms are so generally and so largely magnified (especially has this been the case since the passage of the "Arrears of Pension Act"), that little or no regard can ordinarily be had to them. The objective symptoms may be easily recognized, or be so ill defined that their determination is a matter of

¹ Read before the American Academy of Medicine, at its Annual Meeting, at Pittsburg, Pa., October 12, 1886.

great difficulty. If a gunshot wound has been received which has caused manifest disability in loss of limb, in injury of bone or joint, in destruction of tissue, in grave impairment of nutrition, in evident neuralgia, or in marked disfigurement, there is no question but that the applicant is damaged. If there be present positive disease of lung or heart, or liver or kidney, it will be indicated by the ordinary symptoms of such visceral affection, and the subject of it is evidently a diseased man.

But, on the other hand, the alleged complaint may be one the detection of which will require prolonged investigation or special skill, as in the examination of the eye, the ear, the throat, the nervous system, or be, as it not so very rarely is, an affection which can be simulated; and some old soldiers never lose their skill as malingerers. Existence of disease or injury being recognized, the examiner has next to determine whether or not it probably depends upon military service. In many cases such determination can be made only after careful consideration of the applicant's history, and is therefore not so much within the province of the examiner as of that of the authorities at Washington, who are, or are supposed to be, in possession of a full record of the physical condition from the time of enlistment on. But oftentimes the probabilities of a direct dependence, or otherwise, upon causes in action nearly twenty-five years ago can, and therefore must, be established by the examining surgeon. How much likelihood is there, for example, that to-day's advanced tuberculous disease of the lung depends upon the exposures of camp life or the pneumonia of '63? Is the present hepatic or renal disease a legitimate result of army life, especially in view of the fact that the man is evidently a hard drinker? Are the varicose veins of the leg or the scrotum due to hard marching or rough riding, or are they the result of occupation or of developmental changes that took place at and about the period of puberty, before the man went into the army? Again, is not the present disability the result of syphilis or gonorrhœa, and therefore not incurred in the line of duty?

Further, the examiner having recognized the disease or injury, and having satisfied himself that it is the result of legitimate causes entitling to pension, must determine in what degree it unfits for manual labor—in other words, must rate the disability. Here, certainly, is a wide field for the exercise of good judgment based upon knowledge of the ordinary and to be expected effects of an injury or a disease. Even the most hurried glance at what is required of an examining surgeon will suffice to show that he ought to be well educated, experienced in the detection of pathological conditions, of good judgment, honest and independent, having regard solely to what is right and just to the applicant on the one hand and the Government on the other. Besides the 365,783 pensioners now on the roll, there are 168,619 claims pending, and 111,412 rejected claims, many of which may hereafter be reopened. It is probably safe to say that from 150,000 to 200,000 may have to be examined in the near future, at a probable expense, if the present system is continued, of not less than

\$600,000. Upon the certificates of the medical examiners a first payment of probably not less than \$30 000,000 it may be \$60,000,000 or more, will be made.

In view of what is required of the examiners, and of the immense expenditures which must be affected by their decisions, is the existing system for the best interests of the individuals or the Government? The method of appointment is not one likely to secure the services of those most competent to investigate complicated and doubtful cases. The large number of appointees necessarily causes great variations in the rating of practically the same disease or injury, with corresponding injustice to those pensioned. Local prejudices for and against the applicants are likely to exist in direct proportion to the number of localities in which the examiners reside. Would it not be better to have a small permanent corps, adequately paid, not engaged in private practice, but occupied solely with the work of examining applicants? The establishment of such a body was a few years since strongly advocated by the authorities of the Pension Bureau. Without hesitation the question may be answered in the affirmative, provided that the *personnel* of the corps be determined by the results of thorough high-grade examinations, in which due regard is had to "aptitude for service." But if its members should be simply selected by the Medical Referee, by the Commissioner, by the Secretary, by any official, high or low, the greatest of the existing evils would be perpetuated.

I have long thought that the best of all plans would be to entrust pension examinations to detailed officers of the Medical Corps of the Army and Navy, familiar as they are with the mental, moral and physical peculiarities of enlisted men, and with the effects of prolonged service. That this might be done both corps would have to be considerably enlarged. There might, for example, be added to the Army medical staff sixty, and to that of the Navy twenty assistant-surgeons. Then, in like number and proportion, eighty experienced medical officers could be assigned to pension work at forty different places in the country; the Government, if necessary, paying the traveling expenses of applicants ordered to report at the central points. Their examinations would be carefully and thoroughly made, without fear, favor or affection. Deserving applicants would get what they deserve, and the ratings would be far more uniform than at present. The cost to the general Government would be materially diminished. There would be no more complaints or charges that pensions were recommended or advised against because of the applicant's connection with this or that political party. That so small a body of examiners might the more readily and certainly do the work at present performed by thirty times their number, they should be relieved of a large part of that clerical labor that now consumes so much of the time devoted to examinations, labor that could as well or better be done by ordinary clerks or stenographers.

Professionally, whether there was a special new corps or enlarged old ones, we might expect benefit in the recorded and reported condition of the soldiers

and sailors of twenty and more years ago. The end results of excisions and amputations, for example, might be determined, as now they cannot be. The slowly developed organic changes arising from, or at least associated with known causes, and not dependent upon time, occupation and habits, could be studied and analyzed. The Government would be benefited, meritorious soldiers and sailors in some degree rewarded for privations, sickness and wounds, scientific medicine advanced, and regard be had to the just demands for an elevation of the plane of medical practice.

A NEW PERIMETER.¹

BY LEROY S. DIBBLE, M.D.,

OF ST. LOUIS, MO.

Perimeters are admitted by all practitioners of ophthalmology to be a necessity. But they are so heavy and unwieldy that they have been looked upon

as a nuisance in the office, hardly to be tolerated. A perimeter that best meets all the demands for which they are used, is light, neat, and of moderate price, will commend itself to all. These conditions I have tried to meet, with what result I leave my professional brethren to judge. I do not claim great originality; I have simply utilized principles already existing.

The base, A, is of cast iron, japanned, and with the legs, BB, forms a tripod. The quadrant C, of brass, japanned black on the upper side, is cut out by a lathe and is absolutely correct. It has a radius of twelve and one-half inches; a smaller radius I con-

sider useless for testing a presbyopic eye. The chin-rest, E, is of brass lined with black velvet. It slides on the standard, D, and is held at the proper point by the thumb-screw, M. The eye of the patient is placed just above the eye-piece, F, which prevents the head from moving too far forward while looking at the point of fixation, c. The movement of the color-carrier, I, is practically the same as in the Förateo instrument, which I consider a great improvement over the usual method of moving the color-carrier by hand, in which case the patient is liable to anticipate the object. I have proven this by actual experiment. The milled head, H, is connected with the pulley K by an iron rod passing through the head of the stand, A. The cord, bb, running over the pulley, K, and the small pulleys, aaa, is attached to the color-carrier, I, which is moved up or down by turning the milled head, H, with the fingers. The dial-plate, G, gives the angle of the quadrant, C. The chin-rest and legs are held

in place by the thumb-screws underneath, and can be detached, so that, when not in use, the instrument may be packed away in a neat cherry box provided for it.

This perimeter only weighs 12½ pounds. 3147 Washington Ave., St. Louis, Mo.

MEDICAL PROGRESS.

ENTEROTOMY FOR ILEUS.—In reviewing the various opinions hitherto expressed of the relative value of enterotomy and laparotomy for the relief of ileus, DR. F. FUHR, of Giessen, and DR. F. WESENER, of Freiburg, compare the two methods together critic-

¹ Read in the Section of Ophthalmology, Otology and Laryngology, at the Thirty-seventh Annual Meeting of the American Medical Association.

ally, and decide in favor of enterotomy. One case is given. A widow, æt. 47, had worn a pessary which had pressed the sigmoid flexure of the colon against the sacral bone and here caused local circular inflammation, which subsequently led to a stricture of the gut. Ileus set in, and the patient's life was saved by enterotomy performed in the left inguinal region, the transverse colon being stitched to the wound. The fæces, however, could pass the artificial anus in part; and as they could not pass the strictured gut, in the course of time the intestine between the artificial anus (in the transverse colon) and the stricture in the sigmoid flexure became enormously distended and pressed upon the abdominal organs to such an extent that death ensued, under the symptoms of constipation, ascites, icterus, vomiting, singultus, dyspnoea and œdema of the lungs—about two years after the operation. An ovarian tumor (cysto-adenoma) was also found at the post-mortem, which had not materially influenced the case.

In speaking of the merits of enterotomy as compared to abdominal section, the authors point out how the protrusion of the greatly extended intestines through a laparotomy wound prevent their replacement. Puncturing the gut with a fine needle they consider too dangerous, for the reason that the internal existing pressure cannot be sufficiently accurately estimated, which might be considerable enough to force out the contents of the intestine into the abdominal cavity after reposition. They concede, however, that the antiseptic method renders laparotomy a less dangerous proceeding than it formerly was. The personal inconvenience attending artificial anus is not at all great, and its existence is not even suspected by those ignorant of it. The fact that statistics show an equal amount of mortality after both operations is accounted for on the ground that the laparotomies attended by fatal results are rarely published.

As to the objection sometimes urged against enterotomy, that a portion of the stenosed gut itself might be opened, and thus no relief be obtained, the authors believe that the abnormal gut may be recognized by the fact that it contains transudated blood. Nor is there much danger of opening a loop of intestine too near the duodenum, if the operation of enterotomy be done in the inguinal region.

The authors explain the fact that enterotomy frequently leads to radical cure of ileus, by pointing out how the operation affords more space in the abdominal cavity, so that the invagination and axial torsion of the gut may be redressed. The danger exemplified by the case given, however, still remains an objection to enterotomy. Accumulation of fæces between the opening and the occluded portion of the gut may cause a fatal issue.—*Deutsch. Zeitsch f. Chir.* Bd. 23. Hft. 3, 4. March, 1886.—*Annals of Surgery*, September, 1886.

THE DIETARY IN CATARRH OF THE STOMACH.—The late Dr. T. A. MCBRIDE gave the following diet list:

Milk cold or warm.
Bouillon.

Beef tea prepared cold.

To one pound of beef cut up in pieces the size of dice, add one pint of distilled water and 10 drops of dilute lumatic acid. Let stand in refrigerator 24 hours; strain and season to taste, and if desired, warm, but not enough to make cloudy.

Peptonised milk.

Zwiebach not sweetened, crackers, rusk, toast.

Natural Seltzer and Vichy waters, carbonated distilled water.

II.

Soft boiled or raw eggs.

Rice or sago boiled soft in milk.

Clear soups.

Puree of potato.

Vermicelli or "noodle" soups.

Raw oysters.

Calves brains,

Sweet breads,

Pigeons,

Chicken,

Calves feet (?)

} boiled, roast, stewed or broiled.

No vegetables, except those mentioned to be allowed with soups.

No "wheaten grits," hominy, barley, oatmeal.

III.

"Minced" or finely cut boiled ham.

" " " rare beefsteak.

Coffee and tea.

Articles under I and II as advised.

IV.

Rare roasted beef and veal, especially cold.

Roasted chicken, and pigeons without sauces, especially cold.

Venison.

Partridges, woodcock and snipe, not too fresh.

Boiled fish.

White bread (stale).

Macaroni.

Baked apples.

Fruit jellies.

A very small amount of butter, otherwise no fats at any time.

Only dry wine; no beer; no ale or porter. Rye whiskey or brandy diluted with the waters mentioned may be used with lunch and dinner when pronounced necessary.—*Jour. of Reconstructives*, October, 1886.

ASSAFOETIDA IN HABITUAL ABORTION.—PROF. PAOLO NEGRI reports two cases of habitual abortion treated by assafoetida. The first case, was that of a lady, young and in apparent health, who had been married seven years. The first pregnancy was arrested at the third month, the second went to term, and then followed five more which were interrupted at periods ranging from the second to the seventh month. Both the lady and her husband were free from disease of any kind, and nothing abnormal could be detected on examination of the genital organs to account for the repeated miscarriages. Various measures had been tried in previous pregnancies, but without relief. Upon the appearance of symptoms indicating the beginning of another

pregnancy assafoetida was ordered, the patient took the remedy regularly, and though there were occasional slight hæmorrhages, the pregnancy went on to term and the woman was delivered of a living child. The second case was that of a lady who had had four miscarriages in succession, none of her pregnancies ever having gone on to term. When in the third month of her fifth pregnancy she was seen by Dr. Negri. No signs of syphilitic disease could be discovered in herself or her husband, nor was there any other apparent cause for the repeated abortions. Assafoetida was at once ordered, and the patient persevered in the treatment, taking toward the end of her term as much as 18 grains of the gum resin per diem. The pregnancy was uninterrupted by any accident, and went on to full term. Although the number of cases was so small, the results were nevertheless so good as to warrant the author in advising a trial of assafoetida in all cases of habitual abortion for which no cause can be assigned.—*Lo Sperimentale*, August, 1886.

ACORN COCOA IN THE TREATMENT OF DIARRHŒA AND VOMITING IN CHILDREN.—Acorn cocoa is a preparation of ordinary cocoa powdered and freed from fat, to which are added the soluble parts of roasted acorns without cellulose, and a little sugar and roasted flour. Liebreich suggested this combination, and that it should be tried in the treatment of diarrhœa and vomiting of children, and it was found that of one hundred and two cases of diarrhœa with vomiting only six died, and the remainder recovered in from one to eight days. This combination is now manufactured as a substitute for tea, coffee, or cocoa, and is refreshing, tasty, and nutritive even for adults. DR. F. W. ELSNER (*Australasian Med. Gazette*, June, 1886), has also had a considerable experience with this remedy in this class of cases, and has obtained marked success by its use. His mode of administration was to mix a teaspoonful of it with cold water in a small cup, and then to boil it, constantly stirring, and this quantity is administered thrice daily by means of a spoon or feeding-cup. All other food and medicine is prohibited, and the quantity may be gradually reduced. Dr. Elsner has notes of twenty cases of continuous and exhausting diarrhœa with persistent vomiting, which had continued for three weeks in two cases, and for shorter periods in the others. In half the cases various remedies had been employed before the acorn cocoa was administered; in the others, however, it was the first drug given, and its effect was rapid and complete in each instance, and it never took more than two days to bring about improvement, while twelve days was the outside limit of time in which a complete cure was effected.—*Medical News*, October 30, 1886.

TOTAL EXTIRPATION OF SCAPULA WITH EXCISION OF THE HEAD OF THE HUMERUS AND THE ACROMIAL PORTION OF THE CLAVICLE FOR CARIES.—DR. SCHULZ, of Sonnenburg, in Neumark, reports the following case: A farm-hand, æt. 16, was admitted to the Johanniter Hospital in Sonnenburg, August, 11, 1884, for pain, redness and swelling of the

shoulder-joint. He had gone to sleep July 1884, and, on awakening, could not move his arm. Treatment with tr. iodine. After one week incision liberating pus. Fistulæ remained below the spine of scapula and in the internal aspect of the upper third of arm. Movement was greatly impaired. Pressure caused pain; temperature 40° C.; pulse feeble; occasional fainting spells. Treatment—tonic, eggs, wine, quinine, phosphates; repeated incision and drainage; arm maintained in fixed position.

Subsequently improvement set in. But incision of an abscess above the spine of the scapula became necessary; the focus was scraped out with the sharp spoon. Roughened bone could be felt over the whole of the scapula with probes, and joint-affection was established.

September 1. Arsenic given, with general improvement; subsidence of suppuration; increase of appetite. Soon, however, another abscess appeared near the acromion demanding incision.

December 12. Extirpation of scapula; incision from spine to angle; subscapular, artery tied; head of humerus excised, as well as acromial end of clavicle, both being carious. Sublimate dressings; reactionary temperature 38.0°; subsequent convalescence.

February 10. Patient up and about; can move fingers and forearm, and rotate and swing upper arm, but cannot abduct it.

May 6. Dismissed with a support; can write; was seen after five months again, still improving.

Some remarks are added and brief mention of twelve other cases is made.—*Deutsch. Zeitschr. f. Chir.* Vol. 23. Hft. 3 and 4. March, 1886.—*Annals of Surgery*, September, 1886.

LANTANINE.—Lantanine is an alkaloid discovered by M. NEGRETE, and extracted from Yerba sagrada of the family of verbenas. M. Buiza has observed that, like quinine, this alkaloid had some action on the circulation. It slows the nutrition, and at the same time lowers the temperature. The most delicate stomachs tolerate lantanine. Intermittent fevers that prove refractory to quinine have yielded to the influence of 2 grammes of lantanine. In order to produce antipyretic effects in febrile conditions the dose employed is from 1 to 2 grammes in twenty-four hours, given in pills of 10 centigrammes. In intermittent fevers the drug is administered immediately after the paroxysm. Ninety-five times out of a hundred a further paroxysm will not appear. The tincture of latana cannot be employed owing to its intense bitterness, which cannot be masked by syrup or wine.—*Lancet*, Oct. 16, 1886.

IODOL IN EAR DISEASES.—DR. STRETTER, who has used iodol, the new inodorous substitute for iodoform, in a large number of cases of ear disease, finds that in acute purulent inflammatory affections iodol applications rapidly produce marked benefit, but that in chronic inflammations of the middle ear it is generally quite useless, or at best no better than other more common methods of treatment.—*Lancet*, October 16, 1886.

SOME POINTS IN THE TREATMENT OF COM-
POUND FRACTURES.

At the first autumn meeting of the New York County Medical Association, DR. FREDERIC S. DENNIS read a paper on "Some Points of Special Interest in the Treatment of Compound Fractures; including a Report of over Five Hundred Consecutive Cases." A remarkable point about it is the vast contrast which his statistics present to those of the ablest surgeons both in Europe and America before the days of antiseptic surgery. An analysis of his cases, 516 in number, shows 107 fractures of the skull, 47 fatal (39 dying within the first forty-eight hours); 15 of the arm with 1 death (a severe case of railway injury, fatal within forty-eight hours); 23 of the fore-arm, with 1 death (within twenty-four hours); 53 of the thigh, 5 fatal (all within forty-eight hours); 150 of the leg, of which 15 required amputation, and of the remaining 135, 125 recovered. Out of the remaining ten, 2 were removed from the hospital, at their request, immediately after reception, and 8 died (all within forty-eight hours). There were 37 fractures of the hands and feet, all accompanied by much damage to the soft parts; one died from other injuries, the others recovered; of 23 of the shoulder, elbow and wrist, all recovered; 40 of the hip, knee and ankle, 4 requiring amputation, 3 proving fatal (in none of the latter was septicæmia the cause of death); 24 fractures of the carpal, metacarpal, tarsal and metatarsal bones, all recovered; 28 of the jaw, all recovered; 13 of the ribs and nasal bones, 1 died within thirty-six hours; 1 fracture of the ilium, and 2 of the malar bones; all recovered. In the 516 cases there were thus 59 deaths, 19 cases requiring amputation,

and 2 cases in which, owing to early removal from the hospital, the result was unknown. Of the 59 fatal cases, 49 died within the first forty-eight hours. Of the remaining 10, 1 died of tubercular meningitis (there was no septic trouble); 1 of uræmia; and of the others, only 2 could be attributed to septic infection of the wound. One, with a fractured skull, died fifty-three hours after trephining; the other was a man over 60 years of age, whose foot was very badly crushed.

According to the most reliable statistical tables, the mortality of compound fractures in hospitals before antiseptics was from 26 to 68 per cent. Since the introduction of antiseptics the death-rate has fallen to 4 per cent. In Dr. Dennis's cases, there was not a single case among the fractures of the extremities of death from septic-pyæmia. This magnificent result, as we all know, is due to the science of bacteriology, and for such a triumph the profession is indebted to Sir Joseph Lister, whose name can never be disassociated from the march and progress of surgery.

In regard to the treatment of compound fractures Dr. Dennis holds that, while absolute cleanliness is essential, and extension necessary, no fixation apparatus should be allowed to remain in position longer than eight days without an inspection of the parts; as otherwise, the result may be unsatisfactory. The seat of fracture should be inspected at the end of eight days, and again at ten days; after which the dressing may remain untouched as long as required. He is more and more impressed with the very great importance of the first dressing; and he thinks this should be made with the same care and attention to detail as in cases of resection of bones or laparotomy. The treatment consists, first, in securing perfect asepticism; and, second, in the application of an efficient plaster of Paris support. For some time past Dr. Dennis has instructed the ambulance surgeons in the 99th Street Hospital to make antiseptic irrigations and apply antiseptic dressings in all cases of compound fractures before lifting the patient into the ambulance; and the results thus secured have been extremely satisfactory.

The first of the special points to which Dr. Dennis calls attention is *meningeal hæmorrhage*. In cases in which this occurs it has hitherto been the common practice to tie either the common, or the external, carotid. In a number of cases, however, he has controlled the hæmorrhage without doing this. In the first of these cases he removed the bone to the extent of about six inches, and endeavored to grasp the middle meningeal artery with the forceps, but on

account of the receding of the dura mater he could not do this until he ran a tenaculum through the dura, and then brought it out in such a way as to include and raise the lacerated and bleeding vessel. In this way he was able to catch the artery and tie it easily. This method may perhaps be regarded as bold, but the results show that it is justifiable when compared with former statistics. In connection with this point he presented specimens showing that meningeal hæmorrhage may be produced by *contre-coup*.

The second point of special interest is *fat embolism*, to which the attention of the profession was first directed by Wagner and Zenker. While this condition is usually fatal, in connection with fatty liver or tuberculosis, it is usually by no means so serious a complication of compound fractures. The symptoms, in general, resemble those of secondary shock, and the occurrence of Cheyne-Stokes respiration is not infrequent. In several cases Dr. Dennis has found an abundance of fat globules in the urine. Fat embolism is more frequent in the aged than in younger subjects. He points out the differential diagnosis between this condition, secondary shock, and pulmonary embolism, and says that one of the principal points in this is the matter of time (fat embolism always occurring within three days). Treatment consists in the administration of ether, on theoretical grounds for the purpose of dissolving the fat, and of appropriate stimulants. He mentioned a case of fat embolism now under treatment in Bellevue Hospital, which occurred in connection with a simple fracture of the fibula. Two days after the accident the patient was suddenly seized with great dyspnoea and depression, and the temperature ran up to 104° , while the urine was found loaded with fat globules. Under the administration of Hoffman's anodyne and carbonate of ammonia the patient was relieved.

The third point is *insanity following fracture*. While insanity is sometimes undoubtedly due to traumatism, it is usually difficult to trace it to a fracture of the skull. Dr. Dennis has seen some such cases. In one of these the patient is now insane. In another, idiocy and imbecility resulted. In one in which constant severe headache, accompanied by more or less mental aberration, followed a fracture, Dr. Dennis trephined, and the patient was cured. In three cases of traumatic epilepsy, in which there was more or less disturbance of the mind, he also effected a cure by trephining. He is convinced, however, that in epilepsy there is little to be expected from trephining except in cases in which there is well-marked depression. He rightly speaks of the importance of always raising a depression of the skull

as soon as possible after the injury, whether there be any symptom due to the depression present or not. By such a procedure the patient may be saved much trouble, and possible insanity in the future.

The fourth special point is *malignant disease*. Dr. Gross pointed out the fact that about one-half of all the cases of malignant disease may be traced to traumatism, and Dr. Dennis has been able, in quite an extended experience, to confirm Dr. Gross's researches; although it is not often easy to trace such disease to fractures. Sarcoma is usually the variety of malignant disease that results from traumatism. Epithelioma may also develop indirectly; but this almost always originates in the soft tissues, in connection with a sinus leading down to the bone. When malignant disease occurs, early amputation is indicated.

The fifth point is *tenotomy*. Two years ago, Dr. Dennis called attention to the value of tenotomy in many cases of compound fracture; and since then he has met with a considerable number of cases which have further confirmed him in this opinion. While it is of great utility in all oblique cases, in which there is difficulty of reduction, it is useless in vertical fractures. He has practised it not only on the tendo Achillis, but also on the hamstrings, and the tendons of the arm and fore-arm.

The sixth point was *healing by Schede's method*. Fluid blood and blood-clots, if perfectly aseptic, are undoubtedly valuable aids in hastening and perfecting repair by primary union; but if rigid antisepsis be not carried out, they may be a source of great danger. This is doubtless the reason why this method was not adopted earlier, as it is only since the days of antiseptics that it has become practicable.

The last point is *amputation*. Formerly, this was resorted to in a great majority of all compound fractures admitted to large hospitals, as the procedure was necessary in order to prevent blood-poisoning. In Bellevue it was practised in every serious case; and a fracture into the knee or ankle joint was regarded as affording a positive indication for amputation. But now the case is entirely different, and the loss of a few inches of the shaft of a bone (although some permanent shortening may result), does not justify amputation. The limits for this operation are now extremely narrow and contracted; and this may be considered one of the greatest advances in modern surgery. When amputation is found to be necessary, it is proper to defer the operation for several days in cases in which great shock is present; while formerly this was not possible without subjecting the patient to the greatest possible shock.

MR. TAIT ON PELVIC HÆMATOCELE.

As our readers have been already informed, the Ingleby Lecture for this year was delivered by MR. LAWSON TAIT, on September 3, his subject being "Pelvic Hæmatocele." Those who are familiar with the writings of Mr. Tait would naturally suppose that he could not deliver a lecture on a surgical subject without severely criticizing some one, and the lecture under consideration is no exception to his general rule. And by this very fact Mr. Tait not infrequently lays himself open to just criticism. In this lecture, for example, he gives to Bernutz and Goupil the credit of having brought hæmatoceles into professional notice, in 1866, apparently forgetting, what he almost immediately mentions, that Nélaton wrote on the subject in 1850, and that Récamier described a case in the *Lancette Française*, in 1831. We must suppose, however, that Mr. Tait is so occupied with his surgical work, certainly the most marvelous that the world has ever seen, that he has little or no time to plod through ill-arranged literature. And however severe his criticism may be his experience is so great, and his results so good, that the surgical and gynecological worlds give attentive ear to all that falls from his lips.

Mr. Tait thinks that the term "pelvic hæmatocele" ought to be retained to cover all effusions of blood which have their origin in the pelvis; and he advises this because it would then cover the vast majority of cases of effusion of blood into the peritoneal cavity—"for if we exclude the results of traumatic lesion there are very few effusions of blood into the peritoneal cavity which have not a pelvic origin—a fact which is at once indicated by the extreme rarity of the occurrence in men." In the pelvis or abdomen an effusion of blood must be either within the peritoneum or outside of it; though it will be remembered that Bernutz held that true hæmatocele consisted of an effusion of blood within the peritoneum, while Simpson held that there could not be such a thing as an intra-peritoneal hæmatocele or effusion. One has only to remember his anatomy to see the differences as to lesion and results between an effusion of blood into extra-peritoneal tissues and an intra-peritoneal effusion. A peri-nephric effusion would be extra-peritoneal, and could scarcely be so extensive as to be fatal unless a large trunk were ruptured. But when a vessel ruptures into the peritoneal cavity there is no cellular tissue to confine it, and act somewhat as a compressive hæmostatic, and the bleeding would be likely to continue until death or very serious collapse ensued. "All of us who

have experience in abdominal surgery know that when blood flows in quantity into the peritoneal cavity, probably by reason of its dilution by the lymph always present there and easily excited into excessive flow by any abnormal condition, it does not show much tendency to coagulate, save in a very fitful and fragmentary way. One of the most remarkable proofs of this is the influence of the drainage-tube in arresting hæmorrhage. If the cavity is kept dry by frequent withdrawal of the blood oozing from torn pelvic adhesions, the bleeding will soon stop; but if drainage is not kept up the bleeding will probably prove fatal." Now what will happen when a small vein ruptures in the tissue and between the folds of the broad ligament? Very much the same thing as in the case of a peri-nephric effusion, except that the cellular tissue here is more limited in quantity than in the region of the kidney. There is a space between the folds of the broad ligament which is incapable of rapid and indefinite extension, and there are two processes by which the tendency to excessive hæmorrhage is arrested: "the first is the natural tendency on the part of the interstices of the broad ligament to limit the bleeding; and, again, the pressure of the broad ligament itself, as a membrane distended and resisting further distension, exercises pressure upon the bleeding point, and becomes a powerful natural hæmostatic."

These anatomical considerations, combined with what is known pathologically of hæmatocele, justify the division of these effusions into extra- and intra-peritoneal hæmatocele. It must be admitted, with Mr. Tait, that there is much confusion on this subject in the works of English writers. Mr. Tait gives two causes for extra-peritoneal hæmatocele; one very common, the other very rare: "The first is a sudden arrest of a metrostaxis, which may either be normal menstruation or the pseudo-menstruation which occurs so constantly after abdominal operations. On examination the uterus will be found to be fixed on one side, sometimes on both, and this occurs with a suddenness that puts inflammatory effusion out of the question. In the majority of cases the effusion is not extensive enough to be felt above the brim of the pelvis, but in severe cases it is, and then it forms a rounded and distinctly limited tumor, with a feeling of distinct fluctuation." He concludes that this accident is almost, if not entirely, devoid of mortality. He gives one important diagnostic sign of extra-peritoneal hæmatocele which cannot occur in the intra-peritoneal variety: the blocking up of the rectum by effused blood dissecting around the rectum outside the peritoneum and causing a stricture. In

cases of extra-peritoneal effusion by sudden arrest of metrostaxis, apart from operation, the uterus will be felt fixed and generally pushed forwards, with a boggy swelling behind or one side of the uterus. and, if the effusion be large, the mass is felt distinctly limited by the distended broad ligament above the pelvis, this latter condition being the essential diagnostic difference between the two varieties of hæmatocele. Another cause of effusion of blood into the broad ligament, much more rare and probably much more fatal, says Mr. Tait, is the rupture of a tubal pregnancy about the twelfth week. This rupture may be into the cavity of the broad ligament, causing an extra-peritoneal hæmatocele, and may become fatal by a further rupture of the broad ligament cysts and hæmorrhage into the peritoneal cavity. But when the second rupture does not occur, Mr. Tait is sure that the ovum dies and everything is absorbed, in the majority of cases; but that in rare cases the ovum does not die, but develops into a broad-ligament pregnancy. Certainly this seems the best explanation of what seems otherwise inexplicable. Mr. Tait's conclusions concerning extra-peritoneal hæmatocele are that, save under three sets of circumstances, this is an accident free from danger; these are: when a secondary rupture of the cyst occurs with continued bleeding into the peritoneum; when it is merely a stage in the growth of an extra-uterine pregnancy; when it goes on to suppuration.

The most common cause of intra-peritoneal hæmatocele is rupture of a tubal pregnancy, according to Mr. Tait, and there is no reason to doubt that this assertion is correct. But whatever be the cause the indication is clear: the abdomen must be opened and the hæmorrhage stopped. Mr. Tait, in three years and a half, has operated upon twenty-five cases of ruptured tubal pregnancy, and saved twenty-four patients, who would have died but for the operative interference. "Intra-peritoneal hæmatocele is fatal with such almost uniform certainty that so soon as it is suspected the abdomen must be opened and the hæmorrhage arrested."

LOCAL ANÆSTHESIA.—Many devices have been resorted to for inducing local anæsthesia sufficient to relieve neuralgic pains, and to enable the surgeon to perform many operations without causing pain, and without the dangers of general anæsthesia. In a short, but interesting article on this subject, in the *New York Medical Journal* for November 6, DR. J. LEONARD CORNING, of New York, claims that very efficient local anæsthesia can be produced without

pain by first rendering the skin over the part to be anæsthetized more porous by perforating it with needles in the manner practised with the instrument of Baunscheidt, and then apply over the surface a sponge electrode saturated with a 2½ per cent. cocaine solution, and keeping it connected with the battery from three to four minutes, of sufficient intensity to cause a slight sensation of heat. He suggests that the method can be made more efficient if the surface to be rendered anæsthetic or insensible is rendered bloodless by the pressure of Esmarch's bandage immediately before the needle punctures are made. The whole method as proposed and practised by Dr. Corning, is worthy of attention and fair trial.

COLUMBUS MEDICAL COLLEGE, OHIO.—Three or four years since the diplomas of this College were refused recognition by the West Virginia State Board of Health, much to the detriment of the reputation of the College. We are informed that the same Board of Health has recently reversed its former action, and placed the Columbus Medical College on the list of colleges in *good standing*, its diplomas to be recognized for registration on the same basis as those of all other reputable medical colleges.

ARCHIVES OF GYNECOLOGY, OBSTETRICS AND PÆDIATRICS.—The publishers, Leonard & Co., 141 Broadway, New York, give notice that these publications will be issued *monthly* instead of *bi-monthly* as heretofore.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF VIRGINIA.

Seventeenth Annual Session, held at Fredericksburg, Va., October 26, 27, and 28, 1886.

(Concluded from page 557.)

WEDNESDAY, OCTOBER 27.—SECOND DAY.

EVENING SESSION.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President—Dr. Bedford Brown, of Alexandria, Va.
Vice-Presidents—in the order named: Drs. Alex. Harris, of Jeffersonton, Culpeper Co.; Herbert M. Nash, of Norfolk; and L. Ashton, of Falmouth.
Recording Secretary—Dr. Landon B. Edwards, of Richmond.
Corresponding Secretary—Dr. John F. Winn, of Richmond.
Treasurer—Dr. Richard F. Styll, of Richmond.

Chairman of Executive Committee—Dr. Wm. W. Parker, of Richmond.

Chairman of Committee to Nominate Applicants for Fellowship—Dr. Wm. D. Turner, of Fergusson's Wharf, Isle of Wight Co., Va.

Chairman of Committee on Publications—Dr. C. W. P. Brock, of Richmond.

Chairman of Necrological Committee—Honorary Fellow Dr. Samuel C. Gleaves, of Wytheville.

To deliver the Annual Address to the Public and Profession, Session of 1887—Dr. Wm. S. Christian, of Urbanna, Middlesex Co.

Subject for General Discussion, Session of 1887—School Hygiene.

Leader in Discussion—Dr. Hunter McGuire, of Richmond.

Delegates to American Medical Association and State and other Societies—To be appointed by the President.

Place of meeting of Session (about November, 1887)—Richmond, Va.

Examiner on the Virginia State Board of Medical Examiners from the State at Large (to fill unexpired term of two years of Dr. Dabney, who has just resigned because of being elected a Professor in the University of Virginia)—Dr. I. S. Stone, of Lincoln, Va.

Dr. Rawley W. Martin, of Chatham, Va., the retiring President, was elected an Honorary Fellow of the Society.

DR. C. W. P. BROCK, of Richmond, introduced resolutions looking to the establishment of a Virginia State General Hospital, which were favorably considered, and referred to a committee of five for perfection of plans, etc. This subject will, no doubt, be brought up for further consideration at the next annual session of the Society, in advance of the assembling of the next Legislature of Virginia.

THE TREASURER, DR. R. T. STYLL, of Richmond, presented his annual report, showing a balance of \$213.11 on hand after the payment of all outstanding obligations of the Society.

DR. JOHN S. APPERSON, of Town House, reported on

ADVANCES IN PRACTICE OF MEDICINE.

He began by taking up the *reflex neuroses*, instancing the late views regarding the pathology and treatment of hay fever as a decided advance. Ord's theory as to the cause of *pyrexia*—that it is chiefly due to the fact that new tissues are not built up to replace disintegrated tissues, and that the heat which should have been used up accumulates in the body and raises its temperature—was dwelt upon. The necessity for the exercise of caution in the use of antipyrin was pointed out. The subject of *bacteriology* engaged much space, and the record of Pasteur with regard to hydrophobia is believed to be an advance.

THURSDAY, OCTOBER 28.—THIRD DAY.

MORNING SESSION.

DR. R. M. SLAUGHTER, of Theological Seminary, Fairfax Co., presented the report on

ADVANCES IN CHEMISTRY, PHARMACY, MATERIA MEDICA, AND THERAPEUTICS.

He gave the recent literature on the newly discovered physiological alkaloids—*leucomaines*—and spoke of their relation to autogenesis of certain diseases. Under the division of chemistry, he shows that *lanolin* was spoken of in 1590 in the "Pharmacopœia of Florence." This report is full of details; such as how to mask oils, to deodorize iodoform, to preserve chloroform, etc. Under the heads of Materia Medica and Therapeutics, the many uses of cocaine, the value of nitro-glycerin in angina pectoris, and of a five per cent. solution of antipyrin as a hæmostatic, etc., are detailed. Hypnone and urethran are spoken of favorably as hypnotics. Sparteine sulphate as a cardiac tonic is mentioned. The experiments being made with salol or salicylate of phenol as an antiseptic, antirheumatic and antipyretic, and with kola as a stimulant and prophylactic against dysentery, are recorded.

DR. JACOB MICHAUX, of Richmond, read his report on

ADVANCES IN OBSTETRICS.

He first noted the rhythmical contractions of the gravid uterus, a sign first pointed out by Mr. J. Braxton Hicks, of London. Mr. Lawson Tait declares it to be a more certain one than any other, and can be appreciated by laying the extended palm gently upon the abdomen of the woman, when there will be observed perfectly apparent alternate, rhythmical contractions and relaxations of the organ, by which at one time it will be "hard as a cricket-ball, and at another soft as a cushion." He next described Hegar's sign of pregnancy, and quotes Dr. E. H. Grandin as saying that this condition is the most reliable of the earlier signs, and consists of the increased transverse diameter of the uterus as revealed by bimanual examination and rectal touch. *Electricity* as an oxytocic, was next noticed and fully described. The treatment of puerperal fever is claimed to have been improved by the use of antipyrin to reduce temperature. Prof. Mundé believes that the drug owes its value to its action as a sudorific. He also advises the use of the ice-water coil over the abdomen to reduce local inflammatory action. The use of the curette to remove decomposing secundines from the cavity of the womb to be followed by antiseptic douches, carefully administered, and discontinued as soon as the cavity is found to be clean, is believed to be proper and safe.

DR. BEDFORD BROWN, of Alexandria, presented "*A History of My Personal Experience in the Observations and Treatment of Puerperal Eclampsia during a Practice of Thirty-Five Years.*" (See THE JOURNAL OF October 13, p. 533.)

DR. OTIS F. MANSON, of Richmond, Va., read a paper on

MALARIAL HÆMORRHAGE.

He gave a résumé of the history of hæmorrhage occurring as a phenomenon in connection with malarial fever, from the time of Hippocrates, to the present day. He gave, *in extenso*, the facts in rela-

tion to its seat, frequency, mortality, type, diagnosis, prognosis, anatomy and treatment.

The symptoms varying according to the organ from which the hæmorrhage proceeds—from the simple benign epistaxis down to the gravest forms occurring in paludal fever, in which the flow of blood proceeds from the lungs, stomach, intestines, uterus and kidneys—are minutely detailed, to which are added illustrative cases terminating in health and death. From this collection of facts, he endeavors to prove that hæmorrhage has never, until recently, been regarded as a prominent or diagnostic symptom in malarial disease; that with the single exception of epistaxis, (a common result of arterial tension in many diseases and even in conditions such as plethora, scarcely worthy the name of disease) that hæmorrhage from vital organs in malarial disease has been a rare occurrence; and that although a certain number of cases of its various forms may be gleaned from the vast field of medical literature, still it has been considered by all rather as an anomalous and unexpected event; in short, that malarial intoxication has never been classed among hæmorrhagic diseases until within the latter half of the present century. During this period, however, the scene has altogether changed. Organs which previously had been those most rarely represented as the sources of hæmorrhage—the kidneys—now play the most important rôle in malarial fever, and the so-called *malarial hæmaturia* has assumed a fearful interest from its frequency and fatality. The writer confidently asserts that before the year 1850, the cases of hæmaturia, having the remotest connection with malarial disease, may be counted upon one's fingers; whereas, since that date, it has appeared almost simultaneously, from the Western boundaries of our country to the distant islands of Eastern Africa, as a sporadic, endemic and epidemic disease. The writer's view of the comparative infrequency of this disease from the time of Hippocrates down to the present century is based upon the fact, that, although he has perused the works of nearly every distinguished authority on malarial diseases to be procured in America or in Europe, embracing the contributions of twenty-three centuries, not more than six writers make the slightest allusion to it, whilst since that period he has collected contributions of more than seventy writers who have devoted very many pages to the subject, and which united would form several large volumes.

From this array of facts, the natural and inevitable inquiry arises as to the causes of the recent frequency and fatality of this last form of malarial hæmorrhage, which the writer discusses at length. Finally, the various methods of treatment which have been found to be most successful by those possessing the greatest experience in this and other forms of malarial hæmorrhage, are related.

In closing Dr. Manson expressed the hope that his contribution may stimulate others possessing greater opportunities of observing malarial hæmorrhage to investigate the subject more fully in order, that its pathology may be perfected, and its therapeutics improved.

DR. M. A. RUST, of Richmond, presented a paper on

THE ETIOLOGY OF ZYMOTIC DISEASES,

which forms a continuation of his remarks last year on the same subject.

He dwelt on the importance of a study of bacterial life in general, in order to arrive at a better comprehension of the causal relations of pathogenic microbes to disease. He gave illustrations of the ubiquity, prolificacy and tenacity of life in the common or putrefactive bacteria; enlarged on their physiological and noxious actions, upon the human organism; their power to manufacture poisons (ptomaines). He directed attention to the important question of the *constancy* and *inconstancy* of bacterial forms. He finds the theory that the pathogenic microbes originate by transmutations from the common bacteria, not sufficiently sustained by facts, nor in harmony with clinical phenomena. He considers it a reasonable and warrantable assumption, that the microbes of human diseases have been evolved from the putrefactive or common bacteria at that remote time when civilization and its concomitant accumulation of filth began to prepare for them the fit medium. This medium still continues to constitute the fostering ground for their development. Like every other organism, man and human mind included, bacteria are acted upon by the medium in which they exist; bacterial mutations, however, move in a well defined circle, the type being always preserved. Dr. Rust considers the crowded houses of large cities, constructed, as it were, to exclude air and sun, the most fertile hotbed for bacterial life. He thinks the great mortality of infants in summer, from cholera infantum and other diseases of the alimentary canal, to be mainly due to the contamination of food, especially milk, which stands about in that pent-up vitiated air. He finds the sources of contamination in the bricked-up and walled-in houses of the wealthy, during the summer months, more numerous than in the most miserable suburban hut.

DR. JOSEPH S. WHITE, of Richmond, read a paper on the

RESULTS OF CLINICAL WORK AT THE RICHMOND EYE, EAR, THROAT AND NOSE INFIRMARY, WITH PRACTICAL REMARKS.

He referred only to eye work, and reported 3,729 cases, of which 2,857 were diseases of the anterior portion of the eye, and which ought to be diagnosed and treated by any practicing physician without reference to the specialist. Corneal diseases predominated over any other class, and were especially frequent among negroes. One thing of special interest in regard to this race was the fact that Dr. White had never seen, in all his experience, a case of tracheoma or granular lids among them. He gave the results of his experience as to the best treatment for the commonest affections of the eye, such as blepharitis, purulent ophthalmia, phlyctenular ophthalmia, etc. Under the head of *errors of refraction* he referred to the increase of nearsightedness among children from imperfect school hygiene, and to the importance

of correcting it. The operations performed on the eye in the institution were 1,227 in number. There were 102 extractions of cataract. All were successful in restoring useful vision except one case, which had partial atrophy of the optic nerve, resulting in complete atrophy. Four of the 102 cases were over 80, and thirty-two between 70 and 80 years of age, and all made good recoveries. Dr. White was of the opinion that extraction without iridectomy was not applicable to all cases, as some recent writers seemed to think. He also laid great stress on the method of opening the capsule, and entered into other details of the mode of operating. He has tried Michell's method of dressing in nine cases, and concludes that it is not suitable to childish or intractable patients, although he was much pleased with it in docile and tractable cases. Cocaine has been used in about fifty cases of cataract extraction, and other operations aggregating several hundred; and although 2 per cent., 4 per cent. and 10 per cent. solutions have been used with great freedom, he has never had any ill effects from it beyond a dizziness and abrasion of the epithelium of the cornea. He always dissolves it in a solution of bichloride of mercury (1 to 5000), and has never seen ulceration of the cornea from it.

DR. JOHN GRAMMER, of Halifax C. H., Va., offered a paper on *Some of the Obstacles to the Progress of Therapeutical Truth*.

DR. HUGH M. TAYLOR, of Richmond, read a paper on

NERVOUS MIMICRY.

The first part of the report discussed mimicry of diseased joints. Cases representing the different phases and the differential diagnoses of such mimicries, and their intimate and important bearing upon the study and practice of gynecology, were reported. The second and most important division of the subject was the part the mind and imagination play in the production and augmentation of gynecological troubles, and the influence of mind over mind in their cure. Encouragement is one of the most valuable remedial agents at the command of the gynecologist. If patients of a neurotic temperament can honestly imagine that they have a diseased joint, and suffer as much as they do; if they can "mimic" pregnancy, tumors, aphonia, deafness, blindness, paralysis, etc., then it is just as possible for them to concentrate their morbid imaginations upon some of the pelvic organs, and successfully mimic their common disorders.

It is no easy matter always to say positively that the reflex phenomena associated with, and, in most cases, attributed to, ovaritis, etc., are due to changes in the pelvic, and not in the digestive or nervous systems. This position is sustained by the frequent recoveries after Battey's operation has been advised to the patient. Dr. Taylor was satisfied that not a few such cases had been subjected to Battey's operation when there was no necessity for it. He has seen patients wearing pessaries who have no appreciable pelvic troubles; he has seen others consigned to a life of invalidism because they imagined that they had womb disease. He was satisfied that he had

cured some such cases by assuring them that their cases were curable; by the administration of continuous and large doses of *encouragement*. A number of cases were reported in which recovery followed an impression made upon the patients, to the effect that they *would* get well, *were* getting well and, finally, *were well*. In not a few gynecological operations, some of the good resulted from the stimulus of hope infused by representations of the benefits to follow the operation.

DR. A. Z. KOINER, of Roanoke, Va., read the report on *Advances in Hygiene and Public Health*.

DR. WM. W. PARKER, of Richmond, read a paper on *Christian Burial versus Cremation*, to reply to a paper read last year by Dr. J. Edgar Chancellor, of Charlottesville, in which cremation was advocated.

DR. I. S. STONE, of Lincoln, read a report on *Advances in Psychology and Neurology*.

DR. JOSEPH TABER JOHNSON, of Washington, D. C., by invitation of the Society, presented a

HISTORY OF FOURTEEN CASES OF ABDOMINAL SECTION, WITH REMARKS UPON OVARIOTOMY, AND THE METHODS OF BRITISH OPERATORS,

as seen by himself during a protracted summer vacation this year. Of the fourteen cases, there have been twelve recoveries—one case being under observation at this writing. He thinks experience in this operation a great help to success. Most of the failures of authors have occurred in their earlier experiences. Much is attributable to the kind of operation performed; but much more to the *little things* in individual cases, which experience suggests are best suited to the case in hand.

DR. FRANK DONALDSON, JR., of Baltimore, Md., by invitation, read a paper describing his method of operating on nasal, post-pharyngeal and other growths, chiefly by means of electrolysis. He brought with him and exhibited an ingeniously contrived electrolytic battery, costing only \$10, which could also be used as a galvanic battery, or to run electric light or sound electric alarm bells.

DR. ARCHER ATKINSON, of Baltimore, Md., by invitation, presented a paper on

BLIND EXTERNAL FISTULA,

which was well illustrated with the record of cases. After remarking upon the frequency of rectal diseases, the relative frequency of piles, fistulæ, etc., and the most frequent seat of fistulæ, he said that abscesses about the rectum were the most frequent causes of *fistulæ in ano*. He then referred to some of the general causes, gave a definition, and described some of the varieties of such fistulæ, etc., and concluded with some remarks on the importance of the subject for patients applying for policies in life insurance companies.

DR. CHARLES M. SHIELDS, of Richmond, read a paper entitled

EXPERIENCE WITH SOME OF THE MORE RECENT SUGGESTIONS IN THE FIELD OF OPHTHALMOLOGY.

Taking up first the method suggested by Dr. Hotz of treating granular lids by the process of squeezing out the contents of the trachoma follicles, he de-

scribed the way of accomplishing it with the thumbs or forefingers of both hands, but preferred a pair of forceps designed by Dr. C. H. May. They consist of two short blades, having their extremities expanded into an elliptical shape, and curved to correspond with the shape of the tarsal cartilages. The edges are rounded. After the lid is everted, one blade is passed between the lid and the eyeball, and the other over the everted mucous membrane. Steady pressure squeezes out the contents of the trachoma follicle, and very materially hastens a favorable result. He uses nitrate of silver or other astringents in conjunction with it. He very warmly advocated the use of massage in hastening absorption of opacities of the cornea. It is executed by placing one or two fingers over the closed upper lid, and making a rotatory motion of the lid over the cornea for two or three minutes, and repeating it every day or two. The method of dispensing with bandages and dark rooms in the after-treatment of cataract operations, and the substitution of a strip of isinglass plaster to unite the lids, was favorably commented on. In addition he suggested dispensing with the usual four or five days' confinement to bed, and, in proper cases, allowing more latitude in the matter of sitting up when such confinement is very irksome to the patient, and might occasion indigestion and lessened vitality. He discussed the use of the actual cautery corneal probe in obstinate ulcers of the cornea, and advised its cautious employment.

DR. PHILIP TAYLOR, of Richmond, read a paper on the

OPERATION OF EVISCERATION OF THE EYE, WITH THE
PERMANENT INTRODUCTION OF A HOLLOW
GLASS SPHERE,

of the proper size, which increases the rotundity of the eyeball, the movements of the glass eye, and the cosmetic appearance. He reported three cases.

DR. ROBERT J. PRESTON, of Abingdon, read a paper on

ELECTRICITY IN POST-PARTUM HÆMORRHAGE.

The sole objection that could heretofore be used against the recommendation was that we did not have time to get a battery. Now that objection is gone, as there are many portable batteries. Every accoucheur should carry an electrical battery with him to cases of labor, as it may be useful in other conditions than post-partum hæmorrhage. While other remedies may fail to contract the uterus promptly, electricity cannot fail to do so, and it acts *instantly*—as soon as the current is established. Its action, too, can be kept up for hours, if necessary, thereby securing permanent contraction of the uterus, without the risk of the nauseating effect of ergot, etc. Place one electrode over the lower portion of the abdomen, and the other over the symphysis pubis, and open the current, which will then pass directly through the uterus, and expel all non-adherent clots and other extraneous matter.

DR. B. M. WALKER, of Danville, reported a

CASE OF SALIVARY CALCULUS

which was somewhat unique as to the signs and symp-

oms. His remarks impressed the importance of surgeons and physicians paying more attention than they do to "these little things."

DR. R. A. LEWIS, of Richmond, read a paper on

MEDICAL EXPERTS,

showing that, while in some States, physicians called on to testify as experts can demand fees for such testimony, doctors of Virginia cannot decline to testify except at the risk of being charged with contempt of court. His paper concludes by urging legislative action to give the medical expert in this State the same protection of law.

DR. C. T. LEWIS, of Culpepper, read notes of

A CASE IN WHICH FOURTEEN INCHES OF THE SMALL
INTESTINE HAD SLOUGHED AWAY

and passed *per rectum*, with a measurable degree of recovery of strength, etc.

The Society then adjourned to a magnificent banquet, where several hours were spent in feasting and toasting, after which the session was adjourned *sine die*.

MEDICAL SOCIETY OF THE DISTRICT OF
COLUMBIA.

Stated Meeting, September 22, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

T. E. MCARDLE, M.D., SECRETARY.

DR. D. S. LAMB presented a specimen of

EMBOLISM OF THE BRAIN,

and read the following history of the case:

The history of this case so far as it can be obtained, is as follows: A mulatto woman died Aug. 28, 1886, age 65. It is said that four other members of her family had been affected and died in about the same way. About five years ago she was seized with right hemiplegia, from which she recovered. In January, 1885, she had a *second* attack, the same side as before. She breathed stertorously for about one week. For about two weeks she lay in a partial stupor, from which she could be roused for the moment. For about three weeks she had no use of her lower limbs; afterwards she gradually regained their use, but the foot always dragged a little. For about three weeks also, she had no use of her arm and hand; afterwards she regained their use, except in the case of the fourth and fifth fingers which remained powerless, showing that the central origin of the ulnar nerve was affected. Always after this second attack she complained of pain in the head in the region above the left ear.

About the 8th of August, 1886, her face became swollen and her speech thick. She also showed a disposition to repeat several times the terminal word of a sentence; for instance, "Are you going home, home, home?" The swelling, etc., continued until August 22, when the right arm became paralyzed and the leg dragged; there was also total aphasia. On

Monday, the 23d, she walked down stairs and ate a hearty dinner, using her left hand; she could not speak at all, and did not appear to understand what was said to her; she picked restlessly at the tablecloth and her dress. On Tuesday she could not get out of bed, and the pupils did not react to the light. On Wednesday Dr. Parsons saw her for the first time. There was then total loss of motion in the right arm and leg, and partial loss of sensation; the muscles of the face and tongue did not appear to be affected; but she lay in a stupor, breathing stertorously and unable to swallow; the pupils, however, reacted to light. On Thursday and Friday she continued in about the same condition; she still shut her eyes against the light. She was constipated and passed urine involuntarily. The unaffected side was in constant motion. She died on Saturday.

At Dr. Parson's request, I made a post-mortem examination the next day, August 29. The heat was so great and the surroundings such that the examination was limited to the head. The body was well nourished. The skull was thick; dura mater firmly adherent to skull along the longitudinal groove. The arteries generally, especially the larger ones, were much distorted and inelastic; their walls thickened and sclerosed in patches, and the calibre thereby somewhat irregular; a number of miliary aneurisms were seen; the arteries also contained red blood-clots, which in some places showed a slight adhesion to the wall; apparently small flakes of clot had formed on the inner wall (so-called parietal thrombi), and the remainder of the obstructing clot rapidly formed thereon. At the bifurcation of the left Sylvian artery the clot was paler and quite adherent to the wall, showing either that it was a thrombus formed before the others or was the result of embolism.

The brain was too soft to bear much handling; whether the result of the high temperature of the air or of the numerous coagula in the arteries I can not positively say; perhaps of both. On cutting into the left hemisphere a large sized irregular area of softening was found; it involved extensively the island of Reil and third frontal convolution; and the lower and deeper parts of the ascending frontal, and to a less extent the ascending parietal convolutions. The softening was coarsely granular. On stripping off the pia mater about three weeks after the necropsy this membrane was found adherent to the convolutions named and in the corresponding situation. Portions of brain tissue were torn away in removing the membrane; the membrane itself not appearing diseased.

No other lesion was found; no cicatrix or cyst to explain the previous seizures; no hæmorrhage, either old or recent.

Nothnagel says that there is no clinical symptom characteristic either of hæmorrhage, embolism, thrombosis or syphilitic disease of the vessels of the brain. The concurrence, however, of right hemiplegia and aphasia indicating a probability of embolism of the left Sylvian artery and especially at its bifurcation, is further supported by this case. The fact that the woman's age is decidedly above even the ordinary extreme age of brain embolism makes this case more

valuable to report, since her age at death is rather the age of hæmorrhage, and there was no trace of hæmorrhage anywhere. The softening of the left hemisphere was certainly due to the pale adherent Sylvian clot. I call the clot an *embolus*, because it is where it is; exactly where there is the most direct route from the heart and the swiftest current; and where, therefore, a clot coming up from below would most naturally be found, stopping at the bifurcation because too large to enter the branches of the bifurcation; this location is the location of emboli, and not of thrombi. It is true that no examination was made of the heart, and for the reasons stated. There was no symptom suggesting disease of the heart. If clots had been found in the heart or on the valves it would of course have favored the theory of embolism; if they had not been found that fact would not have antagonized the theory.

The formation of thrombi is favored by old age, with its slow pulse and disease of the arteries; we have these conditions here; thrombi form preferably, therefore, in the vertebrals and basilar, and not the carotids. At the same time I believe that some of the numerous red clots in these vessels are thrombi, because of their peculiar formation and adhesion to the vessel wall. The remainder may have been simply post-mortem clots. Cases of thrombosis of the arteries of the brain, giving rise to symptoms, are so rare that if this were such a case it would have particular value in that respect.

The adhesion of the pia mater to the convolutions of the left side suggests a possible relation to the left-sided headache of which she complained after her second attack.

DR. SMITH asked Dr. Lamb if there was any evidence of the first apoplectic attack?

DR. LAMB replied that though one of the clots was evidently an old ante-mortem one, he did not think that it dated back as far as the first attack.

Stated Meeting, September 29, 1886.

THE PRESIDENT IN THE CHAIR.

DR. P. J. MURPHY presented the specimen and reported a case of

EXTRA-UTERINE FETATION.

DR. A. F. A. KING said the Society was indebted to Dr. Murphy for the specimen presented. The case presents the usual characters and results as found in the books. It would be difficult to tell whether it was a case of tubal, ovarian, or abdominal pregnancy, or one of a composite character. From the fact that Dr. Chadwick treated it by electricity, he must have supposed it tubal. Abdominal pregnancies sometimes go to full term and are delivered by laparotomy.

DR. ROBERT REYBURN had not heard the first part of Dr. Murphy's paper, but he would like to inquire whether it were wise, after a diagnosis was made, to let the offending mass remain. Would it not be better to remove it at once by laparotomy, as Mr. Tait is now urging?

DR. MURPHY did not know whether the foetus had

been killed by electricity or died afterwards. Mr. Tait declares a tubal pregnancy cannot be diagnosed before rupture occurs. In this case Dr. Chadwick made a positive diagnosis. Dr. Murphy did not at that time consider it a case of extra-uterine foetation. As to the treatment, he thought he had adopted the only justifiable method. If he had performed abdominal section the woman would have perished.

DR. S. C. BUSEY said the case was interesting for several reasons. The diagnosis had been made early, electricity had been applied, the foetus had been discharged and recovery had taken place. The case is unique as proving the correctness of the diagnosis and the result of the application of electricity by the discharge of the foetus. In such a case there could be no thought of laparotomy. The treatment pursued was the proper one. We cannot, of course, decide whether the pregnancy was tubal or abdominal. Dr. King is perfectly correct in saying that abdominal pregnancies sometimes result in a living child at term.

After some further remarks by Drs. King, Murphy and Reyburn, the discussion was postponed until Dr. Murphy should receive a full report of the early history of the case from Dr. Chadwick.

DR. SWAN M. BURNETT presented the specimen and related the history of a case of

BLACK CATARACT.

The patient, a colored woman, about 65 years old, presented herself at his service at the Central Dispensary about two weeks ago. She said she had lost the sight of her eye two or three years ago. Dr. Burnett thought vision had been lost a longer time, but had not been noticed by the patient. The diagnosis of cataract is usually made with great facility, as the pupil presents a white or grayish appearance. In this case, however, the pupil was black. On examining with the ophthalmoscope an obstruction was discovered, but its nature was in doubt. Was it opacity of crystalline lens or was it in the fluid back of it? There was only one test, getting reflection from the surfaces of the crystalline lens. It is somewhat difficult to differentiate between black cataract and the effusion of blood into the vitreous chamber. The patient was sent to the Garfield Hospital and the lens was removed, cocaine being used. An iridectomy was first made. The incision was large and the lens came out in its capsule. No vitreous humor escaped. Complete recovery without reaction. The lens measured 8.5 mm. by 2.5 or 3 mm. Its size approximated that of the lens in the healthy state. This was the first case of black cataract that Dr. Burnett had seen, but in a week he again saw two in one patient.

Stated Meeting, October 6, 1886.

THE PRESIDENT IN THE CHAIR.

DR. JOHN B. HAMILTON exhibited a specimen of a calvarium removed from a patient at the Almshouse who had suffered from a

DEPRESSED FRACTURE OF THE SKULL.

The trephine had been applied unavailingly. The inner table of the skull was pushed inwards until an arch had formed, and pressure with the elevator could not replace the depressed portion, owing to the fact that pressure simply made the arch firmer. There were paralysis of the hand and tongue, and laceration of the dura mater. Nearly the whole of the squamous portion of the temporal, and adjoining portion of the parietal, bone on the left side were involved in the fracture. Dr. Chew has kindly furnished the notes of the case as follows:

Gotlieb Scheene, an inmate of the work-house, was struck on the head with a brick on Saturday, September 25, and was brought to the Washington Asylum Hospital about five hours afterwards. He had recovered from the shock and was conscious. There was a cut about two inches long on the left side of the head, with a marked depression of the skull of considerable extent directly over the Rolandic space. Pulse 40, respiration slow, pupils normal on both sides, and fixed. Facial paralysis on right side was marked. There was complete paralysis of the tongue, which he could protrude only with the assistance of his hands. On the next day he could protrude it, but there was paralysis of its right side. The treatment was at first croton oil, followed by calomel, by which he was freely purged, and then iodide and bromide of potassium. He continued in about the same condition until Monday night, Sept. 27, when Dr. J. B. Hamilton kindly consented to trephine. The operation was done Tuesday morning. Patient rallied well from the anæsthetic, and continued in the same condition until Wednesday night. He then became unconscious. There was paralysis of the right side. He gradually sank, and before death, which occurred on October 25, he became completely paralyzed.

CHICAGO SOCIETY OF OPHTHALMOLOGY AND OTOTOLOGY.

Meeting of June 8.

DR. HOLMES IN THE CHAIR.

DR. H. STARKEY presented three cases of

CONGENITAL ECTOPIA LENTIS,

with the following histories: Mrs. Joseph Peltier, widow, age 44. Congenital ectopia lentis of both eyes. Motility of eyeballs slightly diminished. Tension normal. Right eye lens cataractous; vision = perception of light; left eye, vision = $\frac{2}{20}$ with + 5.5 D. = $\frac{3}{20}$. Ophth. ex. Fundus normal. Accommodation *nil*; lenses dislocated upwards and backwards; irides and lenses quite tremulous. The patient was given + 5.5 D. for the distance, + 9 D. for close work.

Gertrude Peltier, daughter, age 16. Double ectopia lentis backwards and upwards, with tremulous irides and lenses. General health good. Slight photophobia. Vision R. E. $\frac{1}{20}$ with + 7 D. = $\frac{3}{20}$; vision L. E. $\frac{2}{20}$ with + 7 D. = $\frac{4}{20}$. Accommodation of

both eyes = 0. Tension normal. Ophth. ex. Fundus normal. Given + 7 D. oc. u. for distance, + 12 D. oc. u. for reading.

Aaron Peltier, son, aged 7. Both lenses dislocated upwards and backwards. Tension normal. Ophth. ex. Fundus both eyes normal; motility of eyes impaired, irregular, and discordant. Accommodation = 0. Vision R. E. = $\frac{1}{20}$ with + 8 D. = $\frac{2}{30}$; vision L. E. = $\frac{1}{20}$ with + 8 D. = $\frac{2}{30}$. Prescribed + 7 D. oc. u. for the distance. Another son, aged 16, had been examined by Dr. Boerne Bettman, who found both lenses likewise dislocated upwards and backwards.¹ The boy's vision was materially improved by a + 8 D. lens for each eye.

DR. W. T. MONTGOMERY read a paper on

OPERATION BY LIGATURE FOR ENTROPION OF LOWER LIDS.

About two months ago an old man came under my care, who was suffering from complete inversion of all his eyelids and marked narrowness of the palpebral fissures. These conditions had existed for a considerable time, so that the patient was almost blind from pannus. Under ether I made canthotomy on both eyes and Hotz's operation on both upper lids, intending to make this latter operation on both lower lids. Owing to the tediousness of the Hotz operation, and to the fact that it is not nearly so effective in correcting entropion of the lower as of the upper lid, it occurred to me to try the effect of a ligature introduced as follows: A strong curved needle was threaded with No. 9 surgeon's silk, and introduced at a point 4 or 5 mm. below the puncta, and passed deeply through the tissues of the lid and brought out at a point 4 or 5 millimetres below the outer extremity of the lid. The included tissue was then firmly ligated. The inverted lid was completely everted, but the ligation produced such an unsightly puckering up of the lid that I was tempted to remove the ligature, but did not. Both lower lids were treated in the same manner. The ligatures were removed on the third or fourth day, or soon as suppuration began, and the unsightly puckering soon disappeared, the lids assuming a natural position. This patient remained under observation about one month, and there was no appearance of return of his entropion.

I have made the operation about fifteen times, with very satisfactory results so far. It has only failed in correcting the entropion in one case, and this was such an aggravated one that I was not surprised at failure at the first attempt. I have ligated again, and the lid is now everted. The effect of the ligature is modified by the amount of tissue included. It is too early yet to speak assuredly of the ultimate success of this operation. I have not the temerity to call it new. I can only say it is new to me, and being so very simple, if it is even as successful as other operations in correcting entropion of the lower lid, it commends itself.

Eugene Daoust, aged 27; baker, 77 Stanton St. Ten years ago he received a blow on the left eye

with the fist or some blunt instrument, which knocked him down. In falling the left temporal region struck the flat surface of a stone. Considerable swelling and ecchymosis of the lids followed these injuries, but soon began to clear up, and in a short time there was only a slight thickening of the lids remaining. This slight thickening did not noticeably change until about three years ago, when it began to gradually increase, and the surface assumed a knotty appearance. The trouble, though slowly increasing, had not given the patient any inconvenience, except its unsightly appearance, up to the time I first saw him, December 4, 1885. At this time the upper lid was so much thickened that there was almost complete ptosis. The external surface presented a markedly nodular and purple appearance, due to varicose enlargement of blood-vessels. On the inner surface of the upper lid, near the external angle, was found a varicose nodule the size of a pea. The entire palpebral conjunctiva presented an engorged appearance. The lower lid was also considerably thickened by the varicose engorgement. Decided pulsation was felt over the entire upper lid and extending into the temporal region on this side, but was most marked over the outer angle of orbit and over the supraorbital foramen. Firm pressure at these points arrested pulsation in the lid and lessened the vascular engorgement.

I informed the patient that I thought an operation—ligating the principal branches of the anterior temporal artery and the supraorbital artery, with the free use of the electrolysis needle—would relieve him, but was not sure of effecting a cure by these means. Though I endeavored to impress upon the patient the importance of the trouble and urged him to have the operation performed, I did not see him again until May 9. He then stated that three weeks previous, the nodule on the inside of the lid ruptured, and he almost bled to death before he could get it stopped. Dr. J. J. Angear, who was called to see him at the time, has since informed me that he attempted to ligate the main branch of the temporal subcutaneously, but this did not stop the bleeding, and he then ligated the ruptured vessel on the inside of the lid. Dr. Angear was of the opinion that the varix was largely supplied by branches of the lachrymal artery, and that ligation of the common carotid would have to be made. At the time of the second visit of the patient to me the condition of the lids was not materially changed, but the patient was still anæmic and weak from loss of blood. I advised the operation that I had urged in the first place, but warned him that it might be a failure, and that ligation of the common carotid would possibly have to be made. The patient acquiesced, and May 11, under ether, four subcutaneous ligatures, one including the pulsating branches of the supraorbital and three along the course of the temporal branches, were applied. The first of these was introduced at the outer rim of the orbit and the other two at intervals of one-fourth of an inch towards the temporal region. After the sutures were introduced pulsation was only detected at the outer extremity of the lid in a small area. A fine electrolysis needle was then inserted

¹ In all the individuals, the lenses were dislocated upwards and forwards, the lower edge being tilted backwards.

about a dozen times in different directions through the engorged tissues of the upper lid. Cold water dressings were applied, and the patient was ordered to be kept quiet in his room and friends were warned of the possibility of secondary hæmorrhage. Considerable reaction followed the operation. The ligatures had all come away by the end of twelve days without any hæmorrhage, and by the end of three weeks the swelling had subsided to a degree less than existed before the operation. The surface of the lid is now smooth. Pulsation is still felt over outer rim of orbit, and lids yet much thickened.

June 1st. Without anæsthetic I again used electrolysis freely, but little reaction followed. At present, June 8, the lids have not entirely recovered from the last operation, but I think it is safe to say that it will be followed by further improvement.

It is still a question as to whether a cure will be effected by the means instituted, or not. I present the patient for your inspection and advice. I am encouraged to give further trial to electrolysis. We all know that ligation of the common carotid is a hazardous operation, and is not always successful in curing aneurism about the orbit.

There is no doubt about the aneurism in this case starting from the injury of ten years ago, and it is my opinion that the injury was primarily to branches of the middle temporal. It was upon this opinion that my hope of benefiting the patient by the treatment detailed was based.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Reports on Cholera—Cholera in Europe in 1884 and 1885—The Inspection of Ports—The Origin of Cholera.

A supplement containing Reports and Papers on Cholera, submitted by the medical officer of the Local Government Board, has just been issued in connection with the fifteenth annual report of that department. This bulky volume, in addition to the report of Dr. Buchanan, contains a voluminous appendix. To this Dr. Thorne contributes an account of cholera in Europe in 1884 and 1885. He also reports the proceedings of the International Sanitary Conference, held at Rome in the last-named year. Dr. Ballard writes regarding the sanitary survey made in England in anticipation of cholera outbreak in 1856-86. Dr. Blaxall reports on the like inspection of ports and riparian districts, and Dr. Klein concludes the volume with an interesting paper on the question of cholera as a germ-produced disease. In one way this Report is highly reassuring in respect of the sanitary state of our islands, and of the adequate character of the administration which has the duty of controlling sanitary matters. If cholera, as is most unlikely, should ever gain a foothold in England as a foreign importation willing and able to flourish on British soil, it will have to reckon with an active and efficient board of health supervision, to

the want of which, in foreign lands, the continuance of epidemics is largely due. As regards actual cholera attack in England, Dr. Buchanan tells us that as far as the year ending March 31, 1886, was concerned, cholera was practically unrepresented in this country. On one or two occasions only choleraic cases were witnessed in the persons of sailors who had hailed from Mediterranean ports. The disease did not spread to any person, and in this statement lies cause for congratulation. Contrasted with what happens, or rather is allowed to happen, in Italy, Spain, Austro-Hungary, and even in France, this rigid supervision of even suspicious cases of choleraic nature in England is a gratifying feature. The Local Government Board, through its medical side, evidently takes care that such action shall never be wanting throughout England.

In his report on Cholera in Europe Dr. Thorne incidentally reports the great lesson which foreign nations, it would appear, have yet to be taught, viz: that it is to filthy surroundings and to the want of care in ensuring a pure water supply that the repeated attacks and continuance of cholera are due. Dr. Buchanan himself reiterates this wholesome teaching. His words are worth remembering: "The views of England concerning cholera in Europe," says the medical officer of the Local Government Board, "obtained from her own experience and strengthened by what she can learn of other countries, are that for European countries which have secured their soil, water and air against befoulment, there is little or no danger of cholera, no matter though the disease be brought into their midst." He urges that England puts her trust in measures which will secure purity of air, earth and water. This is really all that is needed to avert cholera epidemics, but it is precisely such conditions of cleanliness that are wanting in Continental regions. The local measures for cholera prevention, too, are worthy of remark. When a case of the disease occurs in England no restrictions are imposed, as on the Continent, on traffic between the infected district and other parts of the country. For one thing, the disease is never allowed to assume a diffused or epidemic form. Quarantine, in Dr. Buchanan's view, is utterly needless in face of the ordinary care and precaution with which the beginning of cholera epidemics should invariably be treated. It would seem, however, that English views of cholera-prevention, plain and effective in operation as these opinions are, do not meet with the approval of Continental authorities. This much was seen on the occasion of the Sanitary Conference in Rome. The objections of foreign authorities may be dismissed with an expression of genuine pity for the sanitary ignorance, or the equally reprehensible bigotry, that refuses to see in the tried and proved English measures against cholera, the universal safety of the nations at large.

The question of the exact origin of cholera is one which has frequently been discussed, and Dr. Buchanan reverts to the subject in discussing the report of Dr. Klein, which is included in the volume just issued. Dr. Koch, it will be remembered, in 1883 and 1884, declared his belief, formed as the result of

cholera researches undertaken in India, that the disease was due to certain bacilli or living germs, which he found abundantly in the secretions of cholera-stricken bodies. The difficulty of accepting Dr. Koch's views arises, as Dr. Buchanan points out, from the fact that while in other germ produced diseases these living particles are found in the blood and in the tissues of the affected body, no such evidence is at hand regarding the so-called cholera bacillus. In other words, while the bacilli are present in the digestive system, they are not found in the blood, and this latter situation is precisely that which they not only affect in other germ diseases, but is also one which it would be expected they should specially occupy in the case of a sudden and fatal ailment like cholera. The English commission which was sent to India to study this question of cholera causation, arrived at opposite conclusions to those advanced by Dr. Koch. They found, indeed, that Koch's bacilli were rarely, if ever, absent in cholera cases, but that they were the cause of the attack the English commissioners unhesitatingly deny. It is more than probable that the germs in question are present even in healthy bodies. One authority asserts that these microscopic particles are natural denizens of the healthy mouth and normal digestive system. As matters stand, Dr. Buchanan declares we are in the same position as before, of ignorance as to what may be the relation of cholera to bacterial or germ life. This conclusion, it will be noted, by no means excludes the possibility, or indeed the probability, that cholera is germ-produced. It really stands in the same position as small-pox or scarlet fever. Even if Dr. Koch's views are unacceptable, that is no reason why the future should not demonstrate the real facts of the case. Dr. Snow, in 1849, was very forcible in his declaration that to water polluted by cholera and typhoid excretions we owe the continuance and dissemination of these diseases. Dr. Buchanan would have it remembered that Snow's conclusion remains sound and unopposed at the present time, and this although it is at present impossible to point to the exact nature of the cause or material to which the pollution of water supply is due.

Mr. George Lawson, F.R.C.S., has been appointed Surgeon Oculist to Her Majesty, *vice* Mr. William Cooper, deceased. G. O. M.

DOMESTIC CORRESPONDENCE

PUERPERAL SEPTICÆMIA.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—Some errors occur in the report given in THE JOURNAL of November 13, of my remarks upon puerperal septicæmia, before the Virginia State Medical Society, two of which please allow me to correct. I expressed a preference for Bozeman's catheter over Chamberlain's tube when intra-uterine injections were indicated, and for Hegar's rather than Molesworth's dilators, if previous dilatation of the os was required.

I did not admit, in reply to Dr. Wellford, that the puerperal condition, so far as any blood-changes were

concerned, was an essential factor in the production of septicæmia, but that the wounds of the genital canal or of the interior of the uterus were necessary conditions for the entrance of the infection—without a wound no poisoning occurs, no matter what alterations of the blood induced by pregnancy or labor may be present. Respectfully,

THEOPHILUS PARVIN, M.D.

Philadelphia, November 15, 1886.

NECROLOGY.

MRS. CHARLOTTE MILLS STEPHENSON, wife of Dr. Robert Stephenson, of Adrian, Michigan, died November 4, 1886. She was born in Macclesfield, England, June 18, 1828. She came with her parents to Adrian, Mich., in 1838, and was married to Dr. Robert Stephenson in 1851. The deceased was an earnest Christian woman, zealous in all good works, and beloved by all classes of society. She was one of the principal founders of the Ladies' Library Association of Adrian, and was one of the Board of Directors at the time of her death. Dr. Robert Stephenson has been a member of the American Medical Association since 1876.

THE DEATH OF DR. JULIUS F. MINER, of Buffalo, N. Y., has been announced during the present month. Dr. Miner was born in Peru, Mass., in 1823; graduated in the Albany Medical College in 1847, and became a resident of Buffalo in 1855, where he acquired a high professional reputation and extensive practice. For several years he occupied the chair of Special and Clinical Surgery in the Buffalo Medical College, and was one of the editors of the *Buffalo Medical and Surgical Journal*. He has been a member of the American Medical Association since 1864, also a member of the Medical Society of the State of New York, and of the local Medical Societies of Buffalo and of Erie County.

INTERNATIONAL CONGRESS.

NINTH, INTERNATIONAL MEDICAL CONGRESS.—*Office of the Executive Committee.*—In response to various questions from European correspondents as to the *time* absolutely required for attendance on the Congress, it is now stated that it is *possible* to do it in thirty days; say ten days voyage out, ten days in the United States, and ten days return voyage. The session of the Congress will occupy six days. Reduced rates of travel are in contemplation, and will be hereafter published. HENRY H. SMITH, M.D.,

Chairman Executive Committee.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Sec-

retary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

MISCELLANEOUS.

THE BUFFALO CREMATORY.—There has been erected in the City of Buffalo a temple for the incineration of the remains of those whose last wishes in regard to the disposal of their bodies were in favor of cremation, whose æsthetic surroundings please the most difficult taste. The location of the building is in the most beautiful part of the city—about twenty minutes' drive from the city hall, out Buffalo's far-famed Delaware avenue, and fronting one of the most beautiful cemeteries in the United States—Forest Lawn. The idea of those interested in its location and construction has been, to so arrange all the little details, as to render as light as possible the task of the sorrowing one who is left, not only to mourn the loss of a dear friend, but also to dispose of the remains in a manner least grating to the individual feeling and least harmful to the many.

The crematory is built of dark-brown sand-stone, in a plain, substantial style, reminding one of the small chapels built in the north country centuries ago, with square tower and steep slanting roof, covered with ivy and surrounded by sloping lawns. While the hearse conveys the body to room where the undertaker removes it from the coffin and places it upon a bier, the relatives and friends enter the chapel, while the clergyman passes behind the organ to take his place in the chancel. The bier rolls noiselessly into the chancel, the organist begins a prelude to a chant, the ceremony takes place according to the desires of the survivors. The surroundings present the ordinary aspect of an earth-burial ceremony at a church. The body lies on a handsomely draped bier in the chancel. The chancel is beautifully decorated in an early Italian style. There are twenty-one different symbols and devices interwoven in arches of peacock-green and blue, while the windows, of rich stained glass, shed a light, dim and religious; the nave, too, is decorated in the same style. All the surroundings combine to show respect for the dead, while respecting the feelings of the living. The service over, the curtains are withdrawn, and the bier glides noiselessly out of the sight of the congregation. The crowd disperses, the incineration takes place privately, and the ashes are taken by the undertaker, to be disposed of as the body would have been or left to form the nucleus of a columbarium.—*Sanitary News*, Nov. 13, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM NOVEMBER 6, 1886, TO NOVEMBER 12, 1886.

Major J. P. Wright, Surgeon, from Dept. Texas to Dept. Mo.

for duty as attending surgeon at Leavenworth Military Prison Ft. Leavenworth, Kansas.

Major W. H. Forward, Surgeon, from duty as attending surgeon Hdqrs. Div. of the Missouri and examiner of recruits at Chicago, Ill., to Dept. of Dakota.

Major V. B. Hubbard, Surgeon, from Dept. Arizona to duty as attending surgeon at Hdqrs. Div. of the Missouri, and as examiner of recruits at Chicago, Ill. (S. O. 257, A. G. O., Nov. 4, 1886.)

Capt. L. Y. Loring, Asst. Surgeon, sick leave of absence further extended three months on surgeon's certificate of disability. To be relieved from duty in Dept. Cal., and, on the expiration of his present sick leave of absence, will report by letter to the Surgeon-General of the Army. (S. O. 262, A. G. O., Nov. 10, 1886.)

Capt. E. B. Moseley, Asst. Surgeon, assigned to duty as attending surgeon in San Francisco, Cal. (S. O. 94, Div. Pacific, Nov. 1, 1886.)

Capt. Harry O. Perley, Asst. Surgeon, granted leave of absence for four months, on surgeon's certificate of disability. (S. O. 257, A. G. O., Nov. 4, 1886.)

First Lieut. Chas. C. Barrows, Asst. Surgeon, ordered to report to commanding officer St. Francis Bks., St. Augustine, Fla., for duty at Ft. Marion. (S. O. 180, Div. Atlantic, Nov. 10, 1886.)

First Lieut. Jno. L. Phillips, Asst. Surgeon, granted leave of absence for one month, with permission to apply at Hdqrs. Div. of the Missouri for an extension of one month. (S. O. 116, Dept. Dak., Nov. 2, 1886.)

First Lieut. Chas. B. Ewing, Asst. Surgeon, ordered from Ft. Supply, Ind. Ter., to Ft. Leavenworth, Kans., for duty. (S. O. 126, Dept. Mo., Nov. 6, 1886.)

First Lieut. Francis J. Ives, Asst. Surgeon, ordered to proceed to and take station at Ft. D. A. Russell, Wyo. (S. O. 145, Dept. Platte, Nov. 4, 1886.)

PROMOTION.

Capt. Robt. M. O'Reilly, Asst. Surgeon, to be Major and Surgeon, Nov. 1, 1886, vice Clements, deceased.

APPOINTMENTS.

Paul Clendenin, First Lieut. and Asst. Surgeon, Nov. 5, 1886.

Chas. L. G. Anderson, First Lieut. and Asst. Surgeon, Nov. 5, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE THREE WEEKS ENDED NOVEMBER 13, 1886.

Ames, R. B. M., P. A. Surgeon, relieved from duty at Marine Hospital, New York, N. Y., to assume charge of Marine Hospital, Vineyard Haven, Mass. Nov. 1, 1886.

Urquhart, F. M., P. A. Surgeon, to proceed to Norfolk, Va., for duty. Nov. 4, 1886.

Yemans, H. W., P. A. Surgeon, relieved from duty at Marine Hospital, San Francisco, Cal.; to assume charge of the Service at Galveston, Texas. Nov. 1, 1886.

Wasdin, Eugene, P. A. Surgeon, when relieved, to proceed to New York, N. Y., for duty at Marine Hospital. Nov. 1, 1886.

Williams, L. L., Asst. Surgeon, relieved from duty at Marine Hospital, Wilmington, N. C.; to proceed to Pittsburgh, Pa., for temporary duty. Nov. 5, 1886.

Perry, T. B., Asst. Surgeon, relieved from duty at Marine Hospital, St. Louis, Mo.; to proceed to San Francisco, Cal., for duty at Marine Hospital. Nov. 1, 1886.

Ames, R. P. M., P. A. Surgeon, to proceed to Vineyard Haven, Mass., as inspector. Nov. 10, 1886.

Urquhart, F. M., P. A. Surgeon, granted leave of absence for seven days. Nov. 8, 1886.

Wasdin, Eugene, P. A. Surgeon, granted leave of absence for seven days. Nov. 11, 1886.

Magruder, G. M., Asst. Surgeon, relieved from duty at Norfolk, Va.; assigned to duty at Marine Hospital, Chicago, Ill. Nov. 10, 1886.

ADDRESSES.

SOME OF THE CAUSES OF THE DISEASES OF WOMEN.

The Annual Address before the Chicago Gynecological Society by the Retiring President,

DANIEL T. NELSON, M.D.

OF CHICAGO.

Another year of the history of our Society has completed its cycle, and it is well for us to briefly review its history, and profiting by the past experience, arrange more comprehensive plans for its future usefulness.

While the fountain does not rise as high as its source, the usefulness of a Society like ours is really greater than the combined work of its individual members; for I am sure we have all appreciated, during the past year, that there has been a reflex benefit to each of us from the work and discussions of the Fellows which does not appear on the records.

The work of the past year, I am sure you will all agree with me, has been the best in the history of our Society, both in quality and number of the papers presented, and in the attendance and character of the discussions.

The partially inaugurated plan of discussing special subjects at stated meetings, with papers carefully prepared upon these topics to guide in the discussion, is believed to be a good one, as a sufficient time is likely to be given to the paper to make it worthy of careful discussion, and, as we have seen, these discussions are likely to be of value not alone to ourselves, but to the whole medical world. And the stimulus to good work in the preparation of the papers is not the least advantage of the plan.

These special topics need not debar volunteer papers, reports of cases, and the like, as either or both may be made the order of business at any meeting by vote of the Society, or extra meetings may be held, as this year during the vacation, when two extra meetings were held (July and August). The plan, it is believed, will increase the quantity of the material presented to the Society, and improve its quality.

It is recommended that the officers of the Society, the President, the two Vice-Presidents, the Secretary, and Editor, or other committee of five, be elected at each annual meeting, to constitute an Executive Committee, whose duty it shall be to arrange the

topics of business for each meeting, and notify the Secretary in time to give due notice to the Fellows, and so far as possible report to the Society the papers and topics for discussion at least quarterly in advance, making such changes from time to time as they may deem advisable or the Society may direct.

And I would raise the query, Can this Society in any way stimulate a greater amount of original research in our department of medicine? Would a prize of \$25 or \$50, offered under proper restrictions, each year, bring out any good original investigations among our members? And need it be confined to our own membership, provided the work be meritorious and within the scope of this Society? If the plan seems wise, would it not be better to raise the fund needed by subscription rather than by taxation?

No more fruitful topic for research, and hardly one more difficult, could be proposed than the Diseases of the Placenta, for even its anatomy and physiology are believed by some not to be fully established. Would not a better knowledge of the diseases of this organ explain many of the miscarriages and stillbirths which are not now even attempted to be explained? If the causes were understood, might not the means of preventing be found out?

Some preventive measures have been discussed during the past year, such as the prevention of the laceration of the perineum and cervix; but there is still a legion of ills which may be termed reflex diseases—the headaches, the backaches, the hot flushes, the chills and sweating, the palpitation, the fainting, the difficult breathing, the dyspepsia, the constipation, the anæmia, the neuralgia, or in a word, the hysteria, or if you prefer, the neurasthenia. Are these diseases increasing? Would we could hope they were not! But can they not be prevented? And where is their primal cause, and what the prevention? Why the dysmenorrhœa, spanmenorrhœa, and the amenorrhœa? Why the displacements, the cellulitis, and the peritonitis? the tumors, both fibroid and ovarian? Are there not causes for these diseases which can be found out, and being known, the diseases avoided? And would not these be grander achievements than have been accomplished by a McDowell, a Sims, a Wells, or a Tait? More lives would be saved, more suffering would be prevented, more children would be born. The State would be enriched and the individual made better and happier. Said the late Dr. Samuel D. Gross, not long before his death, at the dedication of the McDowell monument: "Young men of America, listen to the voice

of one who has grown old in the profession, and who will probably never address you again, as he utters a parting word of advice. The great question of the day is not this operation or that, not ovariectomy or lithotomy, or a hip joint amputation, which have reflected so much glory upon American medicine, but *preventive medicine*, the hygiene of our persons, our dwellings, our streets.

"The day has arrived when the people must be roused to a deeper and more earnest sense of the people's welfare, and suitable measures adopted for the protection, as well as for the better development, of their physical, moral and intellectual powers. This is the great problem of the day, the question which you, as the representatives of the rising generation of physicians, should urge, in season and out of season, upon the attention of your fellow-citizens; the question which alone and beyond all others should engage your most serious thoughts and elicit your most earnest coöperation."

While like begets like, largely, yet with proper care the children may be *better* than the parents. This has been accomplished in numerous instances among the lower animals, and why should it not be with the highest and most intelligent animal, man, if the same care were exercised?

Among the Jews the physician is frequently consulted before matrimonial alliances are contracted. Other denominations would do well to adopt this salutary custom, for if rightly carried out, it would prevent much disease and suffering among the contracting parties and their offspring.

While hereditary diseases may not be entirely prevented in children, yet if carefully watched and properly treated, the tendency may be largely overcome, especially if the children are so closely watched that the beginnings of disease are noticed, for there are few diseases which are not curable if taken in their incipency. And in the present state of our knowledge are there not few diseases whose cause is really unknown, and therefore not preventable?

The causes of disease in woman may be conveniently arranged, as regards time, under the heads: 1. The diseases of puberty; 2, of menstrual life; and 3, of senility. The foundation for not a few of the pelvic disorders is laid during puberty, which is not to be considered simply the date at which the menses first appear, but rather the whole period required for the development of the sexual organs, the completion of which process is marked by the appearance of the menstrual discharge. No one who is familiar with the diseases of woman will doubt that a large percentage of these diseases, beginning at puberty or soon after, are continued with a varied history during the life of the patient, being increased or decreased according to the patient's good fortune, or perchance from treatment.

It seems to me Dr. Nathan Allen, of Lowell, Mass., has very tersely enunciated the correct basis upon which rests the "Laws of Health and Longevity," and the "Laws of Population and Human Increase," namely, upon a normal anatomy and physiology—"a perfect development of all the organs of the body, so that there shall be a perfect harmony in the per-

formance of all their respective functions." No one of our organs is unimportant; not one can be left out or weakened in its functional activity without the whole body suffering loss, and no one can be perfect without perfection in all the rest.

There is, I know, a law of compensation, whereby if one organ or system of organs is disabled or overworked, another will try to aid it to do its work, as the skin and alimentary canal when the kidneys are disabled, or the fingers and the ear when the eyes are useless; but these are conditions of disease, not health; of pathology, not physiology.

Tried by this law, then, what are the conditions necessary for the normal development of the reproductive organs? Plainly, the normal development and activity of all of the other organs and systems of organs, and conversely, the other systems of organs can only attain their highest functional activity when the sexual organs are perfectly developed. During the period of puberty, then, from 10 to 18 years, or more commonly from 12 to 16, do we ordinarily find the girls in our families possessed of an alimentary, glandular and vascular system sufficiently developed and so normally active that a healthy blood, containing in quantity and quality just the pabulum needed, is carried to each tissue? During these years of puberty which we are considering, the teeth begin to break down, in not a few instances, and as the result digestion is impaired.

But why do the teeth so often decay in girls at puberty and during early married life? Why is it, for example, that the German, Swede and Norwegian girls who come to this country with model teeth and are the picture of health, unless we except the light complexion of the Scandinavians as hardly compatible with the most robust health—why is it that these girls live in our families but a few years before their teeth begin to decay, and they lose the fresh bloom of health which they brought from their native land? And then, if they marry and bear two or three children, they are almost a wreck; their teeth are so decayed as to be of no use for mastication. They are poor and feeble, pale and anæmic, old and haggard, but the shadow of their former selves; in the best possible condition to receive and develop almost any form of disease, tuberculosis and the like. Why this change? It is not simply the change in their habits of life and the climate, though these have doubtless had their influence; but I believe a far more important cause will be found in the quality of their food. The quantity of the food they consume is probably greater than what they would get in the old country; but is the quality as appropriate for the nourishment and development of *all* the tissues? I believe not. For while the carbonaceous and albuminous foods are eaten in greater quantity, the *inorganic* is deficient, and here is an important source of weakness and decay, as I believe. The inorganic portion of the wheat is largely removed in the process of grinding, leaving only the starch and some of the gluten in the white flour which is eaten. While the brown bread from the coarser flour and from rye, which was formerly used largely in this country, and is still in most foreign countries, contained far more of the inorganic sub-

stances necessary for the development and nutrition of the bones, the teeth, and other important tissues, and as the result, the teeth erupted earlier, were better formed, and did not decay as readily, the bones were better developed, and all the tissues firmer.

During pregnancy, if the inorganic foods are not furnished the mother in sufficient quantity, the foetus will even take it from the bones, and especially the teeth, of the mother, for all the tissues, the softest as well as the hardest, must have inorganic food, and while these resources of the mother are freely drawn upon the deficiency may be so great that both the mother and child suffer for the want of them. But it is the rule that the mother will suffer first from the deficiency, her stomach will be disturbed, indigestion, heart-burn, and the like, and her teeth will decay and break away before the tissues of the foetus will seem to suffer. But these symptoms may usually be readily relieved by giving the mother a sufficient quantity of the lime and magnesia salts—in other words, furnishing her with a sufficient quantity of inorganic food.

And the developing tissues of infancy and childhood need more food of all kinds, the inorganic included, than the simply working tissues of adult life. So during puberty the girl needs more of this food for the proper development of the reproductive organs, a whole system of organs developing within a few years. To insure, then, a normal development of the sexual organs at puberty, there must be a suitable supply of *all* kinds of food, and not the least, the inorganic.

Among our American girls there is another important cause of imperfect development, and consequently abnormal functional activity of the generative organs, in the *style of dress* now so nearly universal, consisting essentially of the tightly fitting *corset*, with equally tight outer clothing—for even if the corset may seem to be loose when first applied, and they are never acknowledged to be tight by the wearer—yet it must and does prevent the expansion and development of the lungs and the muscles of the back and abdomen. It displaces the liver and stomach upward, and presses the abdominal viscera downward upon the pelvis, compressing these organs during the important period of their development, and laying the foundation for the congestions, the pelvic inflammations, the flexions, the displacements, and perhaps even the ovarian and fibroid tumors of later years. Among girls of foreign birth the corset is not generally put on until the changes of puberty are complete, consequently its evil effects are not seen as early, usually not until several years of menstrual life, or even after marriage. But our American girls are not *dressed* without the corset, even *before* puberty, so they have its evil effects during puberty, during menstrual life, and generally during the rest of their lives.

Not only does the corset prevent the development of and displace the important organs of the thorax, abdomen and pelvis, but it either alone, or with ingeniously contrived additions, is made to compress and prevent the development of the mammary glands, while it seems to enlarge them.

Dr. DeWolf tells us that statistics show that half of all the deaths are children under five years of age, and that while forty per cent. of all the babies born in the United States die in infancy, only eighteen per cent. die during the same period in Norway.

The chief reason for this frightful difference in the mortality is doubtless due to the fact that so many more mothers can nurse their children in Norway than in the United States, for I will not believe that there are many mothers in any country *who will not* nurse their children when they can. Corroborating and explaining these statistics is the statement that 10,000,000 of nursing bottles were made in this country during the last year. How many were exported and how many more were imported is not stated. Neither are we told how many *tons* of infant foods were manufactured in the United States and imported during the same period. Surely, all must acknowledge that very many of our American mothers cannot nurse their children, or only for a very short period, and that this is one of the important causes producing this frightful mortality among our children. Have we explained in part the reason for this? If so, the remedy is evident.

But so long as the corset is in favor, the gynecologist and the undertaker will thrive, and the wet nurse will be in demand.

But other systems are needed to complete the harmony necessary to the perfect development of the reproductive organs at puberty, beside the alimentary, the vascular, and the glandular. The muscular and the nervous systems have most important functions to perform. Physiologists estimate that the voluntary muscles normally require from one-third to one-quarter of all the blood for their nutritive and functional activity, and *vice versa*, healthy and active muscles are required for a normal blood, which shall be rich in the pabulum needed for the developing tissues. And here our American girls usually fail as puberty approaches, their muscular exercise is restricted, they are confined within doors and their time given to music, drawing, painting, and receiving friends, instead of the more active pursuits which would continue the development of the muscular system, while it aided alimentation; or perhaps what is worse, their time is devoted largely to study, thus calling into undue activity the nervous centres, and so developing the whole nervous system that this is ever afterward the dominant system.

The recent innovation of the manual training schools for boys is in the right direction for them, that their muscles may be developed and trained while their minds are being educated. And is there not an even greater need for similar schools for girls, that their muscles may be developed to correspond with the other organs? As during pregnancy, the developing foetus excites to activity all the other organs and systems of organs, and they in turn furnish the material needed for its further growth, so at puberty the growing sexual organs furnish a new stimulus to activity for all the tissues, and they in turn will exert an influence for good or ill upon these developing organs.

Dr. J. M. Toner, of Washington, D. C., who has

compiled some valuable tables showing the birth and death rate in different States and at different periods of time, says: "With a desire to view this question of birth-rate from a standpoint that would be sufficiently comprehensive, and yet free from even the appearance of preconceived notions or sectional partiality, I have made something of a study of what the records of the U. S. census of 1870 teach upon the subject of population, in its enumeration by ages; also of the births, deaths, etc. From this source I find undoubted evidence of a gradual decline in the population of children under 15 to the number of women between 15 and 50 years of age in our country. I do not propose to adopt any theory or to explain this extraordinary condition. But it is proper that the profession and the country should be made acquainted with the facts, and made to realize that the American people in this particular are showing unmistakable signs of physical degeneracy.

"I have," he says, "embodied facts only, and leave the enlightened understanding of the American people to assign the reasons, from the evidence everywhere around them, and to supply the remedy."

Do not the statements we have made point to some, at least, of the causes of this degeneracy? 1st. In the food not being appropriate for normal development. 2d. In a style of dress which hinders the development of several systems of organs; and 3d. In such habits of life that some systems of organs are developed out of proportion to the rest.

Says the Hon. Francis A. Walker, after comparing the increase in population during the decades 1840-50, and 1850-60, with the increase from 1860-70, the increase should have been three to four millions more. The lack of increase is in part accounted for by the loss of increase of about half a million of colored people, on account of the change in their liberation from slavery, and also by the loss of about a million persons in the Union and Confederate armies, whose deaths were occasioned by the war; and the calling from their homes, during four years of the war, of more than a million men must have had a great effect upon the increase of population.

But he says further, that "another cause may be alluded to namely, the notorious growth of habits of life in many sections of the country, which tend strongly to reduce the rate of national increase, and which, if persisted in, will make the showing of another census hardly so satisfactory as the present, even without a devastating war to account for the loss of hundreds of thousands in hospitals or on the battle-field.

"No one can be familiar with life in the Eastern and Middle States generally, and in the Western cities, and not be aware that children are not born to American parents as they were in the early days of the country. Luxury, fashion, and the vice of 'boarding' combine to limit the increase of families to a degree that in some sections has threatened the perpetuity of our native stock. This tendency is not one that needs be brought out by statistical comparison. It is patent, palpable, and needs no proof."

Of the many causes of disease acting during menstrual and married life, we will take the time to briefly

discuss but one, namely, the effects of the gonorrhœal poison in the female. As long ago as 1872 Dr. Noeggerath, of New York, called the attention of the profession to the importance of this poison in producing a variety of pelvic inflammations, and in 1876, in a paper before the American Gynecological Society, showed the effects of this virus in producing sterility in both the male and female. After these years of experience, many of the profession have learned to appreciate the importance of his observations, but I fear many still do not look for this for an exciting cause in the pelvic inflammations.

The symptoms of the disease have been so well and so fully described by Dr. Noeggerath that we need not now take the time to enumerate them—simply recollecting that an attack of gonorrhœa in the male may produce a slight stricture in some portion of the urethra, or may even affect the seminal vesicles and vasa deferentia, and in these positions remain latent for years, giving the individual no symptoms of its existence and making it difficult for the physician, even, to demonstrate its presence. But intercourse with a previously healthy wife implants the disease in her, and it lights up a series of inflammations which are always tedious and difficult to cure, and may become chronic, lasting through the whole of her menstrual life, and perhaps of her natural life, unless, fortunately, her life be shortened by this inflammation, aggravated by what would otherwise be slight causes.

Beginning as a slight or more severe attack of vaginitis and cervicitis, with likely a moderate attack of urethritis, it may readily be mistaken for the result of coitus in organs not accustomed to this function, or excessively used. But instead of subsiding from simple treatment, or none, as such a form of inflammation should, it extends along the mucous membrane of the whole genital canal, affecting the mucous membrane of the uterus, and even extending to the deeper structures, producing a true metritis; and after a time entering the Fallopian tubes and exciting a salpingitis. And from the peculiar anatomy of these organs—the abdominal end being larger than the uterine—the products of inflammation are readily thrown upon the ovary and into the peritoneal cavity, especially when the uterine extremity is abnormally contracted, as it usually is from the swelling of the tissues. Whence there results a perimetritis, which is usually of high grade in its acute stage, and and very tedious in the chronic. And in the chronic stage is very readily reëxcited into an acute condition by what would otherwise be slight causes—a cold, a fall, skilful manipulation with a sound or other instrument, operations not in themselves dangerous, like those upon the cervix or perineum. And resulting from these inflammations, the woman is very likely to be sterile, or if she becomes pregnant, to miscarry. And after she has been delivered, either at full term or prematurely, is in greater danger of puerperal fever from the chronic inflammation already existing in the pelvis. The gonorrhœal poison, then, in the female, produces a form of inflammation which readily passes into the chronic stage, and is with difficulty treated in either stage.

And how are these consequences to be avoided? Clearly, best by avoiding the original disease. And if these statements are substantially correct, and we believe they are, gonorrhœa is not the simple and temporary disease which it is often considered by both patient and physician—"a colic," "a slight acute disease" easily cured by simple treatment, and completely eradicated. But rather a disease which often continues during the greater part of the life, in the male, is readily transmitted to the wife, in her is, with even more difficulty, satisfactorily treated, and which frequently renders both husband and wife sterile.

As prevention is always the best cure, can there not be some way devised for preventing the spread of the venereal diseases? Should not competent physicians be employed to instruct the pupils in our public schools, of suitable age, the proper use and abuse of the reproductive organs, including the evils resulting from self-abuse, and the venereal diseases? Can we not, as physicians, aid in making vice as degrading and culpable in the *male* as in the *female*? And as gynecologists, hasten the time when our American women shall be the *healthiest*, and so the *happiest* and the *handsomest* of any land, as they are now the *brightest* and the *best*?

WHAT IS THE PROPER TREATMENT OF PENETRATING WOUNDS OF THE ABDOMEN?

BY HENRY H. SMITH, M.D.

OF PHILADELPHIA.

Among the marked changes of surgical doctrine, noted in the present century, none is more striking than the opinions held by many in regard to the development and results of peritonitis after injuries that involve this membrane. That inflammation of serous membranes presents rapid changes of circulation, sensibility and secretion, attended by marked constitutional disturbance, has long been admitted, and the apprehensions felt as to the result have been generally regarded as well founded. Yet such fears have not been universal: Marjolin, in 1832, having stated¹ that "he had often seen wounds of the peritoneum cured without any disturbing accident; whilst it was well known that paracentesis abdominis could be repeatedly performed, without creating peritonitis."

At the present time. doubts on this point are much on the increase; it being noted that the pleura can be perforated and serous effusions evacuated, without inflammatory symptoms, whilst Mr. Gay recommends "such incisions into the serous lining of joints, as will give free vent to pus or other products." Fraser also asserts² "that traumatic peritonitis, like traumatic pleuritis, is usually circumscribed and limited

to the locality of the wound," not producing in every case general symptoms. Gunshot injuries of the peritoneum have also been noted occasionally as unattended by fatal results; thus during the wars of Napoleon I, at the attack on Cairo, in the Egyptian campaign, Larry reported³ a case of gunshot wound that evacuated two ends of a loop of intestine; in which case, in order to relieve strangulation, the wound was enlarged, the intestine returned, and the patient eventually recovered.

So little apprehension is now felt by many gynecologists in regard to free incisions of the peritoneum in cases of abdominal tumors, that they lay open the walls of the abdomen from the sternum or umbilicus to the pubis without much fear of the result. Lawson Tait being recently asked for an opinion on the nature of an obscure tumor of the abdomen, said⁴ "Cut the patient open and find out," and it was done and the patient saved. "Surgeons," says he, "are beginning to understand that laparotomy is not such a dreadful operation after all." That it is a capital operation he admits—so are many others that no surgeon hesitates to perform, and "the idea," he says, "is rapidly becoming a thing of the past, that the peritoneum is a structure which must not be touched." In the same tone and on the same subject, Dr. Fowler, in an address as Chairman of the Surgical Committee of the Medical Society of Kings County, New York, speaking of the work done by Tait and Treves, says:⁵ "But there is yet work to be done before men, and good men too, can be induced to come out of their shell of conservatism, so-called, and with a bold front help to break down the prejudices and misgivings based upon an ill-founded fear of the peritoneum and its behavior under the knife. A very marked demonstration of the tolerance of the peritoneum under the knife was recently shown by Mr. Barker in the London Clinical Society, where an intussusception of the ileum, with complete obstruction of the bowel and acute general peritonitis, was operated on successfully by laparotomy; the inflammatory products being mopped out of the peritoneal cavity with sponges moistened with carbolyzed water, and the wound dressed with salicylated cotton and iodoform; the acute symptoms being at once relieved by the operation. Mr. Bryant, in complimenting Mr. Barker on the success of his treatment, stated he "did not consider peritonitis a bar to the operation."⁶

With such views freely expressed, especially by gynecologists, are surgeons justified, in any case of gunshot wound penetrating the peritoneum, in opening the abdominal walls, checking hæmorrhage, removing foreign substances and giving free vent, by drainage-tubes or other means, to the pus, etc., found in connection with wounds? This important question can only be regarded as yet "*sub judice*." In a recent report⁷ of gunshot wound of the intestines successfully treated by laparotomy by Dr. Bull, of the New York Hospital (all the small intestines ex-

cept the duodenum being examined out on the abdomen, and numerous wounds sutured), the treatment being subsequently discussed, January 27, 1885, in the New York Surgical Society,⁹ Dr. Bull stated as a proposition that "given an abdominal wound, with a patient in good condition, and without any symptoms which would enable the surgeon to determine whether or not the intestines have been perforated, he believed it proper first to explore the wound, and if it was found to enter the peritoneum, then to open the peritoneal cavity by operation and endeavor to remedy the damage done." In the course of the debate Dr. Weir, of New York, "believed it justifiable to make an exploratory incision and to examine with the finger," etc., but Dr. Sands said whilst "he should feel strongly inclined to follow the practice adopted by Dr. Bull, he yet thought it impossible, at present, to formulate our experience so that it would enable us to determine positively when to operate."¹⁰

As this recent debate and recent cases hereafter quoted show that there is such diversity of opinion on this subject as renders the surgeon's treatment open to the charge of malpractice; especially in those cases of gunshot wounds which result from violence and expose the attacking party to the grave charge of murder, it is very important that there should be some expression of professional sentiment that will free the surgeon from the charge in a court of justice, that the patient's death was the result of the treatment, and not positively caused by the wound as first created. I present this question, therefore, to this Section, as the highest authority on surgical doctrine in our country, and hope to elicit the judgment of those present whose attention and experience has enabled them to form an opinion.

In order to show that a *healthy* peritoneum as well as a diseased one, can sometimes be freely incised and lacerated without fatal results, I shall briefly allude to three well-known cases. In 1806 Dr. Samuel White, of Hudson, N. Y., removed a silver teaspoon on August 7, thirty days after it had been swallowed by an insane patient.¹¹ The spoon had passed from the stomach into the intestines, and was perceptible to the touch. By an incision three inches long, parallel with the epigastric artery and extending upwards to near the level of the crest of the ileum, he divided the abdominal muscles, opened the peritoneum with a lancet, caused the lower turn of the intestine, containing the spoon, to protrude, pierced the intestine over the end of the handle with the same lancet, and extracted the spoon with dissecting forceps. He then closed the opening in the intestine with the Glover's suture, dressed the external wound with adhesive strips and lint, and the wound healed by the first intention. There was no Listerism at that date. Renaud, of France,¹² likewise successfully removed a silver fork from a young man's stomach by gastrotomy. Houston reports¹³ a case of a woman who fell from a hay-mow upon the handle of a pitchfork, which en-

tered the vagina, passed up into the abdomen, perforated the diaphragm, and passed into the thorax till it struck the second rib. It was withdrawn; the patient lived many years subsequently, and an autopsy showed some of the abdominal viscera had protruded into the thorax. Brigham, of Utica, reported¹⁴ an incision of the abdominal parietes made by an insane woman with a pair of scissors, with which she also cut off seventeen inches of her intestines, and subsequently recovered. Dugas, of Georgia, reported¹⁵ a case in which the intestines were twice cut by a bowie-knife, closed by the Glover's suture and replaced, the abdominal wound sutured, and the patient recovered under a water dressing. Many similar wounds of the peritoneum and viscera are well known and need not now be cited.

The following cases may be mentioned: "Wound of the stomach" (St. Martin) by Joseph Lovell, Surgeon-General U. S. Army. *Am. Med. Recorder*, vol. xiii, p. 14, 1885. "Case of excision of part of the spleen" (the patient recovered after peritonitis) by W. B. Powell, M.D., Kentucky. *Am. Jour. of the Med. Sciences*, vol. i, p. 481, 1828. "Penetrating wound of the abdomen and section of the intestinal canal successfully treated on the plan of Ramsdohr," by Zena Pitcher, M. D., U. S. A. *Am. Jour. of the Med. Sciences*, vol. x, p. 42, 1832. "Case of gastrotomy, successful," by J. E. Manlove, M.D., Tennessee. *Am. Jour. of the Med. Sciences*, vol. x, N. S., p. 532, 1845. "Perforation of the abdomen (four inches long) by a fence rail; intestine protruded covered with dirt; cleaned and replaced. Recovery." By Robert G. Jennings, M.D., Va. *Stethoscope*, vol. i, p. 490, 1851. "Puncture of the stomach with protrusion of this organ for six hours; nearly the entire stomach protruded. Wound closed by sutures; water dressing; cure." By Chas. Wm. Ashby, M.D., Va. *Stethoscope*, vol. 1, p. 660, 1851. "Wounded intestine treated by suture; recovery," by J. J. Chisholm, M.D., Charleston. *Charleston Med. Jour.*, vol. viii, p. 615, 1853. "Incised wound of left side, three inches long, between the eighth and ninth ribs, followed by protrusion of the stomach and its strangulation. Reduction and recovery." By W. W. Hart, M.D., Miss. *Western Jour. Med. and Surg.*, vol. xi, p. 496, 1853. "Abdominal Wound," by Thos. P. Bailey, S. C. *Charleston Med. Jour.*, vol. ix, p. 604, 1854. "Wound of small intestine successfully treated by the interrupted suture," by J. C. McGee, La. *New Orleans Med. and Surg. Jour.*, vol. xi, p. 23, 1854. "Perforation of the stomach; recovery," by C. Haffield, M.D., Charleston. *Charleston Med. Jour.*, vol. x, p. 341, 1855. "Punctured wound of the abdomen; protrusion of intestines; their return obstructed by a band," by A. Fleming, M.D., Philadelphia. *Am. Jour. of the Med. Sciences*, vol. xxxiii, p. 321, 1857. "Incised penetrating wound of the abdomen with wound of and protrusion of intestines; recovery," by J. J. ¹⁴ This case is quoted from Agnew's Surgery, vol. i, p. 352, 1878, as taken from the Amer. Jour. of the Med. Sciences, vol. ix, N. S., p. 355, 1845, but I could not find it by his reference.

¹⁵ Southern Med. and Surg. Jour., vol. viii, p. 407.

McGuire, of Richmond, at the meeting of this Section in 1881,¹⁵ ably discussed the question of the treatment of gunshot wounds of the abdomen; reporting four cases of shot wounds of the peritoneum that did not wound the intestines, showing that a bullet *could* glide between the intestines without wounding them—an important fact in the prognosis and treatment of these cases, by demonstrating that such wounds, without visceral complications, are not impossible. Death, it is true, occurred in all these four cases; but in Dr. McGuire's opinion "it was the result of blood-poisoning, produced by absorption of the bloody serum poured out by the peritoneum after the wound." Might not a free incision and evacuation of this serum have been useful? In continuing his paper Dr. McGuire asks, as I now do: "Is it not time that we were trying some other course of treatment in cases of this character in place of the expectant or do nothing plan generally resorted to?" and he then proposes laparotomy and "a thorough inspection of the injured parts."

Dr. P. S. Conner, of Cincinnati, in his valuable article on this subject,¹⁶ says: "The experience of the past twenty years has clearly demonstrated that the laying open the peritoneum is not as dangerous as had been previously thought; that this serous membrane is a great lymph sac that will absorb septic material most readily and rapidly, and that for a preventive of a fatal result from such absorption, drainage must be secured. When, then, the symptoms clearly indicate that extensive bleeding has occurred or is taking place, or that the stomach or intestines have been opened, it certainly seems to be proper and the surgeon's duty to perform laparotomy, turn out the clots, cleanse the cavity, and provide for the ready outflow of any fluid that may afterwards be poured out."

That this opinion of the liability of absorption by the peritoneum of the diseased products of injuries is sound, is proved by the anatomical study of the tissues, it being well known since the days of Bichat that serous membranes are only a modification of connective tissue, and that there is an identity of functions and affections between the two, as both are continually engaged in the great work of exhalation and absorption; the main difference being that the peritoneum is a more condensed membrane than connective tissue. The peritoneum has also a basement membrane and an epithelium, and is furnished with a great abundance of exhalant pores and absorbents which carry on their functions with great activity.¹⁷ This has been proved by their readily receiving a mercurial injection, which diffuses itself over their whole surface and causes the membrane to appear as if formed entirely of such vessels. Mascagni, whose beautiful plates are well known, asserted that the power of absorption continued in this membrane many hours after death, and Leidy, several years since, established the existence of minute foramina of the peritoneal coat of the stomach; these orifices being, in Horner's opinion, probably formed by

meshes of lymphatics; just as the gastro-intestinal follicles are formed by meshes of veins. Unquestionably some communication exists between the arterial system and the peritoneum, as proved by exhalation and morbid phenomena.¹⁸ Bleuland, at Utrecht, and Vanderkolk in Holland, have made preparations which prove that the peritoneum contains blood-vessels. A drawing of the capillary vessels of the peritoneum covering the liver, minutely injected, is also furnished in Smith's anatomical atlas.¹⁹ In the healthy state, the peritoneum is not sensitive, as may be proved by the impunity with which it may be irritated in living animals; though nerves were traced in it by Purkinje, and in the pleura by Bourgery. When serous membranes inflame "they become, as is well known, acutely sensitive, though they resist inflammation for a long time; but when inflammation extends to them, the portion of the peritoneum nearest the seat of disease manifests it by adhesions and disorganization, without the whole membrane becoming involved."²⁰ The establishment of peritonitis often becomes important in connection with the treatment of wounds of this membrane, and it should not be forgotten that percussion gives a clearer sound in the commencement of peritonitis than in health, and that this clearness day by day becomes more obscure, especially at the lower part of the abdomen, whilst auscultation reveals a friction sound (*bruit de frottement*) analogous to that of pleurisy or pericarditis.²¹

Knowing, then, the active absorbing surface that exists in the peritoneum covering the walls and contents of the abdomen, and the rapidity with which blood-poisoning follows absorption of diseased products, an additional reason is presented (only, it is true, on theoretical grounds), for the evacuation of such products, the cleansing of the tissue and the destruction of diseased germs by the judicious use of antiseptics, and again the question presents itself, how is this, in the case of wounds, to be best accomplished? This question is yet awaiting practical facts and the history of cases in which it has been performed, whether successfully or otherwise, and it is to be hoped that there are some present who can offer them. The extended information furnished by the war of the Rebellion is graphically described by the late Surgeon Otis,²² of our Army, in the "Surgical History of the War," and I give it as his opinion "that laparotomy will henceforward be employed with increased frequency, not only in the treatment of morbid growths, but also in obstructions and wounds of the abdominal organs."

Admitting, then, that this operation may be correct in certain cases, it is important to remember that when it is performed, the incision should generally be in the line of the linea alba, and be free enough to explore the injured region; that a clear and decided statement should be made by the surgeon to

the patient or his friends of the very serious nature of the wound and the uncertainty of the result; presenting clearly the fact that the operation will possibly give an additional chance of recovery, the patient subsequently wearing an abdominal supporter to guard against hernia. Under anæsthetics; with the caution and technique pursued in laparotomy for the removal of tumors, and with the knowledge, as before stated, that in cases of a judicial character, the defendant's lawyer is sure—if possible—to charge death on the surgeon, rather than on the original wound, the treatment of wounds of the abdomen by laparotomy will doubtless be carefully weighed by the evidence in its favor, now slowly accumulating. To collect this evidence, and show the present sentiments of experienced surgeons on this mode of treatment, is the object of the discussion now opened.

DR. B. A. WATSON, of Jersey City, said that if it could be determined that the intestine was perforated laparotomy was demanded, as this procedure would limit fæcal extravasation and control hæmorrhage; that the difficulty was in making the diagnosis, and as this was not always possible, it should be remembered that the opening of the abdomen in gunshot wounds did not materially increase the danger. If the cavity was opened, perfect antiseptic precautions should be employed, and the cavity thoroughly cleansed. That it was not prudent always to wait until dangerous symptoms had developed before operating. The consent of the patient should be obtained, and the operation, if undertaken, should be thorough, and should include the removal of all albuminous fluids from the cavity and an accurate and exact examination made to determine fully the damage inflicted by the wound, and a perfect cleansing of the parts made.

DR. E. H. GREGORY, of St. Louis, said that the condition of the patient, rather than the character of the wound, should control the practice adopted; he waited until urgent symptoms had developed and plainly expressed a need for operative interference. Where the intestinal canal was undoubtedly opened, then the operation was always proper. He did not think that the presence of inflammation, the result of the injury, influenced unfavorably the result of operative interference, for able practitioners believed now that opening the cavity of the abdomen and thoroughly cleansing it with washes was good practice in acute peritonitis; he further stated that traumatic inflammation was limited and not diffused; that the wound from the injury and the wound from the operation would both produce local inflammatory process, and unless some other agent, possibly sepsis, intervened, the inflammation did not necessarily result fatally.

DR. J. B. HAMILTON, U. S. Marine Hospital Service, said that he believed dangerous symptoms did not always develop until death was imminent; that he would not wait for such signs, but where he believed the intestinal canal had been wounded he would proceed at once to an operation, without waiting for inflammation. He related a case which came under his observation, where a man suffered from a

gunshot wound of the abdomen with perforation of the intestines, in which he waited for the development of urgent symptoms, and the patient died. Subsequently another case similar in character came under observation, and was subjected to immediate laparotomy, and in which eleven wounds were found in the small and two in the large intestines. This case recovered after the operation.

DR. H. O. MARCY, of Boston, thought that the hæmorrhage following a puncturing wound was often a concealed one, and that fæcal extravasation or hæmorrhage gave rise to septic infection and inflammation, and he considered the exploratory operation justifiable. Speaking of the sutures to be used in intestinal wounds, he said that fine chromotized cat-gut sutures were most applicable; that he had made excisions of the gut and united them by double lines of continuous sutures.

DR. D. W. YANDELL, of Louisville, remarked that some patients would get well under any plan of treatment; that he believed the operation should be done at once or not at all; that the size of the ball had but little to do with the demand for the operation, and further stated that, in his opinion, patients frequently died without the development of urgent inflammatory symptoms.

DR. R. A. KINLOCH, of South Carolina, stated that he believed he was the first man who opened the abdominal cavity and sutured the intestinal canal for gunshot wounds of the abdomen. He also claimed that he was the first to free the bowel from the adhesions at the site of the artificial anus and to reunite them. He thought fæcal extravasation was not a necessary consequence of penetrating bullet wounds, even where they traversed the intestinal canal, but that he could not believe, however, that traumatic inflammation was always limited, as it extended rapidly in the abdominal cavity, possibly as a result of septic inflammation.

DR. J. MCF. GASTON, of Georgia, said that much depended upon the ability to arrive at a clear diagnosis of the extent and nature of abdominal wounds preliminary to laparotomy. In punctured or gunshot wounds of the abdomen the doubt as to existing lesions of the intestinal canal may, in most instances, be resolved by passing two tubes through the opening, which should be enlarged if requisite for this purpose; one of which is connected with a Davidson's syringe, and of sufficient length that it may reach the most dependent portion of the abdominal cavity, leaving only the terminal opening; while the other, of corresponding proportions or somewhat larger, should have openings upon the sides for two or three inches at the lower end. A saline solution containing one ounce of the chloride of sodium to the quart of water, at a temperature of 100° F., should be thrown in and allowed to pass out continuously through the escape tube, so as to carry off any accumulation of blood or any fæcal extravasation. If the outward flow should be arrested by clogging of the fenestrated tube, it must be removed and cleared of obstructions, either by clots of blood or fæcal matter, when it is to be replaced and the process continued until the water returns free from admixture with the

contents of the abdominal cavity. The tube that connects with the syringe should then be removed, and the remaining fenestrated tube attached to the other extremity of the syringe, when, upon working it, a suction through the tube will remove any surplus fluid from the cavity of the abdomen.

While this process ought to remove either blood or the extravasated contents of the alimentary canal, the absence of the latter admixture in the fluid discharged cannot be relied upon for a final decision as to penetration of the intestinal wall, as the opening may be so small that the hole will be closed up by the natural contractility of the muscular tissue of its coats. But apart from the aid in diagnosis, this measure is advisable as a curative agency in removing sanguineous effusion; and this saline solution is not found to prove detrimental, but, on the contrary, salutary to the peritoneum.

In regard to awaiting the development of symptoms, as recommended by one of the speakers, after a diagnosis of intestinal perforation, there are examples of favorable results; but with the light before us, an exploratory opening of the abdomen is warrantable in any case presenting indications of a penetrating wound of the coats of the intestine. The speaker referred to two cases²² of abdominal section in his personal experience, which terminated fatally from the delay of one day and three days respectively, during which peritonitis had become developed and constitutional symptoms supervened from the extravasation of pus in one, and the sanguineous effusion in the other. Hence, it was thought best to operate at the earliest practicable period after such injuries.

ON ELECTROLYSIS;

With Special Reference to its Trial in Inflammatory Products in the Female Pelvis.

A Preliminary Report.¹

BY JAMES HENDRIE LLOYD, A.M., M.D.,

INSTRUCTOR IN ELECTRO-THERAPEUTICS IN THE UNIVERSITY OF PENNSYLVANIA.

During the past Spring the writer began a series of exact clinical observations upon electrolysis in the human body. The object was to determine: (1) the utility of the process at all; (2) the diseases in which it was applicable and useful; (3) the best methods of applying it with precision; (4) the current strength—*i. e.*, the greatest potency with the least pain and damage. The observations were intended to be entirely clinical, because (1) it was considered that the theory of electrolysis was sufficiently established without further experimental proof, and (2) it did not appear, after some reflection, how experiments on other tissues, or the lower animals, would give us any facts which could not be as well observed in the diseased tissues of the human body. The first disappointment met with was the difficulty

of obtaining a sufficient number and variety of clinical cases. This was, no doubt, due largely to the summer vacation, when all medical work in this city suffers a great hiatus. This will explain the fact that this paper is preliminary to a report which the writer hopes to make in the future, and to have as complete as possible; and must constitute an apology for trespassing upon your time with much less material than it was his original intention to present. The cases presented below, if few in number, have at least been thoroughly observed. Dr. I. P. Willets gave much assistance in this work.

It may be well to remind you that electrolysis is the breaking up of a fluid, or substances held in solution, into its constituents, by the passage through it of an electric current. Thus, water is resolved into hydrogen and oxygen, as may be readily observed upon passing a mild current through a tumbler of this fluid. In compound fluids, or salts, the acids seek the positive while the alkaline bases go to the negative. The subsequent chemical actions of these acids and alkalies are just the same as would be the case if they were introduced from without, and constitute the secondary actions of electrolysis. These changes are in exact quantitative relation to the strength and duration of the current—that is to say, with so much current-strength continued a certain time (or, technically with so many *coulombs* of electricity), just so much hydrogen, oxygen, or whatever the simple atoms or compound radicle may be, will be liberated. In such a simple fluid as water the figures of this problem are exactly known, but in such a complex, organized series of tissues and fluids as exist in the human body (while doubtless the changes are just as constant and according to law), the figures are not known, and may never be. It is, of course, understood that the galvanic current is here referred to, as induction-currents are without practical electrolytic effects. In addition to these true electrolytic effects there are other effects, both physical and physiological, which are important to be understood. First of these in importance is the so-called “electrical osmosis,” formerly called the cataphoric action of electricity. Dr. Amory, in his recent work on Electrolysis, lays great stress upon this action. When an electric current is passed through two fluids separated by a porous septum the fluid itself will pass in the same direction as the current, *i. e.*, from the positive to the negative. This is demonstrated outside of the human body. Dr. Amory speculates that this nutrition is affected, the parts being literally robbed of their pabulum by the osmosis, or flow of nutrient fluids toward the negative pole. But, theory aside, we have an array of clinical facts—fortunately accumulating—that there is a decided solvent action in the electric current, both upon normal and abnormal tissue. This may, or may not, be strictly according to the known facts of electrolysis or osmosis. It is probably partly because of them, and partly because of other factors regulating the vascularity and nutrition of the parts, which are but little understood. The chief observers of exact facts have been Cinicelli, who studied aneurisms; Dixon Mann, who studied the quality and

²² Reports of these cases will be found in the Southern Medical Record, Jan. 20, 1885, and in the Medical and Surgical Reporter, June 12, 1886.

¹ Read before the Philadelphia County Medical Society, October 27, 1886.

quantity of clots formed in blood by an electric current; Duncan, who has cured many cases of nævus by galvano-puncture; and Fox and Hardaway, who have removed supernumerary hairs by the current. In addition, we have Newman and Bruce Clark, who report, especially the latter, such candid and exact details of electrolysis in the cure of stricture, that we are scarcely permitted to doubt; Mundé, who empirically and without sufficient detail, reports success in inflammatory products in the female pelvis; Engelman, who has removed a uterine fibroid with very strong currents; Kelsey, who has cured hæmorrhoids, and Reeve, who uses electricity as a reliable emmenagogue.

Conditions of Observations.—The series of cases upon which this paper is based was chosen because of the comparative ease of observation (most of the phenomena being readily accessible), and, also, because of the importance and general prevalence of inflammatory, vascular, neuralgic and functional lesions in these parts. These cases all had a history of cellulitis, followed, probably, by the state of relaxed circulation so well described by Emmet, and characterized still further by neuralgic pains in loins, abdomen, ovaries and limbs, while the menstrual epoch was usually deranged—dysmenorrhœa being especially prevalent, with leucorrhœal discharge in the interim. Touch revealed in all these cases more or less fibro-plastic deposit, causing pain on pressure and more or less fixation of the womb. The *disadvantages* of this series of cases were, chiefly, that the application of electricity had to be made through mucous membrane (which, undoubtedly, must diffuse some of the current to surrounding parts), that some of the most urgent symptoms were subjective (and, therefore, not always reliable guides), and, finally, that the vascular condition would vary from day to day or week to week, and tend to confuse the observation of the permanent effects, if any, upon the adventitious products.

The Method.—The patients were put in the dorsal position, and, first, the negative electrode was introduced into the vagina and well against the point of apparent greatest deposit. This negative electrode was at first cylindrical in form, about $1\frac{1}{2}$ inches long and $\frac{1}{2}$ of an inch in diameter, nickel-plated and fastened upon a flexible insulated stem about 8 inches long. The nickel-plated end was covered with absorbent cotton thoroughly soaked in warm water. Later, the cylindrical form was substituted by a small, olive-shaped electrode, also nickel-plated and covered with absorbent cotton; this was done in order to concentrate the current more effectually. The circuit was completed by applying a large flat sponge positive electrode to the abdomen. The position of this electrode was changed at times, according to circumstances; where there was much ovarian pain, it was put over the ovary; where there was lumbar pain, over the lumbar region, etc. The polarity was never changed. The cells used were the blue-stone cell, known as the Siemens-Holske modification of the Daniel. The number of cells was not usually noted in the reports, as the current strength was taken entirely by a galvanometer, which was

kept in circuits as desired. This galvanometer was made by Flemming, and was guaranteed by him to be an accurate clinical instrument. It is vertical, graduated in milliampères, and patterned, in the main, after the Hirschmann instrument. The lowest strength used in these cases was 6 milliampères, the greatest strength was 24 milliampères. These extremes were used only occasionally—the greatest strength, in fact, but once, and then inadvertently and with the effect of cauterizing the mucous membrane. The average strength used was about 14 milliampères. The duration of treatment was almost invariably 10 minutes; in some exceptional instances the treatment was continued to 15 minutes. The vaginal electrode was occasionally shifted about or passed, firmly pressed upon the mucous membrane, from one side of the vagina to the other. The *immediate* effects of these applications upon the patients were almost *nil*. No complaints were made of pain, except by one patient in whom there existed almost a vaginismus, and who suffered from the introduction of the instrument rather than from the current. Even in the instance when the mucous membrane was destroyed by a too powerful current, no complaint was made of pain, and, in fact, the accident was not discovered until the following day.

These cases were kindly sent by Dr. Wm. L. Taylor, from the Gynæcological Dispensary of the University Hospital, and the treatment was conducted in the Nervous dispensary.

Case 1.—C. S., 46, married; three children, youngest 20 years. Complains of metrorrhagia. Treatment: February 23, 1884. Slight dilatation of cervix, and endometrium curetted, with removal of granulations. Ergot, etc.

August 20, 1885. Returns, complaining of "cramps in bowels." Some congestion of uterus, with slight tenderness on pressure.

April 20, 1886. Returns after attack of peritonitis (cause unknown); was sick for a couple of weeks. Touch: Cervix undergoing absorption; fundus anteflexed and fixed; tenderness and enlargement posteriorly and to left of body.

April 24. Treatment was begun in the manner related above, and continued with two applications per week. The greatest current strength attained was 18 milliampères, from thirty cells (which were not at their best at that time). There were twenty-two applications in all. After five applications, the patient reported that she was menstruating, the first catamenial show in eight months. After eight applications, the patient reported, and continued to report, her subjective symptoms much improved, *i. e.*, the neuralgic and bearing-down sensations. After the ninth application, Dr. Taylor made a careful examination, and found that actual absorption had taken place, and that the uterus was more movable. This absorption was confirmed by another careful examination, made after the twelfth application. The only set back was caused by the patient doing some heavy domestic labor after the fifteenth application. Until the last application, however, there was some complaint of pain. Treatment was suspended by patient leaving the city.

Case 2.—A. S. 31, married; sterile; puberty at 17. Always had inward weakness, with dysmenorrhœa, since puberty. One year ago she had an attack of inflammation. Since then she has had bloody leucorrhœa, severe pain in each ovarian region, and in hypogastrium particularly; sense of great weight and bearing down. Touch: Uterus firmly fixed by inflammatory lymph; fundus anteflexed; mass extremely tender. Treatment began in same manner and frequency as in the preceding case. The external electrode—large sponge anode—was frequently applied over the lumbar region in this patient, because lumbar pains were among her most distressing symptoms. This patient has had, to this date, twenty-one applications, averaging about 14 milliamperes, continued ten minutes. After four applications, Dr. Taylor reported her condition unchanged. After six applications, the patient said she was much relieved of pain in her back. After eight applications, she had a menstrual flow, which was more free and less painful at the commencement, but became as painful as ever toward the close. The usual cramp-like pains were not as bad as before treatment. After ten applications, Dr. Taylor made another examination, and reported slight improvement, *i. e.*, the parts were more pliant and less painful. After the twelfth application, she had a severe dysenteric attack, with much abdominal pain, which left the left ovary tender and sore. We note evidence of much thickening between cervix and left vaginal wall. The patient, of her own accord, absented herself for about one month at this time. When she came back, she reported that her disagreeable subjective symptoms, pain and bearing down, had returned during the suspension of treatment. After the fifteenth application, she had apparently suffered from an acute, circumscribed peritonitis (or cellulitis), which caused some increase of deposit. She still said, however, that she had less pain. At the sixteenth application, a much stronger current was passed than formerly. This was due to the fact that our cells had been overhauled and supplied with new zincs, thus increasing their electro-motive force, and to the omission to observe with due care the record of the galvanometer. We had, moreover, no rule by which to limit current strength, so that when we discovered the increase (24 milliamperes), it was purposely continued for some minutes. The patient made no complaint of pain at the time, but presented herself next day with the remark that she thought "something was wrong." Examination then revealed a place, the size of a half-dollar, upon which the mucous membrane had been destroyed, leaving a sloughing, ulcerated wound. Treatment was suspended, and after a week the patient had entirely recovered without any untoward symptoms. This patient continues under treatment. There has not been as much improvement in her condition as in the former case, if we regard the absorption of lymph. There has been decided improvement in her symptoms of pain.

Case 3.—I. M., æt. 29, married; one child, 7 years. Four years ago had an attack of cellulitis lasting six weeks. Since then has had aching in back and limbs, pain in hypogastrium—worse at menstrual

periods: menses regular in time and last one week; leucorrhœa; vertical pain. Touch: Cervix low down. Fundus anterior and fixed. Deposit of lymph posterior to uterus.

April 24. Treatment begun as in former cases. This patient had a total of seventeen applications. The current strength on some occasions was allowed to run up to 18 milliamperes; the average used, however, was about 14. The number of cells required for this strength would vary from twenty-five to thirty; but these cells at this time were not in their greatest activity. After four applications Dr. Taylor reported actual condition unchanged. There was ovarian tenderness; on this account the anode was usually applied over the left ovary. The history of this case can be briefly summed up as one of continued improvement. Neuralgic pains, especially, yielded, even more than the deposits, but toward the last it was very evident to touch that the parts were softer and more pliant. The patient finally said that she "had not a pain or an ache," and discontinued treatment of her own accord. This case was not as bad from the start as any of the others here reported.

Case 4.—C. B., æt. 28; married; eight years; puberty at 14; always had severe dysmenorrhœa. This has been increasing in severity. Four or five years ago had an attack of pelvic cellulitis. Since then she had had sharp pain in region of right ovary, pressure on bladder, and sensation of weight in pelvis. Touch: Cervix of uterus low down in hollow of sacrum; fundus acutely anteflexed. In each ovarian region there is great tenderness, with deposit of lymph; also posterior to uterus (which is firmly fixed) there is a deposit, larger to the left.

April 24, 1886. Treatment commenced as in other cases. There have been to date, twenty-eight applications. This patient has been much more sensitive than the others. She has a condition approaching to vaginismus, the whole vaginal tract appearing to be hypersensitive. In consequence, an average less current strength has been used than in the others; this average would be about 13 milliamperes. After three applications, had a menstrual flow more painful than usual. Changes in this case were slow and mainly in the direction of less pain and sensitiveness. After thirteen applications she said that she always suffered some pain after each treatment, which pain lasted several hours, but was not severe enough to be a serious matter. There were, no doubt, some hysterical symptoms in this patient. Her menstrual periods continued very painful for a long time, and she insisted that she always had a febrile reaction with them. After thirteen applications, the evidence of cellutic deposit still existed. After twenty-four applications, Dr. Taylor examined patient, and said that the deposits were much softened and almost gone. He considered patient much improved. This patient is still under treatment. She still has painful periods, but has much less vaginal and ovarian sensitiveness than formerly. This case was more obstinate and discouraging at first than any of the others, but can be claimed, at last, to have yielded to treatment. The evidence of absorption of deposits in this case seems to me to be beyond dispute.

Conclusions and Inferences.—The great objection, in my mind, to the theory of true electrolysis in these cases is the resistance of the mucous membrane and the diffusion of the current; in other words, the weakening and loss of current strength before it actually reaches the neoplasm. This objection does not hold when galvano-puncture is used, as in aneurism and the cure of moles and nævi; also in the removal of hairs, or in subcutaneous treatment of goitre, as the writer has himself practiced it. But in strictures of the male urethra, and in these cases of cellutic deposit in the female pelvis, I do not see how galvano-puncture could be well practiced, certainly not safely in the great majority of cases. However, in the light of clinical results, we are justified in continuing a procedure even if it does not harmonize with some theoretical data. I have always insisted upon the necessity of measuring the current strength, if we design to place our observations on as scientific a basis as possible, and as far removed from the haphazard empiricism which is too characteristic of electro-therapeutics. Without a galvanometer serious damage might have been done in case 2. Without it, moreover, the operator is exposed to a number of other accidents, and, in fact, can never know what he is about. The patients' feelings in these cases were no gauge. I have known the current to be broken by the slipping out of the cord at the binding post, or interrupted by inadvertently turning it through a rheostat. But the most common cause of error is the varying resistance of the human body, and the difference, in this respect, of one patient from another. This is illustrated in the above cases, as follows: On the same day the current from a certain number of cells gave but 6 milliampères in C. B., but gave 14 in A. S. This great difference I was unable to explain, but quite able to overcome. Finally, I have often thought that there might be some analogy between the action of galvanism, under these circumstances, and counter-irritation. Any one who has felt the persistent soreness produced on the skin of the back of the hand by a strong current, with a tendency to desquamation, or even vesication, could readily believe in this resemblance. We have no very good explanation how counter-irritation acts, but still we use it successfully to promote absorption under a great variety of conditions. It seems possible that a strong current (and these currents were as strong as could be well borne) might produce counter-irritation upon the vaginal mucous membrane and promote absorption of inflammatory products within.

The procedure in intra-vaginal galvanism is no doubt, open to the objection of being tedious, and requiring frequent repetition, which is in a measure compensated by its being painless and less disagreeable to the patient than some other methods of treatment; while it seems to offer more relief to some of the symptoms than other plans. Among the special effects noted in these cases was the promotion of menstruation. The current-strength used did not tend to re-excite inflammation except in case 2, in which case, however, the evidence was not entirely conclusive.

HOW THE ILIAC ARTERIES ACT AS VALVES UPON THE VENOUS FLOW INTO THE INFERIOR VENA CAVA.¹

BY CHARLES A. TODD, M.D.,

OF ST. LOUIS, MO.

It is a familiar dictum in anatomy that the veins in the great cavities of the body have no valves. In the cranial and thoracic cavities, this deficiency would not seem to be detrimental. The blood readily drains away from the head through numerous channels. In the thorax the venous trunks are comparatively short, and are, besides, directly subject to the suction action of the respiratory movements of the chest walls. In the abdomen, on the contrary, we have difficulties affecting the flow of blood through the great veins. By reason of the constant patency of the hepatic veins and their opening into the cava just as it pierces the diaphragm, their contents are immediately within the influence of the thoracic suction, and the freedom of the liver circulation is thereby insured; of course, the portal flow is thus facilitated. But between the diaphragm at the opening for the cava and the commencement of that vein on the fourth lumbar vertebra, there is a great column of blood formed mainly by converging streams coming from the pelvis and lower extremities, which must ascend against gravity and apparently under generally unfavorable conditions. Under such circumstances we should expect that congestions of the lower extremities would be extremely common, through the comparative inertia of the blood in the inferior cava and iliac veins. Upon close examination, however, of the anatomy of the region that naturally would be the site of greatest disturbance—the commencement of the inferior vena cava—we find an arrangement of the parts that suggests a solution of the problem.

It will be remembered that the ascending vena cava lies to the right of the abdominal aorta, while its parent trunks, the common iliac veins, both lie to the left of the right common iliac artery, and pass under it to reach the cava. The common iliac veins, therefore, at one point lie between the right common iliac artery and the bone; the vessels being bound together by the firm pelvic fascia. Now this arrangement, I believe, is by no means an indifferent one, a mere survival of anatomical conditions outgrown in the course of evolution, but one that accomplishes a most important end, viz., to supply the place of a valve in the great abdominal vein,—and just where such a support is most needed,—at the bottom of the column of blood and at the mouths of its primary branches, the common iliacs. The valve action is to be found in the arterial pulse: The artery being bound down by a strong fascia, in its pulsations must compress the vein, thereby more or less completely cutting off temporarily the venous current. In this manner the blood column above is supported, while the stream below is relieved, a more steady onward flow resulting.

I have made vivisections upon dogs to demonstrate

¹ Read in the Section on Surgery at the Thirty-Seventh Annual Meeting of the American Medical Association.

this valve action. After opening the abdomen and sufficiently displacing the parts with the hand to allow the finger to rest on the vessels, the iliac vein below the site of the arterial crossing could be felt to swell synchronously with the pulse. Other more elaborate experiments were not successful. A manometer, consisting of a hollow cylinder of thinnest rubber, one end being closed, the other slipped over a glass tube bent at a right angle, was passed up the femoral vein until the guide could be felt in the cava. This apparatus being fixed in position, was filled with water and the changes in its level noted.

The small calibre of the vessels, the influence of the respiratory movements, and probably other causes, deprived these experiments of any positive value for or against. In the human cadaver I have injected the femoral vein with water and clearly demonstrated the fact that the iliac veins were strapped down, so to speak, by the common iliac arteries just below their point of union with the cava. Elsewhere we find similar disposition of vessels. The lesser azygos passes under the thoracic aorta just before opening into the great azygos. I have seen it markedly dilated at this point.

The thoracic duct must be compressed during the pulsation of the aorta, as the two lie together in the osseo-fibrous foramen of the diaphragm. I have, indeed, read in some work on physiology, that fluctuations in the escape of fluid from that duct had been observed, that justified a belief in such behavior of the aorta.

MEDICAL PROGRESS.

UNIQUE CASE OF INJURY TO THE EAR.—DR. LOUIS J. LAUTENBACH reported the following interesting case at the meeting of the Philadelphia County Medical Society, on October 20, 1886.

J. H., aged 36, salesman, came to me February 18, last, on account of a ringing, a feeling of fulness and deafness of the right ear, which he said had come on the previous afternoon. Up to this time, according to his statement, his ears had been of equal hearing power, and he had noticed no defect nor suffered any inconvenience from either ear. On the afternoon of the 17th, while walking along the railroad, the New York express, going in an opposite direction, went past him, his right side being toward the train, when he suddenly experienced a sharp pain in the right ear, which was accompanied by deafness, a marked degree of ringing and fulness being experienced immediately. The pain soon disappeared, but the dulness, ringing and fulness were present when he presented himself to me.

When examined he had no pain, but yet there was slight tenderness occasioned by pressing on the tragus. The watch (of which the average hearing distance is 52 inches) was heard at 11 inches with the right ear and at 3½ inches with the left. The tuning fork aurally was heard equally in the two ears, but by bone conduction it was heard very much more

loudly in the left ear. The anterior wall of the meatus was found to be quite red, and at about three-eighths of an inch within the tragus a stiff, hair-like body was seen to be inserted; following the course of this body inward it was found to perforate the membrana tympani immediately below and very slightly posterior to the insertion of the manubrium of the malleus. The awn, or beard of wheat (for this is what subsequently the foreign body was found to be), was wedged between the inner wall of the tympanum and the wall of the meatus, being bent like a bow. The membrane was decidedly concave outward, it was tense, it was very much congested, particularly along the handle. The outer end of the wheat beard was detached from the wall of the meatus, and by the forceps was withdrawn from the tympanum, requiring an appreciable amount of force—much more than I had expected to exert. As it was withdrawn, a little pus exuded, and this was followed by a drop or two of serous fluid. The hearing of the ear was now reduced to five inches, but the feeling of fulness, of dulness of hearing, and the ringing, entirely ceased. The left ear being examined showed marked evidences of middle ear catarrh. The tuning fork, by aerial conduction, showed no change, but, by bone conduction, it was heard only slightly (instead of markedly, as before) better in the left ear.

The foreign body was a piece of the awn, or beard, of a wheat grain, and was 24 mm. in length; its thick, flat end had penetrated the membrane, and its teeth, or saw-like points, with which it abounds, were directed forward; this explains the force required for its removal, as well as the reason why it lodged so readily in the wall of the meatus. Admitting that there was occasioned by the foreign body an increased hearing distance, it is an interesting question: How was it produced? It may be that the pressure exerted inwardly was sufficient to bring the stapes into a more nearly normal position, thus improving the hearing; the pressure being removed, the hearing diminishing. It is, however, far more probable that the ears were of unequal value before the accident, but that the patient took no note of the difference.

CHLORIDE OF METHYL IN TRIGEMINAL NEURALGIAS.—No agent yet used for the relief of trigeminal neuralgias equals in promptness and efficiency chloride of methyl sprayed upon the parts. The writer has for many years suffered with occasional attacks of neuralgia of the trifacial, the attack being generally confined to the left infra-orbital though sometimes affecting the frontal nerves. Everything by turns has been tried, and though many remedies have afforded temporary relief none of them lasted long, until the method of spraying with fluids of an exceedingly low boiling point was suggested. Ether, and rhigoline were found prompt and efficient, cutting short an attack and giving long periods of rest. Recently methyl chloride was tried, the result being an instantaneous suppression of pain, and thus far there has been no return. Methyl chloride is a haloid derivative of the paraffines obtained by distilling to

gether sulphuric acid, common salt and methyl alcohol (wood spirit). Under ordinary circumstances it is a colorless gas which condenses under pressure into a fluid with an extremely low boiling point. The chemical, as used by the writer, was manufactured by himself, as it is not yet in the market. Indeed, the difficulties in the way of preparing and using it (the extremely low temperature at which the fluid returns to the gaseous state being the chief difficulty) will prevent the common use of the drug until some special means are devised for its preparation, preservation and application.—*St. Louis Med. and Surg. Jour.*, Nov., 1886.

THE PHYSIOLOGICAL ACTION OF MENTHOL.—DR. GOLDSCHIEDER, at a meeting on April 9, of the Physiological Society of Berlin, discussed the action of menthol on the sensory nerves. It was well known that it produced on the skin a sensation of cold, which was commonly ascribed to evaporation. On the other hand, the same sensation, when produced in the mouth by solutions containing menthol or peppermint, was explained by a supposed astringent effect. Dr. Goldscheider had come to the conclusion that neither of these explanations was correct. He made his experiments with a solution of menthol in lanolin, which he rubbed into circumscribed regions of the skin. After the rubbing, the thermometer showed, in all such places, an increase of temperature to the extent of 2° Cent., notwithstanding the marked sense of cold produced. The hypothesis of evaporation was excluded by the fact that the feeling of cold was no less marked when the part rubbed was covered with a watch-glass, and could, therefore, be produced only by direct stimulation of the nerves of sensation of cold. Again, if of two corresponding places on the forehead, where these nerves are most abundant, one were rubbed with the menthol ointment, and the other not, bodies which previously had caused no particular sensation would be felt as cold on the former spot, but not on the latter. Dr. Goldscheider, observing that while some regions, as the forehead, were especially sensitive to cold, others, as the elbow and the volar side of the wrist, were so to heat, found that the inunction of these with menthol produced a sensation of warmth, though less striking than that of cold in the former regions; and he called attention to the recent communication of Professor Herzen, on the precisely analogous results of pressure on the nerve trunks in these regions respectively. He therefore concluded that the sensations in some places of cold, and in other places of heat, produced by menthol, were purely subjective and consequent on the direct stimulation of the special nerves of temperature, those usually cognizant of cold being far more sensitive to its influence than were those adapted to receive impressions of higher temperatures.—*British Med. Jour.*, Aug. 21, 1886.

ELECTROLYSIS IN LUPUS VULGARIS.—GÄRTNER and LUSTGARTEN have treated ten cases of lupus by electrolysis with good results. They give an account of their method in the *Wiener med. Wochenschrift*, Nos. 27 and 28, 1886. Instead of employing

the common method of puncturing the skin with steel needles attached to the negative pole of a galvanic battery, they use a flat electrode consisting of a silver plate slightly curved and set in a hard-rubber ring. The rubber ring is employed to prevent the edge of the plate from acting on the skin. The part to be operated on is washed with soap. A current of five to eight milliampères is allowed to flow through the part for ten minutes. The electrolytic action is confined to the diseased points, the cicatricial tissue or the sound skin between the lupus nodules being almost always unaffected. The lupus nodules, on the other hand, are excoriated and swollen, and give vent to a clear, watery, sticky fluid. After a few hours they sink in and become covered with a brown, leathery scab. The part should be dressed with iodoform and the scab allowed to fall, which it does in from eight to fourteen days. The result is a flexible pigmented cicatrix. The procedure is painless. The operation is indicated by the superficial location of the disease. It may be practiced both in the ulcerating and non-ulcerating forms.—*New York Medical Journal*, Nov. 6, 1886.

QUININE AND OIL OF TURPENTINE IN MALIGNANT PUSTULE.—DR. DON F. RIVAS describes in *La Union de las Ciencias Médicas* some cases of malignant pustule which were rapidly cured by the application of a paste composed of quinine and oil of turpentine. One of the cases was that of a shepherd, in whose flock the disease had manifested itself. He was stung by a mosquito on the forehead, and two hours afterwards the head and neck were extremely oedematous. The paste was applied and the pain and swelling shortly diminished. A couple of days later a large quantity of sanguinolent fluid was discharged, and by the fourth day the man was quite well. Another shepherd of the same flock, who was similarly affected, made use of some of his colleague's paste without consulting a doctor, and was also cured in four days. A third case was that of a woman who had a malignant pustule on the hand, which was unaffected by various remedies which were applied, but on the application of the quinine and turpentine paste the severe pain ceased almost immediately, and the oedema rapidly diminished, the patient being restored to health in four days.—*Lancet*, Oct. 16, 1886.

ICHTHYOL IN RHEUMATISM.—DR. BUBELIR has been using ichthyol in rheumatic cases, both of an acute and chronic type, with success. It is applied, after careful washing and drying of the affected part, either in the crude form or as a compound sulphate of ichthyol and soda or ammonia, and at the same time is given internally in the form of drops or pills, the dose being from 15 to 25 drops of the sulphate of ichthyol and ammonia, or a similar quantity made up into from six to twelve pills. In all cases the pain was relieved, but the swelling was not affected, and the author thinks the drug must only be used in the expectation of relieving pain. He says that where the external applications are for a long time, or without the precautions of washing, a pustular eruption may occur.—*Lancet*, Oct., 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, NOVEMBER 27, 1886.

LAPAROTOMY AS A DIAGNOSTIC RESOURCE.

At the meeting of the New York County Medical Association, on November 15, DR. T. GAILLARD THOMAS read his first paper before the Association, and, coming from such a source, with a subject of such marked significance at the present time, "Laparotomy as a Diagnostic Resource," it will naturally attract much attention. Empiricism, Dr. Thomas said at the outset, has steadily given away before logical deduction; the dogmas of the schools and the dicta of the masters have gone down before clinical research and experimental demonstration; and the theorist of the closet and the bookworm of the library have been replaced by the chemist, the anatomist, and the microscopist.

The modern development of the art of diagnosis has been accomplished by the subordination of theoretical methods of exploration and investigation to those which were purely physical; but throughout the whole domain of surgery there is no field in which diagnosis is more surrounded by difficulties than that of abdominal neoplasms. Formerly the diagnosis of abdominal tumors was allowed to rest upon deductions capable of being drawn from rational and physical methods, the latter of which were limited by the abdominal walls without and the pelvic roof within; but to-day surgeons devoting themselves to this department of our art are fully agreed as to the propriety of opening the abdominal walls for the purpose of exploring the viscera fully by touch, and to a limited extent by sight. After an experience yielded by seven or eight hundred cases, approximately, of laparotomy for various causes, extending over a period of twenty-three years, Dr. Thomas feels that he can

say with truth that he has never once regretted opening the abdomen, and that he has in a dozen cases, at least, deeply regretted not having done so. He thinks it certain that in the future explorative abdominal incision will become the rule in all cases of the following conditions which do not yield to medical means, and concerning the etiology of which there is great doubt: 1, wounds and injuries of the abdominal viscera; 2, intestinal obstructions; 3, the presence of stones in the bladder or kidneys; 4, the accumulation of blood, pus, or serous fluid from any source; 5, the existence of a neoplasm in any part of the abdomen; 6, the occurrence of serious organic changes in certain of the viscera of the abdomen, such as the kidneys, the spleen, the uterus, the Fallopian tubes, or the ovaries; 7, ectopic gestation.

Even under the most favorable circumstances, the most skilful diagnostician is constantly likely to make errors without its aid; and hence it is that explorative incision is peculiarly valuable. In order to better convey his views and give his experience upon this subject, he mentions first some cases in which he had to regret non-interference, and then others in which more active measures produced happier results. The first case related was one of intestinal obstruction which occurred seventeen years ago, in which it was decided not to operate. The patient died, and at the autopsy a loop of intestine was found constricted by a string of false membrane, the result, probably, of some old peritonitis, which could at once have been removed by snipping with a pair of scissors. The second case was one of large uterine fibroid, which caused fatal exhaustion by its pressure on the abdominal viscera. The question of exploratory laparotomy was decided in the negative, and the patient died; but at the autopsy it was found that the tumor, which weighed forty pounds, was entirely unattached in the peritoneal cavity, and connected with the uterus by quite a slender pedicle; so that removal would have been easy. The third case was that of a lady who had a very large abdominal tumor, which was apparently solid. Consequently operative interference was declined; but when she died, about a year afterwards, it was found that the neoplasm was a multilocular ovarian tumor, entirely free from adhesions, with a small pedicle, and which could have been removed with every prospect of success. The reason for the obscurity of the diagnosis in this case was, that the tumor was composed of innumerable small cysts, the walls of which were thick, and the fluid within them colloid. Case fourth was another one of intestinal obstruction, in which it was decided not to operate, and at the autopsy it was found that

the transverse colon at its middle was distended with hardened fecal matter held in an indissoluble mass by a quantity of hay. It is certain that upon abdominal section this would have been readily discovered, and it is probable that by a process of kneading it could have been dislodged and pressed on towards the rectum.

He mentions an obscure case which proved to be one of extra-uterine pregnancy, in which no operation was performed, and said in defense that almost all of this variety of his cases occurred fifteen or twenty years ago; which time carries us back into the ancient history of the subject. Few such cases occur to him now, for the reason that he is a strong advocate of explorative incision as a diagnostic resource. He mentions a few out of the very large number of cases in his later experience which illustrate the brilliant results which commonly attend upon this procedure. The first was one of supposed large uterine tumor with ascites, for which the patient had been repeatedly tapped, until she was in an exhausted condition. Laparotomy was performed, and he found that the fluid was not the result of ascites, but was ovarian fluid, which poured out from a ruptured ovarian cyst, which in its collapsed state occupied the pelvic cavity, giving rise to the belief that it was a fibroid. The operation for removal of the sac was simple, and the patient made a rapid recovery. The second was a case of hæmato-salpinx, in which the excessive distension of the Fallopian tubes gave rise to a sensation of solidity which made the diagnosis before operation very obscure. Both tubes and their corresponding ovaries were removed, and the patient was entirely cured. The third case was quoted as illustrating the fact that cases of abdominal tumor are sometimes utterly beyond the realm of diagnosis until the cavity is opened. For years this patient had a firm tumor behind the uterus, when suddenly she became almost collapsed and suffered greatly from pain in the tumor, which nearly doubled in size in a day or two. Laparotomy was performed, and a large blood-cyst was emptied from Douglas's cul-de-sac; after which he shelled out the skull of a six months foetus. The patient died in ten days from cardiac thrombosis. The fourth case was one of intestinal obstruction caused, as was found on opening the abdomen, by a mass of malignant growth encircling a considerable portion of the large intestine. The patient died about a month after the operation.

There is one class of cases in which in his hands, Dr. Thomas says, explorative incision has yielded particularly brilliant results, viz.: cases of ascites in

the female. In this connection he makes the special point that some cases of excessive ascites, which by repeated tapplings prove fatal, are due to insignificant uterine or ovarian tumors, which are too small for recognition unless specially and carefully looked for, and the removal of which relieves the fluid accumulation which, by its exhausting influence, destroys life. These tumors are sometimes no larger than a small apple, and cannot be recognized except by the careful examination of an expert. In stout women, and often even in thin ones, they cannot be discerned at all after accumulation of ascitic fluid has taken place. Moreover, in some cases even where a tumor in the pelvis as large as a cocoanut coexists with ascites, no connection between the two pathological conditions, as cause and effect, is ordinarily traced by the medical attendant. Should this be the case, should the existence of the neoplasm be not detected, or should the malign influence not be appreciated even when its presence has been diagnosed, the physician will probably endeavor to cause absorption by pressing into action the three emunctories, the skin, the kidneys and the bowels. This usually fails, and if it does not—the cause of the symptom remaining after the symptom itself has been removed—frequent resort must be had to the plan, which in time impairs nutrition and exhausts the vital energies. If, on the other hand, tapping or aspiration be employed, the beginning of the end soon shows itself, and it becomes merely a question of time how long the system of the patient will bear the exhausting drain to which it is exposed. Dr. Thomas has met with a number of cases in which he completely cured aggravated cases of ascites, after tapping had been repeatedly resorted to, and after all hope of recovery had been given up. He feels justified in assuming the position that in cases of ascites in the female, before the patient is relegated to the usual practice of repeated tapping, with its universally bad results as to cure, the most thorough investigation in regard to the possible existence of small neoplasms as important pathological factors should be made; and if signs of their existence be obtained, explorative incision should be made, as a forlorn hope that relief might be obtained.

In closing his valuable paper Dr. Thomas refers to two practical points. The first is the curious fact that in certain cases of abdominal incision, in which diagnosis alone is practicable, and others in which removal of the tubes and ovaries is impossible, great improvement sometimes results to the patient's general and local condition from the explorative effort alone. The second point is the necessity for certain

rules which should be observed in the performance of this simple surgical procedure: 1. Every explorative incision should be made under the strictest antiseptic precautions. As to strict cleanliness, all are agreed; if antiseptics of chemical character are valueless, they at least, in all probability, do no harm. While the question as to their utility is still *sub judice*, give the patient the benefit of the doubt, and employ them. 2. Always employ an anæsthetic. 3. Always make an incision which will admit the whole hand; one which will admit two fingers only is hardly warrantable. If possible, let but one man's hand be passed into the abdominal cavity. 4. Never hurry an explorative incision, but never prolong one unnecessarily. Let discussion as to diagnosis occur after the peritoneum is closed; not while it is open.

THE ABUSE OF MEDICAL CHARITIES.

Several months ago MR. JAMES ERSKINE, of Glasgow, read an interesting paper on this subject, it being more particularly concerned with the abuse of medical charities in his city. But this abuse is not confined to Glasgow, or to foreign cities: almost any dispensary physician in this country who keeps his eyes open in his consulting room and at the dispensary will soon see that there is a fearful abuse of medical charities by people who are not only able to pay for advice and treatment, but who would never think, in all probability, of asking charity in any other way. Even those dispensaries over the doors of which the sign reads, "The poor treated free" are abused by impostors; what then must be the case when the sign reads "Treatment free," without a word as to the poor?

It may perhaps be useless to inquire into the various motives of the people who ask such charity when they are unworthy of it. But one thing is certain: no class of men is so philanthropic and benevolent as medical men; and while they, as a rule, are at all times ready to give the benefit of their skill and experience to the deserving poor, it is time that they make the public understand that they cannot do more public charitable work for nothing than all the other professions put together, and that they cannot give this time and work to undeserving people. Not only should it be publicly stated that a dispensary is only for the poor, who are unable to pay for medical advice, but the circumstances of patients should be inquired into. This is done at the London Hospital and other London institutions; and Mr. Nixon, the Governor of the London Hospital, said about a year ago that this system of inquiry excluded about 50

per cent. of the applicants, especially in the special departments. At a recent meeting of the Manchester and Salford District Provident Society, Mr. John Watts said that they "started out with the knowledge that of the applicants for medical relief at the various hospitals and dispensaries of the city, there were $42\frac{1}{2}$ per cent. who could, if provident dispensaries had existed, have paid provident dispensary fees, and therefore been independent of medical charity. After ten years of their work, that percentage, instead of $42\frac{1}{2}$, was $13\frac{1}{2}$. Thus, directly as dispensaries treat unworthy patients free they are robbing the medical profession of a certain portion of legitimate income. In the City of Chicago there is at least one dispensary, within a stone's throw of two or three physicians, which treats free all who apply. The public have an idea that dispensaries employ physicians of exceptional skill; and is it to be supposed that certain classes of this public will pay for what they can get next door for nothing? As thus carried on a dispensary is an outrage on the profession. Mr. Erskine's paper may be found in the *Glasgow Medical Journal* of November.

But neither Mr. Erskine's paper nor the foregoing remarks direct attention to some of the causes that have exerted great influence in developing the rapid increase of Free Dispensaries, Infirmarys and Clinics, and have multiplied their patrons fourfold during the last twenty years. We allude to causes that have originated in the profession itself, and which are still in full operation, more especially in all the larger cities. If our readers will revert to the social and professional history of the last thirty years, they will see that the growth of specialties in medicine and the multiplication of Free Dispensaries with overflowing patrons in all the centres of population have kept pace with each other so closely as to indicate something more than mere coincidence.

Prior to 1850 almost all educated members of the profession were general practitioners both of medicine and surgery; and it was regarded as the duty of every one to give faithful and kindly attention to such poor patients as might ask for their services, as is still inculcated in our Code of Ethics. If cases occurred involving much expense or too protracted attendance, assistance was almost always rendered by the County Commissioners or Town Supervisors, and in the larger cities here and there a Dispensary was established chiefly for the purpose of furnishing medicines to those who brought prescriptions from physicians stating that they were not able to pay for the medicine needed. Such an institution as the

Dispensary of the present day, with, not only an apothecary to dispense medicine for the poor, but also the regular attendance of a full medical staff embracing one for every recognized specialty, ready to give *special* attention *freely* to the diseases of each organ or group of organs composing the human body, had no existence in our country, at that day. If the physician or surgeon in full practice found more poor patients coming than he could find time to attend to, he sent them to the nearest well qualified young doctor who was waiting for calls and glad to take them, both for the clinical experience he would get and the almost certainty of their proving stepping-stones to other cases that would pay. But the rapid development of *specialties* brought, *pari passu*, the disposition of medical students to educate themselves for *special* or limited fields of practice, and the equal education of the community to look for a special doctor for each region of the body. This soon necessitated the invention of some method by which the young specialist could get himself introduced to the public, and as the Code of Medical Ethics, whether written or unwritten, would not allow them to flood every man's door-steps with hand bills illustrated with the cut of an eye, ear, uterus, speculum or stethoscope, the next thing available was to utilize the public sympathy for the sick-poor in establishing Dispensaries, Infirmaries, Asylums, Special Hospitals, Clinics and Polyclinics, for each of which there must be the names of a few prominent business men or women to serve as trustees, managers, or its patrons, and a medical specialist for each class of diseases the institution is intended to accommodate. By this process the young doctor secures a public position which at once brings him in contact with some prominent members of the community, and in plain English, advertises him as a specialist and a liberal friend to the poor. Meantime he has his regular office fitted up in good style for the reception of ordinary patients, and both for the purpose of securing sufficient revenue and duly impressing his customers with the importance of *special* qualifications, he must charge not less than *five dollars* for the most ordinary examination.

Now, with the same *specialist*, or even non-specialist, making a minimum charge for patients at his own office, equal to what most working women can earn by not less than two weeks' hard labor, and at another part of the same day bestowing the same services at the Dispensary for nothing, how long does it take the laboring classes of both sexes to learn the avenues open to them, and to arrive at the conclusion that they are not able to pay the amount of one or two

weeks' wages for the same professional services that they can get at the Dispensary for nothing. It is exactly this kind of machinery, invented and fostered by the profession itself, that has, during the last three decades, filled all our cities with so-called medical charitable institutions, converted tens of thousands of the working classes from moderately paying patients into full medical mendicants, and robbed the younger class of medical and surgical practitioners of the patronage of the very class of honest working people, that formerly constituted the chief avenue through which they gained in a few years reputation and full practice. If the members of the medical profession have thus fostered a system of extravagant specialism and equally redundant medical charities, by which they find their own pockets empty, the principal blame is upon themselves, and it will require something more than the closer questioning of the applicants at the door of the Dispensary concerning their pecuniary circumstances to correct the evil.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Nov. 1, 1886.

E. J. DOERING, M.D., PRESIDENT, IN THE CHAIR.

DR. ALBERT E. HOADLEY read a report of
FIVE CASES ILLUSTRATING A TREATMENT OF THE MORE
SEVERE FORMS OF STRICTURE OF THE RECTUM.

Case 1.—J. H. G., an engineer, æt 40, with history of piles of eight years standing and stricture two years. Examination revealed a hard carcinoma of the rectum within one and a half inches of the anus, immovable on account of adhesions to the sacrum. The adjacent parts were involved and the bowel completely occluded. The general condition of the patient was bad. Abdomen swollen and very tender. Had not had a passage from the bowels for two weeks. Could not take food without immediately vomiting. Pulse feeble, 120, temperature 102°. At the first examination Dr. Hoadley succeeded in separating the adhesions sufficiently to pass a syringe pipe beyond the immediate stricture. A half-pint of soap water was injected a number of times during the afternoon and evening with the effect of bringing away considerable matter and gas and giving great relief to the patient. Three operations were performed at intervals by which a fair canal through the cancerous mass was made, but without relief to pain. At the fourth operation the lower end of the growth and sphincter ani were divided with one stroke of the knife. There was little hæmorrhage. The relief obtained by the division of the sphincter was tenfold greater than that from all the other operations.

Case 2.—A laborer, forty-two years old, with history of hæmorrhoids, and stricture of five years standing. Examination revealed a firm unusual stricture within two inches of the anus. Syphilis could not be excluded as he was put on large and increasing doses of pot. iod., and a systematic dilatation with an elastic bougie commenced. After four weeks a bougie one inch in diameter could be passed without difficulty. There was no particular irritation at the seat of the stricture, but the bowels were very irritable and there was an increasing diarrhœa. The stricture and sphincters were thoroughly divided and the wound packed with gauze on which dry per-sulphate of iron had been sprinkled. Relief was immediate and complete. Examination two months after the operation showed the wound to be nearly healed and the patient feels better than he has felt for a year previous.

Case 3.—An American woman, aged thirty-nine, the mother of three children; she had a stricture of nine years standing. When the stricture was divided it was found that the rectum contained a carcinomatous mass, almost occluding the canal, higher than could be reached with the fingers. The sphincters were divided back to the coccyx and an incision was made through the mass nearly to the sacrum, and a piece of gauze pressed on the wound to prevent bleeding. A large-sized drainage tube was placed in the bowel above the disease. The rectum was packed and all secured with a T bandage and the patient put to bed. After the fifth day she rapidly improved and left the hospital within a week after the operation. Three months afterward she was comfortable and had gained six pounds.

Case 4.—A German woman of fifty six years, the mother of several children. She had enjoyed good health until the development of the stricture of the rectum about three years before. The stricture and sphincters were divided, and on introducing the finger the bowel was found blocked up with other strictures of a malignant character. These were dilated with the fingers. A violent inflammation supervened and the patient's life was threatened. She made a slow recovery and was convinced that she was made worse by the operation. Dr. Hoadley thought that if the strictures had been incised instead of divulsed, the patient would have derived benefit.

Case 5.—An American of sixty-seven years, the mother of four children. Labor had always been normal and easy. She had a stricture of five years standing. Examination revealed two or three open sinuses and fluctuating abscesses in the ischio rectal region. The abscesses and sinuses were opened and packed with iodoform gauze and the stricture divided, the sphincter being simply dilated. Great relief followed the operation which was made to relieve pain and not with the hope of prolonging life. From a study of these cases, Dr. Hoadley deduced the following principles:

First, it is dangerous to practice divulsion of malignant stricture of the rectum; second, division of a severe stricture of the rectum without dividing the sphincters is of little practical value and has no

tendency to cure; third, division of malignant strictures with the sphincter gives great relief and tends to prolong life; fourth, division of severe non-malignant stricture with the sphincters gives great relief and tends to perfect cure; fifth, division of both stricture and sphincter whether malignant or non-malignant is not attended with danger. Therefore we may conclude, that in all severe strictures of the rectum, whether malignant or non-malignant, complete division of the stricture and all the tissues below it back to the tip of the coccyx affords the greatest relief and of the non-malignant strictures, the best means of permanent cure at our command.

DR. J. FRANK thought that if the author had divided his paper into relief for malignant strictures, and treatment for non-malignant strictures, it would have been a better classification. He had not had much experience with malignant strictures, but had divided one in the manner described by the author, by cutting down through the cellular tissue. He thought there was little danger in performing the operation, and was surprised at the small amount of hæmorrhage. But the benefit from the operation lasted only for a short time, there was relief at first but in six or eight weeks the same symptoms returned. Even in extirpated cancerous growths, as far as his information went, they generally return within a year. He had had one case in which the whole cancerous growth was extirpated, but in six or eight months it commenced to return and in a year's time the patient died with cancer. He thought that in dividing the strictures care must be taken not to go too far up the bowel, or too deep, as the peritoneum might be cut into.

DR. A. E. HOADLEY in closing the discussion said: Dr. Frank suggests that we be careful in dividing the strictures high up; I think if we do not divide them higher than we can reach with the finger, dividing them in the posterior line, there is little danger of opening the peritoneal cavity. The peritoneum does not come down as a rule, where it can be reached with the finger. In regard to hæmorrhage, those cases sometimes bleed profusely even though they are divided right in the median line, where we least expect to find blood vessels; the tissues become vascular, new vessels form, and it is necessary to tampon the wound and in doing so it is best to put in a tube to relieve the bowels of gas. The suggestion made in reference to the division of the paper is quite proper; perhaps it would have been better to have said, report of cases illustrating a treatment. The treatment is palliative in malignant strictures, and in non-malignant strictures sometimes effects a cure. In answer to the question how many inches up may we go; it is a rather difficult matter to reach the peritoneum of the posterior wall of the rectum with the finger, even if the sphincter is divided; you can reach about four inches with the finger by pushing hard, and I think I would hate to divide a stricture further than I could reach with my fingers. Even the inferior mesenteric artery (superior hæmorrhoidal) comes down sometimes, before it bifurcates into the lateral branches, within reach of the fingers and may be

divided, but that is no drawback to the operation because you can put a tampon into the rectum so firm that all hæmorrhage can be perfectly controlled and on the next day you may remove about half of the tampon to relieve tension, and the remaining half will tumble out itself three or four days later. It has been my experience, and it is on the authority of the textbooks, that the vessels there can be controlled with the tampon very securely and with perfect safety. It is best to prepare for it and always tampon where you make that division, because moderate hæmorrhage is sometimes quite persistent.

DR. A. J. OCHSNER read a

REPORT OF A CASE OF ACTINOMYCOSIS,

with exhibition of patient. The patient, a stock raiser, aged fifty-six, entered the Presbyterian Hospital of Chicago, October 13, 1886. Until the autumn of 1877 the patient was in perfect health, following his occupation of stock raising. At that time he was exposed to drafts of cold air during a journey, and experienced severe neuralgic pains in the left antrum of Highmore. He had seven teeth taken from his upper jaw from which all the other teeth had previously been removed, but these proved to be sound and he obtained no relief by their removal. For six months he suffered excruciating pain in the left antrum and in both eyes from sunrise until sunset. In 1878 there was a spontaneous opening of the abscess into the pharynx evacuating a considerable amount of pus and some blood and giving the patient marked relief. A portion of the discharge usually entered the larynx at night, giving rise to severe cough. In May of that year the patient underwent a surgical operation, an opening being made into the antrum above the first molar and the cavity curetted and irrigated. The irrigation was continued two or three times daily for two years, during which time he suffered severely from pain and weakness. In the spring of 1882 the patient went to northern Mexico and spent the summer on the plains and among the mountains between that point and Colorado. His general health and strength were much improved. In July, 1885, the patient began to cough and continued to do so until his admission into the Presbyterian Hospital. During September, 1885 and 1886 he expectorated blood, but thinks it came from the posterior nares. Since the first of October, 1886, he has expectorated mucus and pus streaked with blood which undoubtedly comes from the lungs or bronchi. The patient has lost thirty-seven pounds in weight during the past two years; his position is stooping, chest full in front and a decrease of motion on the left side with dulness, roughened respiratory sounds and numerous mucous râles. Below the upper border of the fifth rib and throughout the right side the sounds are normal. The history of the patient led to a suspicion of actinomycosis of the left lung, which had primarily existed in the antrum. By a microscopic examination of the sputum the characteristic fungus was at once found confirming the diagnosis beyond a doubt. Dr. Ochsner considered the following facts of practical interest in connection with the case:

The patient has been engaged for more than forty years in raising, buying and selling large numbers of cattle. Many of these animals suffered from lumpy jaw, and it was his practice to cure them by freely opening the abscess, by crucial incision, extirpating as much as possible of the lump and introducing about one drachm of powdered arsenic into the cavity. Repeating this once or twice, usually effected a permanent cure.

DR. R. H. BABCOCK said: The case is one of exceeding interest from its rarity, and particularly as it is a case occurring in this country and one of very few that have been recorded, and in this case the diagnosis is so unquestionable that the interest is all the greater. We know that in cattle the disease is manifested by tumefaction in various organs, whereas in human beings it is by suppuration and metastatic abscesses. The disease in the human being may affect any of the organs, not merely the lungs, but particularly the viscera of the abdomen. I would like to ask Dr. Ochsner if there are signs of the disease having attacked other parts of the body than those mentioned, any symptoms which lead him to infer that the digestive organs or the stomach are infected.

DR. R. TILLEY said: This is certainly one of the most interesting questions that has been brought before the society for a considerable time. In the case presented to-night the disease seems to have originated in the antrum, and is therefore especially interesting to those engaged in treating affections of the nose and throat, and the teeth, as in the history of this case, there was a considerable amount of pain associated with the eyes, it is of interest to the ophthalmologist, and as it is now associated with the lungs, it is of interest to those engaged in the study of affections of the lungs. As this case together with the last case presented to the society, in all probability constitute the only indisputable cases that have appeared in English literature, I think it would be of sufficient interest to the society to ask Dr. Ochsner to carry the investigation still further and try and produce the disease by inoculation on one of the lower animals. I will move at the proper time that the Society place at Dr. Ochsner's disposal the necessary funds. I would suggest that Dr. Ochsner accompany his report with a diagram of the fungus as it appears under the microscope. I have looked at the various schematic sketches that are published, and I claim that it would be absolutely impossible for any one with only the information afforded in these articles, without further study, to diagnose the fungi as they appear in the specimens presented. In Dr. Belfield's book I think the diagram is more in correspondence with those we see to-night, but those that are in Councilman's article in Wood's Reference Handbook certainly do not present such an appearance.

DR. J. R. SKEER inquired the condition of the lung at the present time, whether cavernous or indurated.

DR. FRANK BILLINGS endorsed the remarks of Dr. Tilley, and thought the society should afford Dr. Ochsner means to carry on the investigation. It is

not quite settled how this fungus is carried from one tissue to another; in one case it has been proven that it was carried to the heart by ulceration into one of the jugular veins, and it is known that it will spread through contiguous tissue as through the diaphragm from the pleural cavity to the peritoneal cavity. A pure cultivation of the fungus has been made at Berlin.

DR. HAROLD MOYER said: There is great uncertainty as to the manner in which the fungus obtains access to the tissues. I would ask Dr. Ochsner if there is anything in history of this case that would clear up that point. Two very interesting cases have been recently reported, in one case lung actinomycosis was diagnosed during life, and after death of the patient a large actinomycotic mass was found in the lower portion of the upper lobe of the left lung, and in the center of the mass a piece of tooth was found. Israel (*Centr. Bl. f. d. Med. Wesseusch*) demonstrated actinomycosis in the sputum of that case, and so far as I know it is the only case on record in which a diagnosis was made from the sputum. The other case bears on the manner in which the fungus obtains access to the tissues and is reported by Soltmann (*Jahrb. f. Kinderhke*). A child while at play swallowed a head of what is known as fox grass, which was followed by severe pain, difficulty in swallowing, and difficulty in respiration. In a few weeks the head of grass was discharged in an abscess at the left of the vertebral column. In less than six months this case developed actinomycosis. The theory of Israel regarding the first case is that the parasite was carried by the piece of tooth directly into the lung. In the second case the fox grass undoubtedly carried it directly into the mediastinum, which was followed by secondary involvement of the tissue of the lung.

DR. W. T. BELFIELD said: I would like to say in reference to Dr. Tilley's proposition, that experiments on the cultivation or transmission of this fungus ought to be made from fungi obtained from animals and not from man; if from the latter, from pus taken from abscess cavities around the jaws. The reason is that fungi obtained in the sputum are far more delicate in appearance and for preservation. I have found that after a few days they disappear or at least are extremely hard to find, and it is stated by those who have had a great deal of experience that the fungi obtained from the sputum are not so robust as those obtained from cattle or from pus cavities, aside from the air passages, in man. In justice to Dr. Schirmer, I would say that in the case reported by him, the fungus was recognized in the sputum and a diagnosis of lung actinomycosis was made.

DR. R. TILLEY said: The question with me was not that of producing the best possible sample of the fungus, but to place cases in question beyond dispute and give the society further opportunities of studying the question. Necessarily American physicians must be ignorant of the question as a whole because it is impossible to get that accurate information from literature that we can get from the study of the manifestations of the disease. I would not discriminate between this case and that of Dr.

Schirmer, on the contrary, if there is a probability of developing the fungus from pus, and an animal is chosen, I do not think there would be any objection to taking samples from both cases to inoculate the same animal.

DR. A. J. OCHSNER, in closing the discussion, said: As far as we know at present there is no evidence of the existence of actinomycosis in any other portion of the body; the probable reason of this is the fact that the patient has been exceedingly careful never to swallow any of the discharge from the abscess or any of the sputum. The accumulation of the fungus in the lungs is probably not sufficient for ulceration to have taken place into any of the other organs. The amount of sputum during twenty-four hours is between one and two ounces, and some days there will be one or two of these accumulations of actinomycoses of considerable size and a few very small points, and on some days it is impossible to demonstrate actinomycosis. On Saturday there were, I think, a dozen quite large accumulations and quite a number of small ones, so that judging from the number we find in the sputum, and from the physical signs, which are a decrease in the motion of the left side, mucous râles, and very slight dulness on the left side above the fifth rib, the accumulations are not very great, and we do not find any signs of the existence of actinomycoses in any other organ, which answers also Dr. Skeer's question concerning the condition of the lungs at present. Concerning the access to the tissue the patient had teeth removed from the left side of the upper jaw a number of times, during which time he was constantly handling animals suffering from lumpy jaw, which is the same as actinomycosis in man, and constantly handling objects that came in contact with these animals. Another point of interest which might give us some light as to the possible introduction of actinomycosis in man is this: The patient tells me that on the farm whenever one animal has lumpy jaw, a number of animals are very likely to have it soon after. This happens generally in the spring of the year, or late in winter, when animals are likely to rub their necks on the fences. He thinks these animals with lumpy jaw rubbing their necks on the fences are likely to leave some of the actinomycoses and the healthy animals are likely to scratch their skin and break the hide, and in that way become infected. The plants are exceedingly small and could with great ease be introduced into the mouth and the cavities of the teeth, or into the jaw from which teeth had been extracted. Drs. Ross and Robison are treating the patient at present by means of the pneumatic cabinet, introducing into the lungs 1-1000 solution of bi-chloride of mercury. It seems that more of the actinomycoses have been coughed up since this treatment began, but it has been of such short duration that nothing certain can yet be said.

The Committee on Pathology reported through Dr. W. T. Belfield the examination of the case of actinomycosis hominis presented to the society on September 6th. The patient is a man about twenty-five years old, emaciated and feeble. The lateral diameter of the neck is considerably increased by inflammatory thickening of the superficial cervical tissues which

are hard and unyielding; on either side of the neck is a ragged scar and small fistulous opening from which issues a slight serous discharge. The jaws could be separated to only a slight extent; but so far as could be determined, the mouth and throat presented nothing abnormal; no carious teeth were detected.

Dulness on percussion and broncho-vesicular breathing were found over the apex of either lung; on the left side in the supra clavicular region and first intercostal space anteriorly; on the right side down to the third rib.

The patient coughs frequently and occasionally raises considerably sputum. About an ounce of sputum was collected from which slides were prepared and several specimens of actinomycetes were detected.

September 28 an incision was made in the left side of the neck, giving exit to a small quantity of pus, containing actinomycetes. It was the opinion of Dr. Belfield that this patient is the subject of actinomycosis.

DR. BELFIELD said that he had been informally requested by the President to examine the case presented by Dr. Ochsner, and had found the patient exactly as described. He thought there was no question about the genuineness of the specimens exhibited. The diagnosis rested altogether on the detection of the fungi in the sputum, because if that were absent the physical signs might be due to some other cause, but he thought the physical signs in this case were caused by the fungi in the lungs.

On motion of Dr. Tilley, fifty dollars was voted to Dr. Ochsner and two members of the society for the purpose of making a series of experiments with actinomycis.

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Relation of Tuberculosis and Scrofula—Iodol; in Abscesses; in Eye Diseases; Internally—Collyrium for Strabismus.

The question of the identity or non-identity of tuberculosis and scrofula has long been a mooted point in the profession, some pathologists considering them as two distinct morbid conditions, while others confound them in one and the same affection. Dr. Arloing, a well-known experimental biologist, in a communication lately made by him to the Academy of Sciences, somewhat elucidated the subject, but it still remains open as to whether the two affections in question have the same origin or not. In a note addressed to the Academy about two years ago, Dr. Arloing endeavored to show by experimental researches that he had prosecuted with guinea-pigs and rabbits, that while these animals were susceptible of being infected with pulmonary tuberculosis, true glandular scrofula did not cause any visceral lesions in the latter. He did not, however, feel justified in

concluding from this fact that the two morbid processes were specifically distinct, but, at the same time, while admitting the hypothesis of a common origin, for the present, for these two affections, its activity was considerably attenuated in scrofula. With this idea, it was interesting to find out whether it was possible to augment the virulence of scrofulosis to such an extent as to enable it to effect the rabbit and guinea-pig indistinctly. The organism of the guinea pig is a soil extremely favorable to tuberculosis and scrofula. The latter invades its economy with such facility, and assumes such malignity, that the author was induced to inquire whether, by inoculating it through several generations, in the guinea-pig, he might be able to increase its activity enough to overcome the resistance offered to its invasion in the organism of the rabbit.

The experiments prosecuted in this direction by Dr. Arloing showed that the passage of scrofulosis in the guinea-pig, during two successive generations, does not augment the virulence for the rabbit, nor does it modify sensibly that which it possessed for the guinea-pig. The result would be different with true tuberculosis under its attenuated forms. Among the osseous and the articular affections of human beings known as local or surgical tuberculosis, some are beyond the resources of art, while others are considerably improved, if not cured, by the intervention of the surgeon. The latter are, according to the author, always manifestations of scrofulosis, the former are those of tuberculosis, but of a milder virulence than tuberculosis of the lungs or of serous membranes. If rabbits and guinea-pigs be simultaneously inoculated with material drawn from lesions of this nature, it may happen that the guinea-pigs present the classical alterations of generalized tuberculosis, whereas the rabbits escape with a little localized suppuration. But if the tubercles developed in the guinea-pigs be inoculated in other rabbits, the latter almost invariably contract pulmonary tuberculosis. Sometimes it is necessary to have two successive cultures to attain this result. This fact, concludes Dr. Arloing, deserves to be taken into serious consideration, as at present there is such a tendency to confound tuberculosis and scrofula in one single affection. It justifies once more the difference that the author had experimentally established between these two morbid conditions. If it is not yet proven that they are the work of distinct viruses, if it must be admitted that they are derived from one single agent, the tubercular bacillus at different degrees of activity, it must be accorded that, in true glandular scrofulosis, it is further from its primary virulence than in local tuberculosis.

Iodol may be applied in different forms, in powder, in solution, or with gauze soaked in the latter. The solution preferred till now is prepared by dissolving one part of iodol in sixteen parts of alcohol and adding to this thirty-four parts of glycerine. According to Dr. Ferrand, of Montpellier, this preparation is found useful in all cases of deep abscesses, fistulæ, or wounds of cavities. In the treatment of affections of the eye, the author recommends preferably the use of the powder of iodol mixed with some

inert powder, as in the following formula: Iodol, 1 gramme, powdered sugar, 5 grammes. This composition, says Dr. Ferrand, has the advantage of never producing any irritation in the eye. He has also employed, with good effect, an ointment composed of: Iodol, 1 gramme; vaseline, 20 grammes. As regards the internal use of iodol, the author thinks that it has been very much neglected, and unjustly so, but speaking from his own experience he could safely recommend it as a valuable therapeutic agent. For the dressing of wounds it is equal to iodoform. It possesses, like the latter, remarkable healing properties, and is its equal as an antiseptic, but it has the advantage over iodoform in being less toxic and being deprived of its characteristic odor, which so often disgusts patients, and sometimes even the surgeon.

Dr. Boucheron recommends the following collyrium for strabismus: Sulphate of atropine, 5 centigrammes, distilled water, 15 grammes; 3 drops to be instilled into the eye, at the commencement of convergent strabismus, and while it is still intermittent. Improvement takes place in a few weeks. Later on, for reading, convex glasses should be worn to remedy the hypermetropia, which is the primary cause of the strabismus. As soon as the convergent strabismus becomes constant, there is nothing else to be done but to practice strabotomy. A. B.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK:

(FROM OUR OWN CORRESPONDENT.)

New York State Medical Association—Gunshot Wounds of the Intestines.

The third annual meeting of the State Association, which was held November 16, 17 and 18, was, like its predecessors, successful and attractive in every way. It convened at Lyric Hall, on Sixth Avenue, instead of at the Murray Hill Hotel, as heretofore; though the pleasant *conversazione* and supper tendered the Association by the Council on the evening of the last day of the session were at this hotel. The address of the President, Dr. E. M. Moore, of Rochester, was principally devoted to an extended critical consideration of Dislocation of the Radius backward (by elongation).

Perhaps the most noteworthy feature of the meeting was the set discussion on "Shot Wounds of the Intestines," in which pains was taken to secure the participation of the only two men in America who have successfully performed laparotomy, with suturing of the intestines, in these cases, as well as a number of other distinguished surgeons, not only from the State of New York, but also from other States, such as Professor Charles T. Parkes, of Chicago. Dr. Theodore R. Varick, of Jersey City, and Dr. Charles B. Nancrede, of Philadelphia. A remarkable fact about it was the entire unanimity of opinion of all the speakers, without any previous comparison of views, in regard to all the essential points entering into the matters under discussion.

The general introduction of the subject was made by Dr. William S. Tremaine, of Buffalo, who quoted from a number of high surgical authorities, only to show that their works threw but a faint light on one of the most prominent topics now upon the minds of the profession. In his conclusions he stated that the calibre of the ball, the proximity of the weapon, and the direction of the missile at its entrance to and exit from the abdomen, were all matters of importance. Prolonged shock, tympanitis, marked pain, restlessness and anxiety, indicate probable perforation of the intestine. Escape of blood from the anus, which was regarded as a valuable sign by the late Professor Gross, was rarely seen sufficiently early to be of any diagnostic significance; but when it was noticed, was a valuable sign. Dr. Tremaine in general recommended laparotomy in gunshot injuries of the abdomen; first, because the intestines might be wounded; second, because in nine cases out of ten, the removal of the blood effused would relieve the patient from much danger; third, because abdominal section added a very small element of danger to the already existing condition of affairs; and fourth, because of the assurance given to the patient that the intestines were not wounded, so that he need not anticipate future trouble from this source. When we were positive that the intestines were wounded, there was no question about the propriety of operating.

Having alluded to the three successful cases reported in America, two by Bull and one by Hamilton, Dr. Tremaine said that the best time for laparotomy was as soon as practicable after the receipt of the injury. Peristaltic action was paralyzed for a time, and this tended to prevent extravasation of fæces; an advantage which would be lost by delay. Delay also increased the danger of peritonitis. He suggested that physicians throughout the country should familiarize themselves with the details of laparotomy by practising on animals; so that when called upon to perform the operation they would be able to do it in a satisfactory manner. In speaking of the technique of the operation he recommended the suture of Lembert, and dwelt upon the necessity of leaving a clear cavity.

Dr. Joseph D. Bryant, of New York, spoke on the diagnostic signs of the involvement of the intestines, and said that there were two classes of symptoms: 1, those referable to the abdomen itself; and 2, those showing the constitutional effects of the injury. In considering the local manifestations it was necessary to study the wound of the abdominal wall, the direction of the missile, the character of the discharges, and the presence or absence of emphysema of the borders of the wound or in the neighboring connective tissue. If the direction of the ball indicated that it passed through the abdominal wall, the presumption was that the intestines were wounded. Still, cases are on record which proved the exception to the general rule. If the bleeding points in the abdominal wall would not account for all the hæmorrhage noted, it was fair to suppose that the intestinal viscera were wounded. The same was true in regard to the occurrence of bloody urine. Escape of the intestinal contents was, of course,

proof positive; but this was rarely seen early. Early emphysema of the abdominal wall was usually regarded as a certain sign of intestinal perforation; but while this was true, as a general rule, he had known of two instances in which emphysema was due to the suction action of the abdominal muscles. If there was any decomposition, also, emphysema might occur without rupture of the intestines; but such a phenomenon was almost always seen late.

Severe pain, tympanites, bloody stools and retention of urine, were all symptoms of considerable importance. While hepatic resonance might in exceptional instances be due to more or less tilting of the organ, or to the pressure of the transverse colon between it and the abdominal parietes, as a rule it was to be regarded as an almost pathognomonic sign of intestinal perforation. Among the other symptoms were shock, nausea, vomiting, extreme thirst, restlessness, anxiety and subnormal rectal temperature. Hiccough usually followed nausea and vomiting. Severe shock might, of course, be caused by profuse hæmorrhage. There were, however, very positive indications of intestinal perforation that were of early occurrence. The loss of hepatic dulness, unless previously modified by change of position or abnormal processes, Dr. Bryant thought perhaps the most reliable.

Drs. W. T. Bull, of New York, Theodore R. Varick, of Jersey City, and Charles B. Nancrede, of Philadelphia, discussed the question: Under what circumstances, and how soon after the injury, should laparotomy be resorted to, and when is the operation contraindicated? Dr. Bull said that laparotomy was indicated, in the first place, for diagnosis. Many cases presented few of the symptoms supposed to be characteristic of involvement of the intestines. Again, it was a well ascertained fact that a bullet which had entered the peritoneal cavity was much more likely to have injured the gut than not. The operation should be undertaken just as soon as the immediate shock of the injury and the removal of the patient had passed. Delay invited septicæmia, and it was best not to wait for symptoms. Exploratory laparotomy would clear up the diagnosis, and it was not without good effect even in non-penetrating wounds.

Since 1877 he had seen eight cases at the Charles Street Hospital. Five of them, treated on the expectant plan, all proved fatal. Of the other three, which were operated upon, two recovered and one died. In the first of these, which occurred in 1884, and had been fully reported, seven wounds were sutured. The second occurred in August, 1886, and had recently been reported at the New York Surgical Society. The patient's age was 25, and he was operated on two hours after the injury. Three wounds of the intestines were sutured. Two wounds of the mesocolon were not sutured, but thoroughly rubbed with iodoform. One of the appendices epiploicæ, of good size, was found torn and bleeding at its extremity, and it was tied at its base with catgut and cut off. The abdominal wound did not heal thoroughly for eight weeks, as a knuckle of intestine protruded through it. By means of a pad of iodo-

form gauze and wool it was gradually pushed back, while the edges of the wound were held together with two "relaxing sutures" of silver wire. To-day the man is perfectly well. The third case has never been reported, and Dr. Bull gave its history somewhat more in detail. The patient was admitted to the hospital November 6, 1886, shot in the abdomen by a pistol of 44-inch calibre. An incision was made in the median line, as in the other cases, and four perforations of the intestines were sutured. The operation lasted one hour and three-quarters, and death resulted eight hours afterwards, probably from the shock incident to the laparotomy.

None of the three cases, he went on to say, presented positive proof of intestinal perforation before the operation was undertaken; but the lesions in the last case, as in the others, indicated laparotomy. Having given a sketch of the five fatal cases referred to, he spoke of the contraindications to laparotomy. In shot wounds of the peritoneal cavity, many of them involved the solid organs, as well as the intestines, and the hæmorrhage was so profuse that no hope of recovery was offered. In injuries of the liver and spleen, and to a somewhat less degree of the kidneys, he doubted our ability to cope successfully with the condition; and uncomplicated wounds of the intestines, not accompanied by profound shock, offered the best chance of recovery. Profound shock he regarded as a decided contraindication. The exposure and handling of the viscera was in itself dangerous. Peritonitis was not necessarily a contraindication. In all cases except where the wound was posterior, and there was no wound in front, the first thing to do was to explore the bullet wound and find out where it went to. The two great rules of procedure were, in his opinion, first, to assure yourself by an exploratory incision, that the peritoneal cavity had been entered; and, second, to repair the injury that had been caused by it.

Dr. Varick said that shock with gradually increasing exhaustion, sinking temperature, and dulness of the dependent portions of the abdomen, with tympanites of the anterior portions, demanded immediate laparotomy. Having referred to tympanitic resonance over the hepatic region, he remarked that the day of the expectancy is past. The surgeon should give his patient the chance offered by laparotomy, however small it may be; for without it there is only a prospect of certain death.

Dr. Nancrede advocated laparotomy in all cases except where certain contraindications were present, and said that it should be performed just as soon as the condition of the patient would warrant the performance of a long operation attended with shock, and proper assistants and other requisites for operation could be secured. When much hæmorrhage was probably taking place it was justifiable to operate at an earlier period than in other cases. Among the contraindications was profound shock not due to hæmorrhage. It was better that every physician should not attempt to perform laparotomy, for these cases would, as a rule, do better if left to nature than if operated on by one not familiar with the procedure. Experience, he believed, was a prerequisite for suc-

cess. If possible, also, only one pair of hands should be allowed to pass into the peritoneal cavity. Unlike Dr. Bull, he thought that acute peritonitis was a contraindication; but he agreed with him that wounds of other organs might prove a contraindication.

Dr. John B. Hamilton, of Washington, D. C., thought that the first thing to do on being called to such a case was to probe the wound, if made by a small pistol, and the instrument that he recommended for the purpose was the flexible spinal probe of Nélaton. If the cavity of the abdomen was found to be penetrated, laparotomy was indicated. In case great shock was present he thought exploratory laparotomy was indicated, as it was probably due to injury of a vessel or nerve or ganglion. As to the essential features of the technique of laparotomy, these did not differ from those of the technique of ordinary laparotomy, except as regards the management of the intestines. Rigid antisepsis should be carried out, and towels wrung out of hot water containing bichloride in solution should be first placed over the abdomen. On opening the cavity bleeding points should be carefully looked for, and no abrasion should be left untouched. The intestines should be drawn out loop by loop by the fingers and allowed to remain on a towel wrung out with bichloride solution; another towel similarly treated being placed over them. When wounds were found, they should be stitched, and it was necessary to reduce pouging mucous membrane. Like the other speakers, he preferred the Lembert suture, and the material he used was catgut. The incision should be closed in the same way as in other cases of laparotomy, after the cavity has been thoroughly cleansed.

Dr. Charles T. Parkes, of Chicago, gave an admirable summary of his views on all the various questions involved in the discussion. If the abdomen was penetrated, he said, it was morally certain that the intestines were perforated, and the surgeon should be deterred from performing laparotomy only on the strongest grounds. Deep-seated emphysematous crackling he had found present in two cases, and he considered it a very valuable sign of perforation. The first thing to do in the way of treatment was to ascertain whether the wound entered the abdominal cavity. He spoke particularly of the dangers to which the patient was often subjected in removal, which should be performed with the utmost possible care when necessary.

As to the question under what circumstances should laparotomy be resorted to? he said, under all circumstances except where the patient was likely to die during the operation. The implication of other organs beside the intestines was, he agreed with the other speakers, a contraindication. As to the time for its performance, he thought it should be done just as soon as the surgeon's necessary preparations could be made. He should be guided by the same rules as in all grave surgical troubles. If perforation was known to be present, there was no contraindication; for we could not say that a case was a fatal one until after performing exploratory laparotomy. In regard to the technique of the operation, he considered the median line as the only proper point for the incision.

The cavity having been opened, the next thing to do was to secure all bleeding vessels. Then the intestines were to be drawn out through the incision, which should be free, and wounds in the large intestine and other viscera looked for. Having stated that the whole small intestine should be passed through the fingers, Professor Parkes devoted considerable attention to the details of repairing perforations in the gut. Lembert's suture was the best, and he preferred puce silk introduced by means of a small round needle, either straight or curved. A double row of sutures he considered quite unnecessary. The abdomen should be closed in the usual way; great care being always taken to avoid ventral hernia. In the after-treatment the most complete rest was essential. Opium in sufficient quantity to secure this was called for, and rectal alimentation was not infrequently of service. It was desirable to keep the temperature low; but if it became high, cold should be applied externally. If it did not rise above 101°, however, no interference was called for.

STATE MEDICINE.

POISONED BEEF, CHEESE AND ICE CREAM.

Synopsis of a Paper read before the Mansfield Lyceum, on Nov. 10, 1886. By R. Harvey Reed, M.D., Mansfield, Ohio.

Sickness from the use of beef, cheese and ice cream, a few years ago, would have been considered a pathological curiosity; at present, but especially during the summer months, the reports of alarming attacks of sickness from eating one or the other of them are a common occurrence. The frequency of these sudden outbreaks of disease, and the alarming symptoms associated with them have aroused the attention of Sanitarians, who have been diligently at work studying out their causes, and the best means for preventing them.

It was only a few months since we had several examples of the effects of eating poisonous dried beef in our own city, and unless the causes producing these toxic effects are removed or avoided, we are liable to have similar results not only occurring from eating dried beef, but cheese, and that, great American luxury, ice cream. It must be remembered that the causes producing sickness from eating dried beef are entirely different from those producing sickness from eating the so-called "measly pork," or pork affected with trichina spiralis. The poison existing in the dried beef belongs to that class of cadaveric alkaloids known as ptomaines poisonous alkaloids formed in the meat through a process of putrefaction, which no amount of cooking or ordinary heat will destroy, while that in "measly pork" is only the living embryo of the tape worm, and can easily be killed and made perfectly harmless, or at least to a great extent harmless, by cooking thoroughly. Dried beef having these poisonous alkaloids, usually is found containing great numbers of micro-organisms, yet our best authorities do not consider these the direct causes of the disease as is readily shown by the

simple experiment of cooking meat with these in, which has not any of the ptomaines, and eating it, which has been found harmless, but meat with or without these micro-organisms in, but containing these cadaveric alkaloids, is still found poisonous whether cooked or not cooked. It has also been very clearly demonstrated that these alkaloids, when extracted by chemical process and given to the lower animals or man, produce the same general symptoms, produced in persons who ate of the meat containing the same particular poison in its crude form.

The question naturally arises, how does it come we have these cases of poisoning occurring now, which years ago was never heard of? The question is easily answered: Years ago the patent quick process of curing meat was unknown. The meat was given plenty of time to cool off after it was killed, and lose its animal heat before it was salted or placed in the curing brine. Pure salt was used or a brine of salt and nitrate of potash and brown sugar, familiarly known as a "sweet pickle," in which the meat was kept for a month or six weeks, until every particle and fiber of the meat was thoroughly saturated with this preserving liquid, after which it was taken out and thoroughly dried and smoked, which usually occupied from a month to six weeks longer, thus giving plenty of time for the pyroligneous acid, which is given off freely in the smoke of an ordinary wood fire, and especially that of hickory wood, to penetrate the meat and act its part in the curative process of the meat, which is no small part I can assure you, and which gives to all smoked meat that pleasant taste and peculiar odor.

Thus you will observe the old-fashioned "Country Method," as it is sometimes called, of curing meat required from two to three months to complete it in all of its details, but if properly conducted the meat was thoroughly cured, and was, if not diseased when killed, "sweet" and healthy meat that would harm no one to use in proper quantities, and would keep for months without spoiling. On the other hand, the meat of to-day is largely supplied to our cities from "packing houses," whose managers adopt the quickest method possible, to put their meat on the market after it is slaughtered. Instead of the old-fashioned process being used, which required months, they have adopted a new process, which enables them to put their meat on the market in almost as many days.

Animals are hardly given time to die after they are taken in hand by the butcher; but a few minutes are allowed for the dressing process, and no time for cooling further than that required for the dressing and cutting into suitable pieces, when it is injected with a preserving liquid, which is actually squirted into the muscular fiber in different places in each piece, owing to the size, when the meat is ready for a little smoke to give it the appearance of cured meat, and it is then ready for sacking and placing on the market, all of which only occupies a few days. It only requires a day or two with the proper kind of a building and fire, to smoke the meat brown, and as that is all they desire, as the pyroligneous acid has already been injected into it in a chemical form with "their preserving liquid," they thus save a great

amount of time in this as well as avoiding the loss of time in the old salting process.

It is in this class of meat these poisonous ptomaines are most liable to form, for the reason that sufficient time is not given, and proper care taken to thoroughly cure the meat, and if ever so free from decomposition when sent out, if not sold and eaten promptly, it is liable, especially in warm weather, to undergo a degree of decomposition, forming these alkaloids and become injurious, or if not it soon becomes sour, and thus favors the formation of these poisons, and besides, is generally filled with great quantities of micro-organisms, which are ever ready to seek a nidus in poorly cured meat, but which may or may not be injurious to the human system.

Another class of meat in which these poisonous alkaloids are liable to form, is refuse meat that is left in the shops until it has become tainted, when it is put through a curing process, and either dried or sold as corned beef, or cooked and sold as canned beef. In this case, these alkaloids may form before it is subjected to the curing process at all, and when once formed no amount of cooking will remove them, or they may, as in the former case, form after it has passed through this process. No meat is fit for use, on general principles, that responds to the acid test, or in other words, is sour, which can be easily tested by wetting the meat and applying litmus blue, which will turn red if sour; especially is meat that is supposed to be cured unfit for use that responds to the acid test with litmus paper. Cadaveric alkaloids are much more to be dreaded in one sense, than either the trichina or cysticercus, for the latter can be rendered harmless by thorough cooking, while the former is unchanged; although the parasites are to be dreaded more if once entered into the human economy than the ptomaines as a general rule, yet they are so much more easily destroyed, that their virulency is very greatly lessened. No expert can tell by looking at a piece of meat with ever so much care, or even by testing it with litmus paper, that it is free from poisonous alkaloids; the outside may be free from them, while the centre may contain them, which can only be told by cutting it open and applying the litmus test, and then it cannot always be told without eating it, or applying a chemical test or microscopical examination. The fact of it being sacked or not, has nothing to do with protecting it from these alkaloids, or of increasing them; all the benefit derived from sacking is to prevent it from getting so dirty, and avoid getting it fly-blown in the summer.

The dirty habit of chipping dried beef as it is done in our groceries is to be detested. If you will take any piece of dried beef or meat of any kind, and if you can't detect the mould on it with the naked eye, you can detect a perfect forest of this fungus with a microscope of very low power, together with dirt and filth of all kinds. Yet our average groceryman will throw a piece of meat into the chipper, and without cutting the outside off at all, which ought to be done every time. He "chips" away at it, dirt, mould and meat, until it is done, while the average dried beef eater munches it down dirt and all, just as received

from his grocer, in ignorant innocence of its filthy condition, while his poor stomach is forced to contend with a mass of filth which the owner would scarcely deign to have on his shoes.

Poisonous Cheese.—Although of less importance as food than meat, yet the amount of cheese used in this country makes it highly important that it be of the purest and best quality; that this is not the case has been demonstrated by the sudden and severe sickness following its use in many places. The frequency of these cases of so-called "cheese poisoning" attracted the attention of sanitarians a few years ago, who soon commenced to seek for the cause and search for its remedy. A few years ago, while I was practising in the Western Reserve, I met with numerous cases of cheese poisoning. More recently Michigan suffered from the same cause, and in 1883 and 1884 reported over 300 cases. Being located in the cheese manufacturing district of the Western Reserve during the occurrence of a number of these cases, I made it my business to investigate into the probable causes of these cases of "cheese poisoning." I discovered that the majority of the poisonous cases come from porous cheese. I also learned at these manufactories they allowed the curd to stand until it commenced to ferment, or get "enough of acid," as they termed it, "to make the cheese light and porous," before they would put them to press. Again, in cheese which had not been allowed to ferment so much, they would fail to press them dry enough, and leave the cheese with more or less whey in it, which would soon ferment, and again we would have a poisonous cheese.

The investigations made subsequently by Professor Victor C. Vaughan, chemist for the Michigan State Board of Health, and reported at the meeting of the American Public Health Association in 1884, showed clearly that this poison consisted in a chemical compound he named tyrotoxinon, and which he found to belong to the ptomaine poisons, and that associated with this were found to be myriads of bacteria. Whether this poison is the result of decomposition, or the presence of bacteria, is a question; although, from the results of subsequent investigations in the same direction, I am of the opinion now that this poison arises, as in the case of the beef, from decomposition, and that the bacteria aid in hastening this fermentive process.

It will be remembered that these poisonous matters were almost always found in those cheeses which, from some cause or another, had been over-fermented either before or after pressing. Thus you will observe only one or two out of hundreds might become poisonous, while the rest would be all right. As yet no person can tell by the general appearance of the cheese which is the poisonous cheese and which is not. In the average cheese manufactory, the care taken in the manufacturing of these products is to be commended, and I think the occurrence of these "poisonous cheese" and their results were a mystery to them and unexpected when they first began to occur, but with our present knowledge their occurrence should be the rarest exception.

Poisonous Ice Cream.—In 1885 one hundred cases

of poisoning from ice cream was reported by the Brooklyn Board of Health occurring from the cream sold by one restaurant, whilst in Michigan, New Jersey and Ohio many other cases of a severe and alarming character have more recently occurred. In this, as in the cheese and beef poisoning, the victims are seized with severe gastro-intestinal irritation, characterized with sudden and irrepressible vomiting and purging, with dryness and constriction of the fauces, associated with more or less griping, with general prostration, and occasionally vertigo. The source of all these dreaded symptoms was eagerly sought for, and their causes, if possible solved by experiments and repeated investigations. After numerous experiments by Prof. Vaughan, of Ann Arbor, it was found that the poisoning occurring from the eating of ice cream was caused, as in the case of cheese poisoning, by a highly toxic ptomaine known as tyrotoxinon, which discovery has been confirmed since by Dr. W. K. Newton and Mr. Shippen Wallace, the analysts for the New Jersey State Board of Health, but "the circumstances under which tyrotoxinon develops, require further study;" yet it has been shown that it may develop in normal milk, kept in clean bottles for three months, although it may occur under other circumstances much sooner, which in still more recent experiments and investigations has shown it to occur in fresh milk in a few hours.

Repeated experiments and investigations have put it almost beyond a doubt that the occurrence of these ptomaines in ice cream is due, as in the case of the beef and cheese, to the result of a ferment of a certain character; it is true that they do not occur every time there is fermentation going on, but every time they do occur there has been a process of fermentation occurring at the same time. The prevalence of cheese poisoning in Germany would tend to confirm this theory, for it is well known that the so-called "Dutch cheese" is subjected to a much greater degree of fermentation than the "Yankee cheese," while the "French cheese" is almost entirely free from ferment of any kind, and it is a remarkable fact that "cheese poisoning" is almost entirely unheard of in France, while in England and America it is of quite frequent occurrence.

It has been clearly demonstrated that it does not necessarily result from the food given the cow, for it will occur when the very best and cleanest food is given and every precaution taken to keep the milk free from all ordinary dirt. But it has been clearly demonstrated by the investigations of the New Jersey State Board of Health, that the shipping of milk before it has lost its "animal heat," especially in warm weather, and been properly "cured" by cooling and airing, does favor the production of these poisonous ptomaines. Prof. Vaughan has suggested the possibility of this poison being the chief cause of cholera infantum in many instances, the suddenness and violence of the attack in each, together with the close resemblance of the leading symptoms, is at least suggestive to the close observer, although as yet it has not been positively demonstrated.

The most important question to us all is, how are we to avoid this toxic agent? When we remember

that not only in poisonous beef, cheese and ice cream, but in the poisonous sausage of Germany, and the poisonous fish cases occurring among the natives along the Volga, they are all traceable to one general source, and that is, the presence of a certain degree of decomposition. This being the cause, then, we must apply the remedy, which is plain to every one. Measures must be taken, either legal or otherwise, to have our meats better cured; such a degree of care being compelled to be taken as will insure the perfect preservation of our meats without the least degree of putrefaction. All meats that are tainted by laying around in the boxes and on the counters of our shops should be condemned, and not allowed to be used at all where there is any possibility of sufficient taint as to favor the formation of these poisonous ptomaines.

There should be a rigid inspection of our cheese factories, and such legal restrictions thrown around them as will not permit the over-fermenting of the cure, or imperfect pressing and curing of the cheese, or of the slightest decomposition of the milk before it reaches the factory, and no cheese should be used for food that shows a decidedly acid reaction with the litmus test, when slightly moistened. No milk should be used for making ice cream that shows an acid reaction with litmus paper, not that all sour milk contains tyrotoxin, but that tyrotoxin has always been found in fermented or sour milk. It must be remembered that the "curdling" of the milk or cheese, by the aid of rennet (or calf's stomach), is not a process of fermentation, but a process of digestion, produced by the peptones of the calf's stomach, which, at a certain temperature, have the peculiar property of coagulating milk, but that after this digesting process has been arrested, and the coagulate has been allowed to stand for a certain length of time, at a favorable temperature, fermentation is easily induced, and it is at this stage, and under these circumstances, these chemical changes take place, and a harmless article of diet is transformed into a violent poison.

MISCELLANEOUS.

CHICAGO GYNÆCOLOGICAL SOCIETY.—The annual meeting of this Society was held on Friday, Oct. 22, 1886. The following officers were elected for the year 1886-1887:

President—Charles Warrington Earle.

First Vice-President—E. C. Dudley.

Second Vice-President—T. D. Fitch.

Secretary and Treasurer—Edward Warren Sawyer.

Editor—W. W. Jaggard.

CHOLERA IN SOUTH AMERICA.—A cablegram of November 22, from Lisbon says: It is officially declared that Rosario, in the Argentine Republic, is infected with cholera. Several points in the country along the Rio de la Plata are suspected to be also infected.

A dispatch from Santiago, Chili, of November 22, says: The Government is preparing plans to prevent

the appearance in Chili of Cholera, which is prevalent in the Argentine Republic. It is stated that a sanitary cordon will be formed in the Cordilleras. Vessels coming from ports where cholera exists will be placed in strict quarantine until visited by medical officers.

ETHICAL QUERIES AND ANSWERS.

WHAT CONSTITUTES A CONSULTATION?

TO THE EDITOR OF THE JOURNAL:

Dear Sir.—We note the query and your answer in THE JOURNAL of July 24, 1886. Suppose we put the shoe on the other foot. A regular is asked to have an irregular—say an eclectic—see his patient. He calls for the eclectic and takes him to the bedside. The patient is examined, the treatment is enquired into, disapproved, and the eclectic makes a prescription, though the attending physician does not accept it, and ignores the latter clauses of Art. IV, Sec. 3, Code—all the worse for him and scientific medicine, as the patient dies—has he not violated both the spirit and letter of the Code of Ethics?

PHYSICIAN.

Answer: The rules given for conducting consultations do not appear to have been adhered to certainly. [ED.]

PERCENTAGES ON PRESCRIPTIONS.

B. W. T., asks the following question:

"Is it considered a violation of *Ethics* for a physician to receive a percentage on his prescriptions from a druggist?"

If the correspondent intends simply to ask whether the practice of receiving from the druggist a percentage on prescriptions violates any expressed rule or clause of the Code of Ethics of the American Medical Association, we must answer, that the Code makes no allusion to such a practice either directly or indirectly.

But if he uses the word *Ethics* as synonymous with correct morals, or principles of honorable dealing, we must answer his question affirmatively. Such a collusion between the doctor and the druggist as the question implies, must be placed on the same moral or ethical plane as a similar agreement between a hospital steward and the grocerymen and provision dealers for a percentage on the orders he may give them for hospital supplies. [ED.]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM NOVEMBER 13, 1886, TO NOVEMBER 19, 1886.

Major C. R. Greenleaf, Surgeon, relieved from duty at Columbus Bks., Ohio, and ordered for duty as attending surgeon at Hdqrs. Div. of the Missouri, and examiner of recruits at Chicago, Ill. S. O. 268, A. G. O., Nov. 17, 1886.

Major Henry R. Tilton, Surgeon, relieved from the duties of attending surgeon at the Hdqrs. Div. Pacific and Dept. of Cal. S. O. 96, Div. Pacific, Nov. 9, 1886.

Major W. E. Waters, Surgeon, ordered from Ft. Spokane to Vancouver Bks., W. T., for duty at that post. S. O. 197, Dept. Col., Nov. 8, 1886.

Par. 8, S. O. 257, A. G. O., Nov. 4, 1886, is so amended as to direct Major V. B. Hubbard, Surgeon, to report in person to the commanding officer Columbus Bks., Ohio, for duty. Par. 3, S. O. 268, A. G. O., Nov. 17, 1886.

Major Chas. Smart, Surgeon, granted leave of absence for one month. S. O. 265, A. G. O., Nov. 13, 1886.

Major D. G. Caldwell, Surgeon, granted leave of absence for one month, with permission to apply for twenty days' extension. S. O. 150, Dept. Platte, Nov. 12, 1886.

First Lieut. C. N. B. Macauley, Asst. Surgeon, granted leave of absence for twenty days. S. O. 118, Dept. Dak., Nov. 8, 1886.

First Lieut. W. D. Crosby, Asst. Surgeon, ordered from Ft. McDowell, A. T., to Ft. Bowie, A. T. S. O. 110, Dept. Ariz., Oct. 29, 1886.

First Lieut. E. R. Morris, Asst. Surgeon, ordered from Ft. Bayard, A. M., to Ft. Thomas, A. T. S. O. 110, Dept. Ariz., Oct. 29, 1886.

PURIFICATION AND SANITATION BY FIRE.¹

BY G. S. FRANKLIN, A.M., M.D.,

OF CHILLICOTHE, OHIO.

We find the following words in the Law of Moses, Book of Leviticus:

"But the remainder of the flesh of the sacrifice, on the third day, shall be burnt with fire." (Leviticus vii: 17.)

"And the flesh that toucheth any unclean thing, shall not be eaten, it shall be burnt with fire." (Leviticus vii: 19.)

"But the bullock, and his hide, and his flesh, and his dung, he burnt with fire." (Leviticus viii: 17.)

"And that which remaineth of the flesh and of the bread, shall ye burn with fire." (Leviticus viii: 32.)

"And the flesh and the hide, he burnt without the camp." (Leviticus ix: 11.)

"He shall therefore burn that garment, whether warp or woof, in woolen or in linen, or anything of skin, wherein the plague is; it shall be burnt in the fire." (Leviticus xii: 52.)

"Thou shalt burn that wherein the plague is with fire." (Leviticus xii: 57.)

"And if aught remain until the third day, it shall be burnt in the fire." (Leviticus xix: 6.)

Latter day philosophers may question if all Scripture was written by inspiration of God, but every true Christian believes it faithfully. Wherever a weak faith would be staggered, perhaps overthrown entirely, the stronger can find secure refuge in the omnipotence and omniscience of God, and in the admitted fact that "now we see through a glass darkly." It is, however, gratifying to the believer when the progress of science brings us to a more exact comprehension and belief in doctrines and practices taught and enjoined by the inspired lawgiver over 3,000 years ago. Of such a character is the sanitary doctrine of purification by fire.

While the practice of burning up things considered to be unclean has probably always obtained to some extent, even before the Law of Moses, it is only recently that science has given us a sound logical reason for so doing—thus extending our horizon of knowledge immensely and to our manifest advantage. In this direction, after a brief preliminary review of the subject, it is our wish to call special attention to cases where we think it will be well for us and our posterity if we destroy foulness and uncleanness by fire.

It will be hardly proper here and now to dilate upon the doctrine of noxious germs, and their spores,

and their methods of multiplication around us. For our purpose it will suffice to say that all the scientific world believes them to be at least the bearers of contagious diseases, the disseminators of sickness and death with their attendant misery and unhappiness. How to limit their action—how to prevent their ravages—how to do away with them altogether, have become the pressing sanitary problems of the age. Any advance conducing to these ends should be worthy of our earnest attention and sympathy.

When the "Committee on Disinfectants of the American Public Health Association," made their report and formulated their "Conclusions," in December, 1885, the *first* and *best* treatment recommended by them "for all spore-containing infectious material," is "fire—complete destruction by burning." "For infectious material not containing spores," is "fire—complete destruction by burning." "For clothing, bedding, mattresses, blankets, rags, etc., soiled by infectious material," the first and best recommendation is, "fire—destruction by burning." Evidently this Committee, well educated and intelligent, with all the aid and assistance to be derived from the brightest lights of modern science, can only endorse and recommend the practice enjoined by Moses—and thus aid in proving, to reasonable men, the inspiration of the sacred volume.

One question remains to be discussed before we are ready to apply our doctrine of purification by fire—and that is: What are "spore-containing infectious materials?" This question opens up a boundless sea of inquiry, whose limits have been only partially surveyed by science, and its chart only here and there dotted with the islands of known facts; while numberless undiscovered continents of facts are still waiting the advent of the enthusiastic searchers who are surely on the way to find them. We know already that small-pox victims can give off contagion—that clothing, blankets, bedding, rags, soiled with its infectious germs, can disseminate the disease. Of typhus fever, typhoid fever, yellow fever, scarlet fever, diphtheria, measles, etc., we know that contagion spreads from one to another in various ways. In the lower animals we are assured that anthrax fever, pleuro-pneumonia, Rinderpest, glanders, actinomycosis, hydrophobia, hog cholera, chicken cholera, etc., are all easily transmitted after their kind. This is positive knowledge, known facts, ready for us as sanitarians to act upon in a well defined manner and after scientific methods. But who can tell us where noxious germs do not find a habitat and

¹ Read in the Section on State Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

a breeding-place? Who can say in what kind of filth an innocent germ, finding a resting place, may not develop morbid tendencies, and thereafter breed agencies of death and destruction? Who can tell where the first seed-germs of small-pox and typhus fever come from? Who can deny that every decomposing dead body may not originate a poisonous something which will be inimical to the life or health of its neighbor? We know that the history of sanitary supervision of large cities and towns shows a magnificent result for feeble efforts to destroy noxious germs and their spores or seeds, and to enforce cleanliness. The earnest labors of the health officers of London have diminished its mortality nearly 100 per cent. The bringing of purer water, comparatively uncontaminated with germs, to Munich, is said to have almost banished its greatest scourge, typhoid fever, from that city. We have no doubt that the near future will see even greater benefits from scientific sanitation, more especially when purification by fire is used to its fullest allowable limit.

And now—how, when, and where, and in what cases, shall we employ this first-class, most excellent purifier?

How to make use of Fire as a Purifier.—Expensive crematories, though all right in their place, are by no means necessary even for the decent disposal of dead human bodies. We can erect at a small cost, on a side hill, something like an old-fashioned lime-kiln, consisting of stonework for the stack, an opening below and in front for ash-pit and draft, above that an opening for a fire-box, closed by an iron door, with grate bars both above and below; above that, on the upper grate bars, with entrance and exit through a proper iron door, the place for incineration of the dead body; still above and on top of the stack, a large opening, to be closed by an iron door when necessary, serving for vent to gases of combustion, and also for the introduction of dead animals whose ashes we do not wish to preserve, or for dumping a cartload of household waste that we wish destroyed. To build and operate such a crematory would certainly be inexpensive, while it would as certainly be efficient for all purposes. Convenient brush piles could be made useful for many necessities of purification. Open fireplaces in house or kitchen could destroy many things condemned by sanitary laws. A sheet-iron oven, made to be placed over an opening in a kitchen stove, has been recommended for the destruction of the organic waste of a household. The same device, fitted to an old stove in the back yard, might be utilized to destroy the poisonous excreta of cholera, typhoid fever, etc.

When and Where to use Fire as a Purifier.—Though our knowledge on this point is limited as yet, we believe that Moses was in accord with, perhaps in advance of, our modern science, in directing nitrogenous waste to be burned on the third day, without the camp. We already know that infection becomes powerful by the third day, that zymotic and septicæmic diseases at that time reach their first acme, and that putrefactive processes are then well developed in a dead body. A widespread belief, not thoroughly authenticated as yet, so far as we know, declares that

the combustion of infected material, such as bedding, can carry contagion through the air. If this be true, it would seem necessary to burn infected material "without the camp."

In what Cases shall we Purify by Fire?—First, by the cremation or complete destruction by fire of all the human dead, by the third day, if not before in the case of infectious diseases. It is not material here to do much more than to record the rapid acceptance among educated men, and especially among physicians, of the doctrine of the cremation of all human dead, as a necessity of recent advances in sanitation. Science points to it with unerring finger as the best method of disposing of the dead who are known to have been slaughtered by infectious diseases, and not much less decidedly of those whose less infectious bodies are known to develop the lethal gases of decomposition and the deadly ptomaines. Very few persons will deny the propriety of burning up the bedding, etc., of a victim of small-pox, for a sad experience has taught us that it is necessary. That a human body dead of the same disease can give off contagion is no less certain—hundreds of cases tracing their infection to a public funeral, bear witness to this admitted fact. Even if we bury such bodies hurriedly, and at dead of night, who can say how long, even in the grave, the contagious material remains efficient and powerful for evil? We know well that rags may hold infection for a long time, especially when deprived of light and air. We know that every marked excavation of earth, even in house building, or railroad cuttings, is liable to cause sickness in the vicinity, and what is the earth everywhere but the graveyard of the animal and vegetable kingdoms for ages past! We know that to build over an old graveyard is to invite death into the house. We know that water draining from a graveyard is liable at the very least to contain a dilution of noxious nitrites and deadly ptomaines, and is considered a fair explanation of a sickly neighborhood. The argument from cases of small-pox comes home more strongly to untrained intelligence, but physicians know that every dead body, not quickly and completely disinfected, is a hotbed for poisonous gases and for chemical products as deadly as prussic acid. Shall we, then, hesitate to encourage cremation of human dead, when we know that our air, soil and water, are daily making their protests against the unsanitary method of burial in the ground? With all its admitted disadvantages, and there are some hard to deny, the scale of science and reason leans most unmistakably in favor of the cremation of all human bodies.

Second. But if our present method of disposing of dead human bodies is very objectionable and decidedly unsanitary, who can defend the usual practice of allowing the dead bodies of the lower animals to lie exposed on top of the ground, or to be cast into our running streams? Do not such decomposing bodies also give off infectious diseases, and also give off the horrid putrefactive gases, and generate deadly ptomaines? Is it not a known fact that anthrax fever has been transmitted to man in the form of malignant pustule, and especially to butchers, tanners, wool sorters, furriers, horsehair cleaners, hostlers, etc., who

handle the diseased animals or their products? Is not that terrible disease, glanders, frequently caught by man? Only our great lack of definite knowledge as to the diseases of animals and their contagiousness by man limits our view in this direction. If, then, we continue to allow dead animals to decompose on top of the ground, and their remains to be mingled with the dust to be carried anywhere, everywhere, by the winds of heaven, how can we hope that the almost indestructible spores of disease may not assault us even in the seclusion of our homes and by our firesides, where we ignorantly believe ourselves secure? But even if we bury them under six feet of soil, that grand apostle of microbes, Pasteur, has conclusively proved that the humble earthworm may bring the death-dealing germ to the surface, deposit it on vegetation, or allow it to be tossed into the air by the wind, and thus permit it to begin a new cycle of destruction. Truly it would seem as if the whole animal kingdom, including man, were engaged in a most serious struggle for existence with the pestilential germ; the battle is *à l'outrance*, and we can afford to neglect no precaution that will ensure us the victory. The only safety seems to be to call to our aid the great purifier, fire, which the most recent teachings of science tell us is ready and able to utterly destroy both germs and spores that, less efficiently controlled, would increase and multiply till the whole earth might be as full of them as Russia is said to be of the dreaded Rinderpest. When will the day come when active, efficient, intelligent Boards of Health, all over the land, will bend their energies to the complete solution of this great sanitary problem; when the prevention of disease in men and in animals will be entrusted to enthusiastic and skilful hands, giving us some hope of definite progress towards health and prosperity for all?

Third. Does decaying vegetable matter breed sickness and death? Should purification by fire be applied to decomposing materials of this character? These questions have been practically answered in the actual experience of cities where great ovens have been constructed where wagon-loads of household waste, bread, meat, vegetables, bones, rags, etc., are daily purified by fire until only a valuable fertilizer remains. The decreasing mortality in such cities is a loud-voiced argument in favor of this practice, and it does not need dilating upon, because neither sentiment or reason would oppose it, except on the ground of expense.

Fourth. The most recent developments of science are warning us to be more careful about the sputa of consumption. Very few educated men are now found willing to deny that consumption is contagious, and that the germs of contagion are contained in the expectoration. If the sputa are deposited on the floor, on the street, or in running water, who can tell where the germs may finally land, or who may be the next host! Who can say that ignorance or neglect as to the proper disposition of such infected sputa, may not transform even the most eligible health resort into a place where it is dangerous to send a consumptive patient, because the germs are there becoming more and more widespread and abundant! The cer-

tainly adequate remedy is to deposit the infected sputa in antiseptic sheets of paper, or in a cheap medicated paper cup, or on rags, or even on fine handkerchiefs in an emergency—each and every one of these receptacles to be subsequently purified by fire. The sputa of diphtheria, considered highly contagious, should be carefully treated in the same way.

The excreta of typhoid fever, and of cholera, are certainly known to contain the particulate germs of those diseases. The sad experience of Plymouth, Pennsylvania, where the excreta of one case of typhoid fever were carelessly allowed to contaminate the drinking water of the city, is trumpet-tongued in its commands to us to thoroughly purify all such excreta. What purifier can be so safe, so cheap, and so easily applied as fire?

Fifth. Does the allowable limit of purification by fire end here? Not at all. Every blighted or dead tree, or a branch of a tree, or a plant, or a vine that threatens to carry infection to its kind, should be utterly destroyed by fire. Failure to do this is a sad mistake that horticulturists frequently make, to their damage and discomfiture. They should fight the germs of infectious disease in their orchards and gardens whenever they can be found, and no agency can be used so certain and sure in its action as fire; let them tear out the offending plant and allow this beneficent purifier to do its perfect work.

The infectious diseases of the graminaceous plants are most efficiently treated in this way. The diseases called smut and rust are the best known, and cause very serious damage to crops. The straw and the stubble of such grain should be sedulously burned. Rotting corn shocks, decaying straw stacks, decomposing hay ricks, are generally the sources of infectious disease after their kind—that farmer who permits such uncleanness will surely regret it. To detail all the cases where such an efficient purifier can be, ought to be, used, would extend this essay beyond proper bounds, therefore we enunciate as a general doctrine which admits of very few exceptions—that *infectious material, foul-smelling things in process of decomposition, organic waste, useless rubbish, should be burned up completely.*

PLEUROTOMY FOR EMPYEMA. RECOVERY.¹

BY F. C. FERNALD, M.D.,

OF WASHINGTON, D. C.

J. M. T.; male; colored; aged 40; married; one healthy child; always well until two years ago, when he had a severe attack of dysentery, followed by a hepatic abscess that pointed in the epigastrium, where it was opened by a physician; a drainage-tube was inserted and antiseptic injections employed; no antiseptic dressings; discharge ceased in four months, after which he regained his usual health.

He had no other illness until April of this year, when he began to have malaise. In June he began to have pain in right shoulder and arm; no pain, however, referable to hepatic region; later pain

¹ Read before the Medical Society of the District of Columbia, on October 20, 1886.

changed to right side of chest; then he lost flesh and strength; had hectic, night sweats, anorexia, slight dry cough, gradually increasing dyspnoea. Until he came under my care, August 8, he had worked as usual but, although his duties were very light, he was scarcely able to perform them.

Physical Examination—Inspection.—Patient looked much worn and very ill, marked dyspnoea, moderate emaciation, movements of right side of thorax in respiration markedly diminished, fulness of intercostal spaces on that side; decubitis on back, right side being too sore to lie on, and, if lying upon left side, increase of dyspnoea; right side measured one inch more than left.

Percussion and Auscultation.—On left side, exaggerated respiratory murmur, increased resonance. On right side, the usual signs of fluid in a pleural cavity. The whole of lower back was flat on percussion, upper back dull; in front flatness extended to upper border of fifth rib, and a little higher in axillary region, when patient was erect; in recumbent position the line of flatness noticeably lower, but its exact position was not accurately noted.

The patient was informed that there was probably pus in his chest, but that an exploratory puncture would be necessary. To this he consented, provided it was deferred for a few days. Four days later, at his house, the exploration was made. A long needle attached to an ordinary hypodermic syringe was used; a syringe of dark-colored fluid, free from odor, was obtained. Patient was told that immediate aspiration was demanded, but that it would probably be necessary soon to open his chest and introduce drainage-tubes.

On the next day, August 13, T. 103°, P. 110, R. 30. Assisted by Dr. Cuthbert, I aspirated in the sixth intercostal space posterior axillary line; needle went in one and a half inches without striking fluid; it was then pushed a little further, and felt to pass through some resisting substance, after which fluid was obtained; aspiration was done very slowly; patient experienced no discomfort whatever, not even coughing; thirty-eight f. 3 of thick fluid drawn off, of consistency and color of thick chocolate, odor of beef tea.

Microscopical examination of fluid by Dr. Shute and myself, independently, revealed a great quantity of leucocytes, granular and fatty detritus, clumps of amorphous coloring matter which was amber where thin, where thick, reddish; no liver cells and no crystals of any kind; a few red blood corpuscles.

He slept well that night; no pain. On the following day he breathed easier, appetite better, respiratory murmur over whole of previously flat area. In a few days later, however, patient gradually got worse, fluid reaccumulated; *pleurotomy* was decided upon.

August 22d, day of operation, nine days subsequent to aspiration, T. 100°, P. 120, R. 30. Noticed bulging in right axillary region, apparently due to serous infiltration of subcutaneous tissues, but no pitting on pressure. The seventh intercostal space posterior axillary line was chosen as point of incision; an exploratory puncture made at that point proved the

presence of fluid, which was free in the cavity as indicated by change of line of flatness with change of position of patient. A great amount of serum oozed from the subcutaneous tissues at the point of puncture, and noticeable diminution of the bulging mentioned ensued. Fifty minims of four per cent. solution of cocaine were then injected along the line of proposed incision; five minutes later a free incision was made through the tissues into the pleural cavity. Patient suffered no pain, and was hardly conscious that anything had been done. Full antiseptic precautions were taken, including carbolic spray. Thirty-two f. 3 of fluid of same kind as that previously obtained by aspiration, escaped. Cavity was *not* washed out. Two one-fourth inch rubber tubes were inserted, their ends barely reaching the inner wall of chest; they were then fastened by a safety pin and by adhesive plaster, their ends cut off close to the skin. The following dressing, devised by Dr. A. T. Cabot, of Boston, was then applied: First, a handful of antiseptic gauze, loosely made into a ring, was put around the tubes; a little loose gauze placed over this; next, a piece of Mackintosh, about twelve inches square, large enough to go beyond the gauze in every direction on to the bare skin; finally, twelve layers of antiseptic gauze, outside of which a layer of cotton wadding was laid, and the whole firmly bandaged, a turn being taken over the shoulder to keep the dressing from slipping down.

Patient was much more comfortable after than before the operation. Drs. Cuthbert and Shute assisted me. That evening patient was very easy; temperature normal, being 1½° lower than in the morning. The dressing was soaked through somewhat, but was not changed. Subsequently, with one or two exceptions, the dressings were changed every morning under the spray.

Two days later the urine became olive-green when passed, almost black on standing. A 1 to 15 solution of chlorinated soda was then substituted for the carbolic acid in the spray, and in a day or two later, as the urine continued dark, the carbolic acid was rinsed from the gauze that went next the skin; a few days later still bichloride gauze was used throughout.

After September 17 gutta-percha cloth used instead of Mackintosh. One of the tubes was omitted as soon as the discharge became considerably diminished.

Nothing of interest occurred until about a week after operation, when there was a slight rise of temperature for a few days, during which patient complained of pain and tenderness of right side. August 31, just after taking morning temperature, patient had an urgent call to evacuate bowels; on coming from closet, said he had passed a large amount of matter like the discharge from his side, but had not preserved it; temperature had fallen 6°. The two following days he said he had five or six similar evacuations, all accompanied with slight pain, but he did not save them, although directed to do so.

Up to that time the discharge from chest was very copious, but from that date there was a marked decrease in quantity; color gradually became less and less chocolate-like, but more yellowish, until it was only a few drops in twenty-four hours. On Septem-

ber 26 the tube was removed, just thirty-five days after operation, and the following day he went to his work.

Improvement in his general condition followed immediately the operation, and marked improvement from the time of the unusual discharge from the bowels. He was kept in bed but two or three days.

On October 10 the sinus was entirely healed; he had gained twenty pounds in weight, and was feeling perfectly well and strong. Patient was examined by Dr. Cutbber and myself, and we found but little retraction of the chest wall, lung normal, except a little enfeeblement of respiratory murmur at the base.

The medicinal treatment consisted of the exhibition of: Stimulants, $\frac{1}{2}$ 3 doses of sulphate of soda for a few days to counteract the toxic effects of the carbolic acid; tinct. of chloride of iron and tinct. of digitalis for about a week; afterwards, elixir of iron, quinine and strychnine and cod-liver oil.

Having given the history of the case, I wish now to discuss, as briefly as possible, its most interesting features.

Diagnosis.—It is sometimes difficult to differentiate right sided pleurisy from a large abscess of the convexity of the right lobe of the liver. In this case, however, the variation of the line of flatness with the position of patient indicates the presence of free fluid, which can only be the case of fluid in the pleural cavity. The purulent character of the fluid can only be determined with certainty by the exploratory puncture, although the hectic night sweats and great constitutional disturbance lead one to suspect such. A writer in "Pepper's System" says that œdema of the chest wall is almost characteristic of pus in the pleural cavity. This symptom was present in my patient.

Here I desire to make a plea for the more frequent use of the hypodermic needle for exploratory purposes; it is of invaluable aid in diagnosis, and with antiseptic precautions is free from danger. A little longer and somewhat stouter needle is preferable in order to insure its passage through a thickened pleura, and to avoid the slight danger of its breaking.

Etiology.—As is usual in empyema, the cause in this case is obscure, yet one can not help suspecting the liver to be primarily at fault, although the evidence in that direction is by no means conclusive. The patient first had pain in right shoulder and arm, a not unusual symptom in hepatic trouble. The fluid is not what one usually gets in empyema, nor can I find a description of such ever having been found, but a writer in "Quain's Dictionary" states that in abscess of the liver a chocolate-colored fluid is sometimes present; he also says, if a patient has a sudden and copious expectoration of such colored matter, we may consider this sufficient evidence that a liver abscess has burst into a bronchus. *May not the fluid in my patient's chest also have come from the rupture of a liver abscess?* Had this been the case, however, one would expect the history of sudden and acute pain in the chest, accompanied by marked prostration or even collapse. The patient had nothing the kind, but he does say that pain and soreness of chest, with dyspnoea, followed and replaced the pain in shoulder.

You will remember that two years ago the patient had a liver abscess. *May not a purulent focus have remained dormant from that time until his present illness?* It is well known that abscess of liver is frequently multiple, and may give rise to no symptoms for years. On the other hand, had the abscess been at the convexity, he may very naturally have referred the pain and tenderness to the chest. The microscopical examination of fluid was negative as far as the liver is concerned. It is to be regretted that the patient's description of the unusual discharge from bowels can not be verified. Assuming that he was correct, *where did the matter come from?* One would suspect from the sudden decrease in the amount of discharge from the chest that followed this event, that there must have been a communication between the pleural cavity and the intestinal canal.

As was remarked before, the etiology of this case is uncertain, although one is tempted to regard the liver as the primary seat of the mischief.

Prognosis.—Cases of empyema after operation by the usual methods, even under the most favorable circumstances, usually require months and sometimes years before the final closure of the cavity. Dr. Cabot reported in *Boston Med. and Surg. Journal*, Aug. 16, 1883, fourteen cases in which he used his dressing; the ages of his patients varied from $1\frac{1}{4}$ years to 33 years; eleven recovered; two died of phthisis; one of unknown cause; the average length of time before removal of tubes was only twenty-four days. He recently told me that he has since used the same method with excellent results, and still clings to the spray. In this case reported above the tube was removed in thirty-five days.

The completeness as well as the rapidity of recovery is noteworthy. This result is due partly to the prompt recognition of the disease and to the speedy performance of the operation, but especially to the peculiar dressing used, its antiseptic character, and to careful antiseptics throughout.

A free opening into a pleural cavity, of necessity, permits ready entrance and exit of air. As a result, the lung is semi-collapsed, and expands only in proportion as the cavity is obliterated by the formation of adhesions between the pulmonary and parietal pleuræ, and by sinking in of ribs. It sometimes happens, under the ordinary treatment, that this process takes place so slowly that the lung is permanently kept high in the cavity by adhesions sufficiently strong to completely prevent its further expansion and descent, recovery then only taking place after resection of some of the ribs.

It is believed that in the Cabot dressing, the Mackintosh, lying snug to the skin as it does, acts as a valve, allowing the exit of air and fluid but preventing the reëntrance of air, thus giving the lung an excellent opportunity to expand fully and at once. The entrance of air is also hindered to a certain extent by the many layers of gauze outside the Mackintosh. The cotton wadding secures elastic pressure and keeps the Mackintosh firmly applied to the skin, yet allowing it to be lifted up for escape of air and fluid.

As to injections into the cavity, one finds equal

authority for and against. It is usually a safe thing to do, but sudden death has occurred with sufficient frequency to warn us to be very careful to use great gentleness, and not to inject a large quantity of fluid suddenly. Carbolic acid should be used neither in the injecting fluid nor in dressings next the skin. Dr. Cabot had serious symptoms in one of his cases from absorption of an exceedingly small amount of carbolic acid. In my case the prompt occurrence of melanuria gave ample evidence of absorption, although there were no other toxic symptoms.

No injections were used at any time in this case, because there were no clots in the cavity, no fetor, and because it seemed to me that by separating the pleural surfaces and by mechanical violence they would prevent the formation of the needful adhesions.

The object of having the tubes barely long enough to reach the cavity is to avoid irritating the pleura, for long tubes and catheters act as foreign bodies, and tend to keep up suppuration.

HYGIENE OF PERIODIC FEVERS.¹

BY W. L. SCHENCK, M.D.,

OF OSAGE CITY, KANSAS.

So commonly accepted is the theory that periodic fevers, neuralgias, dysentery, etc., are caused by a specific poison, that one may feel lonesome in combating it. But truth is not evolved by following the beaten path when it leads away from the truth. As neither the etiology, pathology, therapeutics or hygiene of periodical disease point to the specific factor known as malaria, whether it be a gaseous exhalation, a septic poison, a microscopic germ or a myth, we see no reason for adherence to the dogma.

Correct etiology must always precede scientific and successful hygiene. Without it all results are empirical. And when we resort to a causation of which, as Dr. Bemiss² says, "it must be admitted the substantive essentiality remains as yet undemonstrated," and Dr. Bartlett,³ "neither the strongest lenses of the microscope nor the most careful analyses of chemistry have succeeded in discovering the faintest traces, even, of the composition and character of these invisible, mysterious, yet stupendous agencies," hygiene must still be empirical. If such a factor can account for the pathology of periodic fevers, we should cease to wonder at the incomprehensible results claimed for homeopathic dynamizations. Dr. Bemiss says:² "During a chill the blood driven from the surface must be accounted for elsewhere, and every chill implies a condition of congestion." If this is true, it must be equally true in all cases in which the blood is driven from the surface. What are the conditions that always precede and are associated with periodic fevers? Hot days and cool nights, sensible and more or less marked alternations of temperature, conditions whose effects are always intensified where added moisture enervates during

the day, and by its condensation makes the night more chilling, as in countries abounding in swamps and marshes.

During the heated days of temperate and tropical climates, especially when their impress is intensified by an atmosphere rarefied by excessive evaporation, by excessive exposure and labor and by improper food and habits, there is always physical exhaustion. During the cool nights that follow such days there is a recession of the circulation from the capillaries of the surface, and consequent engorgement of central organs, which, in the enervated condition of the patient, often fail of normal balance. If the congestion of internal organs, through over-distension of their vessels, in fully developed ague, leads to their re-engorgement in twelve, twenty-four, forty-eight or seventy-two hours, the intervening periods growing shorter when the effect is positive and longer as it subsides, or if the febrile reaction and sweating does not wholly relieve the congestion, and because "*ubi irritatio ibi fluxus*," they are again and again engorged, each subsequent engorgement making easier the conditions of its successor, and ultimately sufficient to keep alive the action regardless of its primitive cause, then the same is true of the nightly recession from climatic influences, which must lead up to positive periodic diseases, capable of recurrence from slight exciting causes long after removal from malarial districts.

If this rational etiology is sufficient to account for periodic diseases, why resort to the gratuitous inference of an intangible malaria, which neither explains or is explained by their pathology or therapeutics, and does not aid in their prophylaxis? When we mark how wide a range the advocates of a specific "swamp poison" must give for its production, that it may cover the widespread cases of periodic fevers, we can but wonder at the general adherence to the doctrine. While the common thought is alluvial districts with abounding swamps, in hot climates, it is made sufficiently flexible to cover all cases, and accommodates itself equally well to a want or excess of factors. Thus Dr. Bancroft says: "A humid soil, abounding in vegetable remains, acted on by a heat ranging from 75° to 100° F. is the most favorable for the extrication of malaria." Pringle tells us periodic fevers have prevailed with great violence in the Dutch Brabant, where the soil is dry and sandy. Elliottson says that clayey soils are most favorable to the production of these fevers, on account of the clay retaining moisture. Linnæus wrote his "*Hypothesis nova de febrium intermittentum causa*" to prove that intermittents abound where clay abounds, and only in such places; while McCulloch says that around the Dal in Normandy, where there is a salt marsh, scarce an inhabitant escapes ague. Though prevalent in certain districts, periodic fevers have occurred wellnigh everywhere. In this country they are found among the mountains of New England, throughout the great Valley of the Mississippi, on the Gulf coast and Pacific slopes, while neither the sea-girt isle nor the sand bound oasis wholly escape their presence. But the advocates of a malarial poison not only give it a wide distribution, but make it equal to all emer-

¹ Read in the Section of State Medicine and Hygiene, at the Thirty-Seventh Annual Meeting of the American Medical Association.

² System of Medicine, by American Authors, vol. i, p. 589.

³ Treatise on Fevers, p. 347.

⁴ Op. cit.

gencies. Thus Dr. Bemiss (op. cit.) says it is a specific poison, probably an organism, and not capable of reproduction within the system, but is so slowly removed that after long systemic residence it may cause vernal attacks, though the subjects of these long delayed attacks have never suffered a paroxysmal seizure.

If, in the production of periodic fevers, we can eliminate every etiological factor except alternating heat and cold, and if these alone are not favorable to the production of malaria, or malaria bacillus, and will account for all their phenomena, while an undemonstrated malaria cannot, why longer adhere to an occult entity? A careful study of individual cases of endemics or epidemics will always result about as follows: Aug. 30. Called to see A., aged 7 years. Days hot and nights cool. House healthily located. Patient had remittent fever; had slept for several nights, without cover, between open windows. No other member of the family similarly exposed, and no other case.

Sept. 1. Saw B., aged 30; laborer. Had congestive remittent. Worked hard during the day, and slept in his damp clothes without sufficient cover. D., occupying the same room, put on dry night clothes and slept between blankets, and had no fever. Sept. 2. Saw E., farmer. Had intermittent. Enjoyed the cool of the evening air in his shirt-sleeves and was not careful about keeping well covered at night. Sept. 3. Called to see the family of E. Three members, father and two children, sick with "malarial" dysentery. They were living on the upland prairie, in a newly erected shanty, built in a cornfield, the corn cut up for about twenty yards about it. Want of circulation made the days warm, while condensation by surrounding vegetation made the nights very chilly. The people were poor, badly fed, and regardless of protection against the fall of temperature. And so we find those living on a knoll, near a body of water, especially if the water is shallow and evaporation increased by the heat of the earth beneath, suffering from periodic fevers, while those protected by a belt of shrubbery, or living over the knoll, escape.

On the other hand, we have such cases as that of the English surgeon, who had his bunk erected over a marsh in Hindostan, where, wrapped in blankets, he slept with impunity, while the careless soldiers who slept in the neighborhood were decimated by congestive fevers, and those living on the Pontine marshes in comfortable homes, and careful about night exposure, escaping, while their neighbors, disregarding such precautions, become victims of the Pontine fever. Women, though more delicately organized than men, and more poorly clad during the day, often escape because more careful to cover their nakedness at night, while men and children, of either sex alike, lie half covered at night, and suffer from periodic fevers. So we might continue to elucidate, but such cases are sufficiently suggestive.

The "malaria" so common to swamps, lagoons and marshes, to alluvium subject to overflow, or grounds made damp from other causes, in locations and at seasons when the days are hot and the

nights cool, and not common to other localities, altitudes and seasons, is not a septic poison or a microscopic germ, but an alternating temperature, whose impress is always intensified by abounding moisture, and whose etiology is sustained by the pathology, treatment and hygiene of the diseases induced.

The pathological conditions are so marked they leave no question. Whether fever is produced or not, there are certain well known pathological changes. There is recession of the circulation from the surface and consequent infarction of central organs which, when the chill is severe, is sometimes so great it may be demonstrated by a post-mortem. There is reactive force and engorgement of the superficial capillaries, followed by excessive sweating, consequent upon over-stimulation of the sudorific glands. If the periodic influences are continued, they are marked by certain permanent changes in central organs, usually most prominent in the spleen and liver. In the spleen, for example, there is emphyaxis, and in some cases of the pernicious type, rupture, ulcers or gangrene. Following the splenic engorgement is hypertrophy or hyperplasia and consequent leucocytosis or leukæmia, and hæmorrhages. All these conditions may occur without febrile paroxysm, and when present may keep up the fever without regard to the primary cause, for, as Dr. Bemiss says (op. cit.): "the blood driven from the surface must be accounted for elsewhere," and the mighty chill that follows the exhausting heat of damp climates will produce a corresponding degree of central congestion, and in an enervated system lead up to a pronounced chill and fever.

The advocates of "malaria" admit the necessity of alternating temperature. Thus Dr. Elliotson says: "During the heat of day there is a disengagement of malaria, and consequently when night comes on there is more precipitated. Cold and wet are always most operative after heat." Does the learned professor add anything by assuming a factor that explains nothing? Dr. Bemiss (op. cit.) tells us "there is no other known agency capable of originating the morbid phenomena characterized by such marked periodicity." Periodic reactionary effect marks many diseases not consequent upon "malaria," as uræmic fever, hectic fever, etc. While "malaria" has never been demonstrated, periodic alternations of temperature are demonstrable, and their natural consequent is periodic disease. Periodicity is a great law of nature. It marks every function in the economy of life. As pathology is only morbid physiology, we may infer that pathological periodicity is only a diversion of physiological activity, and it is far more rational to refer it to periodic alternations of heat and cold than to an assumed microscopic swamp devil sent to "torment us before our time."

Therapeutics not only confirms our etiology and pathology, but disproves the idea of a specific poison, whether it be a septic decomposition or a microscopic germ. The sulphate of quinia outranks every other agent in the treatment of periodic fevers, not because it is the most powerful antiseptic or germicide, but

because of its action upon the trophic nerves. Dr. Bemiss but echoes the opinion of all when he says "the great indication is to secure cinchonism as speedily as possible." And yet, we must say this *cum grano salis*. He who gives it as a routinist may kill his patient with the best antiperiodic in the pharmacopœia, for it is powerless to cure when permanent organic lesion keeps up the periodic action. In antiperiodic doses it equalizes vital force by promptly and powerfully impressing the central nervous system, thus relieving engorged and congested central organs. In toxic doses it preserves the restored balance. In antiphlogistic doses, even when there is organic change beyond its reach, it temporarily restores balance, arrests destructive metamorphoses and reduces pyrexia.

What has hygiene accomplished under the prevalent idea of causation? Have any means been discovered to destroy the undiscovered entity—malaria? The drained marsh, until thoroughly dry, has only increased "palludal" fevers by increasing evaporation and consequently intensifying diurnal and nocturnal alternations of temperature. Germicides and antiseptics are impracticable and useless.

The only effective, because the only rational hygiene, is found in avoiding exhausting labor during the heat of the day, replacing, as the chill of night approaches, damp clothing for such as is dry and warm, and sleeping between comfortable blankets, keeping out of the chill and damp of night, or providing against it with proper clothing, and in avoiding all irregularities, and by healthful exercise and diet. By such precautions we may remove from the people the undefined dread of an indefinable malaria, rob the routinist of his ever-ready cry of malaria and its corollary, quinine, and feel as safe at the tropics as the poles; as safe on the swamp as on the mountain.

THE NECESSITY OF ABDOMINAL SECTION, AS ILLUSTRATED BY AN UNUSUAL CASE OF OVARIOTOMY.¹

BY C. R. REED, M.D.,

OF MIDDLEPORT, OHIO.

An ovariectomy to attract the attention of the profession at the present time, must be unique and have some characteristics of peculiar interest. To open the abdominal cavity as an exploratory operation for the purpose of making clear an obscure diagnosis, to remove an ovarian cyst or tumor, a diseased ovary or tubes, to stitch up a wounded viscus, and to remove foreign matter from the peritoneal cavity, is now of every day occurrence, and almost universally admitted to be legitimate surgery. The operation as first performed by McDowell to remove an ovarian cystic tumor when the health and life of the patient was endangered by mechanical pressure on adjacent organs or structures; or that of Battey of removing the ovaries to hasten the menopause, thereby arresting the monthly congestion of the pelvic organs; re-

tarding the growth of tumors, checking hæmorrhages and curing many diseases of the pelvic organs; and the exploratory sections as now advocated by Tait and others are so frequent as to almost cease to challenge attention. Without abdominal incisions and explorations the knowledge of pathological condition is often impossible; the diagnosis is obscure, the indications of treatment are uncertain, the patient does not receive the necessary treatment, the physician's reputation suffers and a post-mortem examination reveals "what might have been." The success attending the operations, the necessity for which are made clear by exploratory incisions of the abdominal walls, is such as to deprive ovariectomy and kindred operations of their former terrors; to greatly enlarge the resources of the surgeon and to give new hope to the otherwise doomed patient.

The following case, I think, is a striking example of the necessity of abdominal incision and exploration without which its nature would not have been known, the treatment would have been unsuccessful, the patient's life would have been a sacrifice to ignorance, and the grave would have kept the secret of its true pathology. As an illustration of the utter inefficiency of drugs in similar cases and the imperative necessity of bold and prompt surgical interference, no more striking instance, I believe, is on record. As a case of simple ovariectomy, after the diagnosis was made clear by abdominal section, there is nothing unique or unusual connected with it; but its history, the attending symptoms, the means used for relief give it, we think, an unusual interest. The symptoms during the few days, immediately preceding the operation, were such as had not before come under my observation in cases of ovarian cyst, neither had I seen similar symptoms described in the literature on the subject. The illness of the woman did not lead us to suspect an ovarian cystic tumor or any disease peculiar to her sex. I expected to find an entirely different pathological condition, and but for the exploratory incision, or an autopsy, the cause of the symptoms and the death of the patient, which I believe would have been inevitable, would still have remained a mystery; but the abdominal section at once made the diagnosis clear and the treatment plain.

In the afternoon of August 25, 1885, I was called in consultation with Dr. J. W. Lilly, of Pomeroy, Ohio, to see Mrs. B., married, 34 years of age, the mother of seven children, the younger two being twins, 12 months old. She was then menstruating, having been regular the past three months. Dr. Lilly had called on me in the forenoon, gave me a history of the case, the symptoms and treatment, and requested me to see the patient with him. I gave an opinion then that nothing but laparotomy or an abdominal incision would reveal the true condition and indicate the treatment. Mrs. B. had been in good health up to within a few days prior to this date. The preceding four days she had vomited almost constantly, the last forty-eight hours it being stercoraceous. There was obstinate constipation, indicating obstruction of the bowels, cathartics, injections and local applications had been used without avail.

¹Read in the Section on Obstetrics, at the Thirty-Seventh Annual Meeting of the American Medical Association.

Her pulse was 120 and weak, extremities cold, body covered with cold perspiration, strength greatly depressed from constant nausea and vomiting; her appearance and general symptoms betokening rapid dissolution. Her mind being clear abdominal section was proposed as a possible means of relief, to which she and her husband readily consented. She was given a $\frac{1}{2}$ grain of morphia sulphas by subcutaneous injection, and Dr. J. H. Hysell was sent for to administer the anæsthetic. She was placed on the operating table, the abdomen laid bare, and washed with carbolized water, when it was discovered that the abdomen was enlarged and irregular which was attributed to fecal accumulation. She came promptly under the influence of the anæsthetic, the A. C. E. mixture, when an incision was made in the linea alba, midway between umbilicus and pubes, four inches long; a tumor appearing at the opening, the incision was enlarged to eight inches, when it was found to be a cyst of the left ovary with adhesions to the abdominal walls and also to the descending colon. The former were readily broken up, the latter with difficulty, and these were believed to be the cause of the obstruction and constipation. There was general peritonitis, both of that portion lining the cavity and that investing the intestines, the tumor had a mottled appearance indicating congestion. The exploring needle of a hypodermatic syringe was thrust into the tumor, when the canula filled with a chocolate colored fluid. We had not come prepared to deal with an ovarian cyst; we had neither trocar, or hæmostatic forceps, and were warned by the gentleman administering the anæsthetic that in the patient's depressed condition no time could be lost in sending for the necessary instruments, but the operation must be completed with what we had on hand. It is worthy of notice that no vomiting occurred after the incision was made, neither did it occur during convalescence. We determined to remove the tumors. After the adhesions were broken up the tumor was punctured with a scalpel and the fluid was conveyed away as best we could, by thrusting a rubber tube into the opening made by the knife. The pedicle was short and thick; it was transfixed by a double silk ligature, one end hanging from the lower angle of the wound for the purpose of drainage; the abdominal cavity was sponged dry, the incision closed by deep silk sutures and adhesive plaster. The patient rallied well from the anæsthetic; her condition improving as soon as the nausea ceased; her bowels were spontaneously moved on the eighth day; convalescence was interrupted on the tenth day by a severe attack of capillary bronchitis, caused by the injudicious use of ice to lower the temperature. The ligatures on the pedicle came away on the fortieth day, and since that time she has had her usual good health; menstruated after the third month and is now two months *enccinte*.

The minor details of this case have been given in this paper because of its obscurity prior to abdominal section; the unusual symptoms attending it; the treatment prior to operation being based on an obscure diagnosis and therefore futile, and the diffi-

culties of an operation in the absence of what are considered essential instruments. In considering the above case the following questions are suggested:

1. Was the ovarian cyst with its adhesions to the descending colon the cause of the obstruction of the bowels?
2. Would the exploring needle have made the diagnosis clear without abdominal section?
3. With the probability of the patient dying under the operation would it have been better practice to have tapped with the trocar, and deferred the removal of the tumor?
4. As it has been shown by the large experience of Lawson Tait and others that abdominal section and exploration is under aseptic treatment, attended with little or no mortality, is it not the imperative duty of the physician to open the abdomen in all cases of doubtful diagnosis where general treatment has failed to relieve the symptoms.
5. In cases of slight enlargement of the abdomen, attended with intestinal obstruction, as in this case, should the physician wait until symptoms of approaching dislocation occur before resorting to abdominal section? And should the operation be performed as a means of diagnosis only, when the symptoms are not urgent?

FRACTURES OF THE FEMUR IN CHILDREN,

Treated by Bryant's Method of Vertical Extension.¹

BY J. M. BARTON, A.M., M.D.,

SURGEON TO THE JEFFERSON COLLEGE HOSPITAL, PHILADELPHIA.

The treatment of fractures of the femur in children has always been attended with great difficulty. The fragments are so short they are not readily grasped by the dressings, and the thigh is usually so comparatively large and soft that the extremities of the fragments are with difficulty maintained in apposition. None but the most firm and secure dressings will be retained, as all the efforts of the sufferer are directed towards their removal. The dressings are soon soiled by the discharges from the bladder and bowels, the frequent renewals interfering with the process of repair. The displacement of the dressings by the patient, causing injurious pressure, and the uncertainty which the surgeon feels concerning the condition of the limb, necessitate frequent examinations, especially when the child shows evidences of discomfort.

The disappointment occasioned by these dressings is perhaps best shown by the fact that in St. Bartholomew's Hospital Reports for 1867, we find that Messrs. Paget and Callender report that they treat many cases of fracture of the thigh in children negatively, without splints, all apparatus being dispensed with, "the child being laid on a firm bed with the broken limb, after setting it, bent at the hip and knee and laid on its outer side."

The plaster dressing is a valuable one in these fractures, and as usually applied, with short splints around the femur and a long splint reaching from the axilla to below the foot, thoroughly covered in with plaster bandages, and either varnished or covered with oiled

¹ Read in the Section on Surgery, at the Thirty-Seventh Annual Meeting of the American Medical Association.

silk to protect it from the discharges, has often given admirable results.

If dressed immediately after the injury, the subsequent swelling may cause injurious pressure, and if the dressing be made loose enough to allow for the swelling, or be deferred until it has occurred, the fragments will be but poorly supported after the swelling has disappeared. Some of the discharges may get under the dressings without being suspected and cause considerable irritation. From these causes and from uncertainty regarding the condition of the limb, it not unfrequently happens that the dressing has to be removed once or more during the treatment.

As it is usual to give ether in applying these dressings, and as the surgeon scarcely cares to delegate it to an assistant, its frequent application is a great objection, especially in hospital practice. On removing these dressings when the treatment has terminated I have often felt considerable uncertainty as to what kind of a limb would appear.

A method of treating fractures of the femur in children by vertical extension is described and claimed as original by Bryant in his "Practice of Surgery," published in 1873, and also in the later editions. This method, though possessing many advantages, is unnoticed by the surgical text-books, and but few surgeons among those of whom I have inquired have had any experience with it. Under these circumstances I feel warranted in bringing this subject before this Association, and reporting five cases that I have treated by this method. Bryant flexes the limbs to a right angle with the pelvis, fixes them by some light splint, and then they are "hoisted upward and fastened to some cradle, hook or bar above the bed." This has been slightly modified, substituting counterpoise weights for the simple fastening.

Case 1.—Mary F., aged 2½ years, was admitted to the Jefferson College Hospital July 6, 1884, with a fracture about the middle of the left femur. I applied the plaster dressing, which had served my purpose well in previous cases, but was obliged on the second day to remove it, and I substituted this method. The usual adhesive plaster, carried well above the knee, the same as is used for making extension in adults in the ordinary method of treatment, was applied to each limb, to the sound as well as to the injured one. After the plaster had become firm, a light wooden frame, extending across the bed and about four feet above it, was placed in position, such a frame as is usually used for swinging fracture boxes, etc., from, consisting simply of two uprights, one on each side of the bed, and a light bar connecting them. In the lower edge of the transverse bar four iron pulley wheels had been fastened, two about the middle, a few inches apart, and one at each end close to the "upright." The limbs of the child were elevated to a right angle with the rest of the body, the cord from one of the adhesive plasters on one of the limbs was carried through one of the middle pulleys and then through the pulley at the end of the bar; here the weight was attached. The cord from the other leg was then carried in a similar manner to the other side. The heaviest weight was attached to the injured limb, and only enough to the

sound leg to keep it fairly elevated. The fracture came immediately into good position, but for greater safety a few short and narrow splints were applied around the seat of injury, supported by a light bandage. The child was comfortable at once and continued so.

The apparatus was removed about the twentieth day, as firm union had occurred, the child was kept in bed a few days longer, and then permitted to creep and walk around the ward. She was discharged thirty-five days after admission with a perfect leg, in which neither shortening nor deformity were detected.

Case 2.—Nils Christian Thompson, aged 4 years, injured on shipboard coming from Denmark, was admitted to the Jefferson College Hospital on July 21, 1884, with a fracture of the femur at the junction of the upper and middle third, a frequent seat of fracture in children, and as the upper fragment has as strong, if not a stronger tendency to be displaced forward than in adults, this method of treatment is particularly well adapted for remedying this deformity. This patient was placed in a precisely similar apparatus, in which he was kept for twenty-five days. The boy was discharged well, with less than one-half inch of shortening, August 10, and with the limb in perfect position.

Case 3.—Gustav S., aged 3 years, was admitted on February 12, 1885, to the German Hospital in Philadelphia. His fracture was also at the junction of the middle and the upper third. After an unsatisfactory trial of another method I placed him, a few days after admission, in an apparatus similar to those before described. He was discharged on April 23, having been running around the wards for several weeks under treatment for another affection. Dr. Rehfuss, the resident physician, who examined him before he left, tells me that the limb was in perfect position, without perceptible shortening, and that he had full and free use of it.

Case 4.—John W. MacA., æt. 6 years, was admitted to the German Hospital May 9, 1885, with a fracture of the upper part of the right femur. He was treated in the same manner, and was discharged July 6 with a perfect result.

Case 5.—Benj. H., aged 2 years 3 months, a private patient, fractured his left femur about its middle on November 2, 1885. He was placed in the same form of apparatus, and made a very satisfactory recovery with good union in about three weeks.

None of these children seemed to suffer the slightest inconvenience or annoyance from their position; they amused themselves by playing with their toys, appeared quite happy and entirely free from pain. As the limb cannot get out of position while full extension is maintained, and is so readily examined, the surgeon need feel no anxiety regarding its condition.

It is rarely necessary to remove the light bandage and splints around the femur, and when necessary can be done without assistance, and without pain or frightening the patient or displacing the fragments. It is quite as easy to measure the length in this position as in the treatment by horizontal extension in the adult. The swelling is usually but slight, but if

great does not interfere with the treatment. I have never seen, while using this method, those huge masses of redundant callus which are not infrequently found in the fractures of restless children.

The child is readily kept clean, a folded sheet placed under the buttocks to receive the discharges, and removed when soiled, is all that is necessary. The nurse grasps the child by the feet, and gently raises it some inches from the bed, and as it is nearly counterpoised, it can be kept in this position with but little effort on her part, while the hips and back are washed and a clean sheet put in position. In winter some of the bedclothes are given a turn around the limbs and hang suspended by the extension cords.

The amount of weight used for extension depends, of course, on the size of the child, but about the same amount as would be used in horizontal extension will be found quite enough.

DR. D. W. GRAHAM, of Chicago, had followed the method described by Bryant, which was the same in practice, but a little more simple in its application, had found it a comfort to the patient and successful in its results, but he did not see the need for using any coaptation splint.

DR. I. N. QUIMBY, of New Jersey, said he could not see any reason why it should be preferred to the horizontal extension and counter-extension heretofore used.

DR. LINK, of Terre Haute, said that for many years he had not used any extension or counter-extension in treatment of fractures of the femur, nor had he found it necessary to use coaptation splints. He simply treated them by flexing the thigh upon the body and the leg upon the thigh, everting the limb and putting it in a position of muscular relaxation on a bed of bran.

DR. GRIFFITH, of Kansas City, expressed the belief that one great advantage in the vertical suspension of the limb in treatment of fractures of the femur, was to be found in the relaxation of the psoas magnus and iliacus muscles.

A CASE OF PLACENTA PRÆVIA.

BY H. VON SWERINGEN, A.M., M.D.,

OF FORT WAYNE, INDIANA.

Believing it to be the duty of the physician to report his failures as well as his successes, I wish to place on record the following case of placenta prævia, making the fifth that has occurred in my practice, and the first and only one that has resulted fatally.

On Sunday, September 26, 1886, about 1 P.M., I was called to see Mrs. J. L., who, as the messenger (the husband) stated, was about to be confined with her tenth child, but had not during the entire period of her pregnancy, felt right or natural, or as she felt during her previous pregnancies, and was therefore in constant fear that all was not well with her. She seemed to have a premonition that she would not live through her lying-in, having spoken of it frequently to her neighbors, friends and husband. Her mother and sister were buried with babes in their arms, each having died of hæmorrhage from

placenta prævia, a fact which no doubt increased her fear, and which would seem to indicate if not a predisposition to that condition, at least a tendency to bleed, or a hæmorrhagic diathesis.

I learned that she had quite a number of spells of flowing during the last three months of her term, and, in fact, an occasional "showing" prior to this period, even from the very commencement of her pregnancy. A few days prior to my visit her family physician was called in, and after making a digital examination, informed the husband that he had better get some other doctor to attend her accouchement, inasmuch as it would not be safe for him to do so because of several cases of blood-poisoning he then had under treatment.

When I saw the patient for the first time she was pale, anæmic, had light hair and blue eyes, a blonde in complexion, of about 40 years of age. She was complaining of slight pains in her back and an occasional flowing. An immediate digital examination confirmed the diagnosis already formed and very naturally suggested by the history of the case, revealing a more rigid os than would naturally be expected, dilated to the size of about a nickel; forcing my index finger through it, its extremity came in contact with a boggy substance, not unlike a firm clot of blood, which, at first I thought it might be, but concluded not to disturb it. Pushing my finger as high as I could to the right of this substance, I succeeded in barely touching some part of the head, which seemed to be gradually descending from the right iliac region. I gave her a full opiate, requested her to remain quiet, and, in the event of any more hæmorrhage occurring, to summon me.

On the following Tuesday afternoon I was again called, simply to see how the case was progressing, and found her in about the same condition as when I left her; her pains amounted to nothing, not even sufficient for dilating purposes. The os was a little more enlarged, probably to the size of a quarter of a dollar, and slightly softer; and the head was so high up that I failed to touch it. I administered oxytocics with opiates and promised to be back and remain with her during the night, assuring her and the friends that the very moment the mouth of her womb was large enough to admit the introduction of my hand I should endeavor to get the babe, for upon its speedy delivery depended her safety. My intention was to apply the long forceps and bring the child (which was now dead) down so that its head or body would cover the site of hæmorrhage, and leave it there for a time as a tampon, until her pains would become strong enough to finish the delivery and prevent post-partum bleeding. I left her bedside and returned directly after tea to remain with her during the night. Throughout the entire night her condition remained about the same, her pains amounting to nothing, no hæmorrhage, however, and the os but very little increased in size. It was about 8 o'clock when I left her on Wednesday morning. Throughout the day I visited her at intervals of an hour or two.

At about 6:30 in the evening I again visited her, and had barely reached her bedside when a very copious hæmorrhage took place. I immediately

tamponed her, using several silk handkerchiefs for the purpose. I now concluded to wait until about midnight before resorting to more heroic measures, feeling hopeful that the tampon itself would not only prevent further bleeding but aid in softening and dilating the os uteri.

Every little while she announced that she was flowing, but an examination would as often prove the contrary; she simply imagined she was. She bore the slightest examination badly, seeming to be super-sensitive to the mildest manipulation, and I therefore decided to get her in position and under the influence of chloroform when I removed the tampon, and directly after the removal attempt the delivery of the child. In the meantime all the necessary preparations were made, the attendants instructed, and the husband informed that if he desired the attendance of one or more physicians he had better notify them to come at once. He replied that he was perfectly satisfied to trust the life of his wife in my hands. Had I not been successful in the treatment of four similar cases, however, I should have insisted upon him calling in one or more physicians. With confidence born of previous success, I therefore trusted in my own ability to conduct the delivery safely. The lesson which the sequel has taught me will not be soon forgotten.

About 1 A. M., she called me anxiously, saying that she was now positive that she was flowing badly, which announcement proved to be only too true, although very little if any impression had yet been made upon her pulse. After getting her in the proper position, I administered chloroform, removed the tampon, and found that by a little effort I could introduce my hand; this done, I discovered that at least half of the placenta was detached and presenting from the posterior lower segment of the uterus, the cord was pulseless, the head was still high up in the iliac region, and hemorrhage was going on. Abandoning the thought of making use of the forceps, I reached up and brought down one foot; reached after the other, and while bringing it down, before the version was effected or completed, a perfect torrent of blood burst forth and all was over; not a pulse-beat, not a heart throb, not a sigh, not a groan—she was dead; dead before the child was fully delivered, and yet not three minutes was required in the operation of version and extraction. My clothes were all saturated with blood, of which a large pool lay upon the oil-cloth upon which I was kneeling during the manipulation. Recovering somewhat from the shock so sudden and yet not wholly unexpected death occasioned, I sent for a physician; desiring that some professional colleague might at least see the situation before it was in any wise changed by those in attendance. In a few minutes Dr. Howard McCullough came into the room, and took in the situation at a glance.

The only difference I have observed in this case from the previous four successful cases, is the fact that in the latter there were no pains of any account whatever, and all the blood in her body seemed to be in her uterus and placenta; also the fact that there was a larger area of surface of the placenta detached, possibly.

MEDICAL PROGRESS.

HEALED SHOT WOUND OF THE SPINE.—At the xvth Congress of German Surgeons, PROF. CZERNY, of Heidelberg, reported the case of a young woman, æt. 22, who, while at her toilet, was shot in the back by her jealous husband, May 6, 1873. The ball entered one-half inch to the left of the last dorsal spinous process. She sank with a cry. The man shot himself dead. I was called soon and found paraplegia, both legs paralyzed to the pelvis, and sensory paralysis on the right to the inguinal fold, on the left of the knee. Reflex irritability was entirely preserved, and all the paralyzed muscles reacted promptly to weak faradic currents. No twitching or contracture in the said muscles. Bladder and rectum were completely paralyzed. Catheterization for three days when the bladder emptied involuntarily on getting full. Pulse and temperature normal, mind always clear. The course of the ball and the complete immediate paraplegia pointed to the conclusion that the cord must have been perforated by the ball. Presumably the bullet had lodged in a vertebra as no symptom of injury to the abdominal organs was noticeable. I therefore did not consider myself justified in sounding, washed the wound superficially with carbolic, covered it with carbolized cotton, and thus the wound healed in a few days. The patient could soon sit propped up in bed, and was placed in a reclining chair after fourteen days. From the beginning of June she rode about several hours daily in a roller chair and continued this, weather permitting, until late in the fall; meanwhile her appetite continued excellent, general condition good and her appearance notably fresh and bright. In the early weeks the paralyzed muscles were faradized daily, yet contractility gradually disappeared. This so excited the patient that further faradization had to be dispensed with. The legs, which so far had remained lax, became stiff and inflexible at the end of summer, and began to atrophy with remarkable rapidity. In November decubitus developed, starting from urine excoriation, and spread rapidly over the sacrum. From this on there was fever, and the fatal end (December 4, 1873) was hastened by an erysipelas spreading from the wound over the whole back and thigh.

The ball was found healed in between the last dorsal and first lumbar vertebræ, to the right of the middle line. The spinal cord was almost completely severed, that below being somewhat thickened, whilst upwards to the second dorsal vertebra it was in a state of suppurative softening. The dura mater presented a scar at front and back, where it was also adherent to the bone. Pulmonary atelectasis of moderate degree, somewhat fatty liver, chronic cystitis.

The objection may be made that a suppuratively softened cord is not a healed cord. We know how difficult it is to distinguish yellow softening of the brain from a fresh abscess, yet to me the preparation makes more the impression of an acute ascending myelitis than of an abscedizing. Then it must be noted that the patient rode about several months in

subjectively good condition, and that the bullet was completely encapsulated.

Since before the time of antiseptics a severe shot wound of the spine has healed through the avoidance of probing and by careful washing out, a similar result ought now with like care to be all the easier achievable.—*Annals of Surgery*, November, 1886.

DIAGNOSIS OF INFANTILE DISEASES.—In a recent number of *L'Union Médicale du Canada*, DR. BRADLEY gives the following summary of points on the diagnosis of disease in infants:

1. Congestion of the cheeks, excepting in cases of cachexia and chronic disease, indicates an inflammation or a febrile condition.

2. Congestion of the face, ears, and forehead of short duration, strabismus, with febrile reaction, oscillation of the iris, irregularity of the pupil, with falling of the upper lids, indicates a cerebral affection.

3. A marked degree of emaciation, which progresses gradually, indicates some sub-acute or chronic affection of a grave character.

4. Bulbar hypertrophy of the fingers and curving of the nails are signs of interference in the normal functions of the circulatory apparatus.

5. Hypertrophy of the spongy portions of the bones indicates rachitis.

6. The presence between the eyelids of a thick and purulent secretion from the Meibomian glands may indicate great prostration of the general powers.

7. Passive congestion of the conjunctival vessels indicates approaching death.

8. Long-continued lividity, as well as lividity produced by emotion and excitement, the respiration continuing normal, are indices of a fault in the formation of the heart or the great vessels.

9. A temporary lividity indicates the existence of a grave acute disease, especially of the respiratory organs.

10. The absence of tears in children four months old or more suggests a form of disease which will usually be fatal.

11. Piercing and acute cries indicate a severe cerebro-spinal trouble.

12. Irregular muscular movements, which are partly under control of the will when patient is awake, indicate the existence of chorea.

13. Contraction of the eye-brows, together with a turning of the head and eyes to avoid the light, is a sign of cephalalgia.

14. When the child holds his hand upon his head, or strives to rest the head upon the bosom of his mother or nurse, he may be suffering from ear disease.

15. When the fingers are carried to the mouth, and there is, besides, great agitation present, there is probably some abnormal condition of the larynx.

16. When the child turns his head constantly from one side to the other, there is a suggestion of some obstruction of the larynx.

17. A hoarse and indistinct voice is suggestive of laryngitis.

18. A feeble and plaintive voice indicates trouble in the abdominal organs.

19. A slow and intermittent respiration, accom-

panied with sighs, suggests the presence of cerebral disease.

20. If the respiration be intermittent, but accelerated, there is capillary bronchitis.

21. If it be superficial and accelerated, there is some inflammatory trouble of the larynx and trachea.

22. A strong and sonorous cough suggests spasmodic croup.

23. A hoarse and rough cough is an indication of true croup.

24. When the cough is clear and distinct, bronchitis is suggested.

25. When the cough is suppressed and painful, it points toward pneumonia and pleurisy.

26. A convulsive cough indicates whooping-cough.

27. A dry and painless cough is sometimes noticed in the course of typhoid and intermittent fever, in difficult dentition, or where worms are present.—*London Medical Record*, Oct. 15, 1886.

EXCISION OF THE HIP IN PULMONARY TUBERCULOSIS.—H. BRESSON reports the following case which bears on the question of surgical intervention in tuberculous subjects. E. G., æt. 9 years, came under treatment May 16, 1885, for hip disease on the left side. No precedent tuberculous history, either personal or family. The beginning of the disease was obscure: for two months there was pain and lameness, and the child was kept in bed for four months. She then went about for six months, until the pain and lameness returned. The limb now shortened and rotated inwards, and soon intense pain at the knee forced the child to go back to bed. The cautery was used without result, and the condition became worse. She was then kept in immovable apparatus for three and a half months, and was afterwards free for six months, her condition having improved. At this time she already coughed a great deal; was pale, thin, without appetite, and with persistent diarrhoea, no albumen in the urine, consolidation at the apices of the lungs, moist râles, etc. The following month an abscess appeared at the upper and outer part of the thigh. At the commencement of July, aggravation of the symptoms suddenly took place, with sub acute inflammation of the joint, and strong fever was observed on the 21st. The purulent collection was opened under strict antiseptic precautions. Throughout the month of August the temperature oscillated between 38° and 40°. Although the tuberculous condition of the lungs caused a long hesitation, at the urgent request of the family, and in consequence of the daily aggravation of the child's condition from the copious suppuration, Dr. Cazin determined to excise the hip, which was done on August 30. The temperature fell from 40.2° and oscillated between 37° and 38° for a fortnight, when it returned to the normal. The wound, which was scraped at the bottom by Volkmann's spoon, united by first intention, and presented nothing untoward. Six weeks afterward a silicated apparatus was applied and the child began to walk with crutches. Since two months she has quitted the infirmary, her condition becoming better every day, appetite returned, sweats and diarrhoea disappeared

putting on flesh, and the stethoscopic signs considerably improved. On March 1 there was scarcely any appreciable dulness at the right apex, and only at the sub-spinous fossa of the same side can a little crepitation be heard on coughing. The child wears no local apparatus, can walk without crutches, and the limb is only shortened $1\frac{1}{2}$ centimetres.

Her condition at the time of operation was almost hopeless; six months after her general health was as satisfactory as possible. The result, no doubt, depends largely on the strict antiseptic precautions; and in freeing the patient from the constant loss by suppuration, her system was put in a better position to resist the pulmonary lesion—*Le Progrès Méd.*, Aug. 14, 1886.—*Annals of Surgery*, Nov., 1886.

POSOLGY AND USE OF SOME NEW REMEDIES.—

Osmic acid: Best administered in pill form (made up with Armenian bole). The dose is $\frac{1}{80}$ grain, which may be repeated several times a day. Used in epilepsy and sciatica. *Agaricine*: Best administered in combination with Dover's powder. Dose $\frac{1}{12}$ to $\frac{1}{6}$ grain. Used for night-sweats. *Aloin*: From $\frac{1}{3}$ of a grain to $3\frac{1}{2}$ grains, in pill form. *Antipyrine*: Dose from 75 to 90 grains, divided into three portions, one of which is to be taken every hour. *Bismuth salicylate*: Dose from 5 to 7 grains, in pill form. In typhoid this dose may be doubled and repeated every hour, up to ten or twelve times. *Canabinone*: From $\frac{2}{3}$ to $1\frac{1}{2}$ grain. Best administered mixed with finely ground roasted coffee. Sedative and hypnotic. *Colocynthin*: Used subcutaneously. The dose is from $\frac{1}{6}$ to $\frac{1}{2}$ grain. It may also be administered in pill form, by the mouth, the requisite dose being from $\frac{1}{3}$ to 1 grain. *Convallaramine*: Internally, in pill form. The dose is from $\frac{3}{4}$ to $1\frac{1}{4}$ grain. *Euonymin*: Best given in pill form, combined with extract of belladonna or hyoscyamus. The dose is from 3 to 10 grains. *Nitroglycerin* is best given in alcoholic solution. The dose is from $\frac{1}{100}$ to $\frac{1}{80}$ grain, repeated several times a day. Rossbach prefers ether as a solvent. His formula for its use is as follows: Dissolve $1\frac{1}{2}$ grain of nitroglycerin in sufficient ether, and add the solution to a mixture consisting of 2 ounces of powdered chocolate and 1 ounce of powdered gum-arabic. Mix very thoroughly and divide into 200 pastilles. Each pastille will thus contain $\frac{3}{32}$ grain of nitroglycerin. Used in angina pectoris, and as a diuretic. *Picrotoxine*: In aqueous solution. Dose from $\frac{1}{8}$ to $\frac{1}{6}$ grain. Used in epilepsy. *Sulphate of thalline* may be given dissolved in wine or water (with some corrigent). The dose is from 4 to 8 grains, or 1 grain every hour. The above is taken in part from the *Rundschau Leitmeritz*.—*Medical Record*, Oct. 30, 1886.

NITRO-GLYCERINE.—DR. L. V. HOLST reports in a St. Petersburg journal a number of observations on the action of nitro-glycerine on heart diseases. He considers that it is especially useful where little or no serious organic change in the heart muscle or valves has taken place, and where the affection is mainly due to a debilitated condition of the organ. In angina pectoris Dr. von Holst has found nitro-

glycerine very useful; in one case, indeed, it produced a permanent cure. He recommends recourse to this drug instead of to camphor and musk in cases where great cardiac weakness threatens immediate danger to life. He considers that the diuretic action is not due to any direct stimulation of the kidneys, but is a consequence of the regulation of the heart's action. He finds that dropsy, if due to heart weakness diminishes under the use of nitro-glycerine, but that the renal form is uninfluenced by it. With regard to the dose, the author advises that small quantities should be given at first, and increased gradually according to the effect on the particular case. The preparation he uses is a 1 per cent. alcoholic solution, and of this he gives from 1 to 6 drops three times a day.—*Lancet*, Oct. 9, 1886.

ADMINISTRATION OF TINCTURE OF IRON.—*Science* speaks of recent experiments with the common tonic, the tincture of the chloride of iron, diluted with water, showing that when thus diluted it acts very injuriously upon the teeth. This is explained by the fact that the peroxide formed in the alcoholic solution is precipitated, when water is present, in such a flocculent form as not to adhere to the surface of the teeth, and consequently, the free hydrochloric acid can act upon the lime salts of the teeth without let or hindrance. When the tincture is given without water, no action takes place; the peroxide which is then formed is of the anhydrous form, and so compact as to adhere to the teeth, and protect them from the action of the acid. These experiments have resulted in determining that there are three menstrua which can be used as diluents of this tincture, which will produce no injurious effects upon the teeth: they are alcohol in some form, Vichy water, and a simple syrup.—*Boston Med. and Surg. Jour.*, Nov. 11, 1886.

ANTIPYRIN IN RHEUMATISM.—DR. JOLEBIEWSKI, while attached to the military forces in Dresden, has observed the effect of antipyrin in seventy cases of rheumatism. He places its action on an equal with acid salicylic. The action was in general very prompt. The average duration of the disease in the above recorded cases was three to four days. He thinks it best to begin with large doses—60 grains night and morning. This dosage was not strictly adhered to when the patients were very weak and thin, or when there were complications with other diseases—a much smaller amount then being given.

Antipyrin proved as much a specific as salicylic acid in chronic as well as acute cases. There was no case of collapse. In only two of the seventy was there urticaria. The amount of perspiration varied extremely with different individuals. Nausea was quite often observed, especially when taken near meal times.—*Va. Med. Monthly*.—*Medical Age*, Nov. 10, 1886.

A CURE FOR NEURALGIA.—DR. HENRY G. DAVIS gives the following prescription for pure neuralgia:

Tr. cinchon. comp.....	3 ij
Tr. nucis vom.....	3 ss
Morphiæ sulph.....	gr. ij

S.—3j every three hours.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

CHICAGO, ILLINOIS.

SATURDAY, DECEMBER 4, 1886.

"HOUSE PLANTS AS SANITARY AGENTS."

A very interesting book with this title has recently appeared, from the pen of Dr. J. M. ANDERS, of Philadelphia. And we may readily admit with the author, that if it be excusable for a writer to offer a new book on a subject already treated of by many others, we may certainly excuse one who presents a branch of scientific literature which, in the form of a book, has not hitherto found an exponent. In fact, when the subject is well handled, and presented in an interesting manner, as in this book, no apology need be offered by the author for its appearance.

The first duty of a writer on this subject would necessarily be that of dispelling the old, and somewhat popular, superstition that plants in sleeping rooms are particularly unwholesome. The superstition was based upon the knowledge of the respiratory function of plants, which consists in abstracting oxygen from and returning carbonic dioxide to the atmosphere. Of course, if the exercise of this function can have any perceptible effect upon the air breathed the result must be an unwholesome atmosphere. But one has only to study the investigations of Von Pettenkofer to see that all objections on this ground to the cultivation of plants in sleeping rooms are invalid. One of the most powerful arguments to the contrary is the fact that no healthier class of men can be found than green-house workmen, even when they work at night, and sleep in the green-house. Claud Bernard pointed out some remarkable resemblances between the physiological processes of the animal and vegetable kingdoms, and his lectures before the Park Museum of Natural History have had the effect of causing a change of scientific

opinion on this subject. This view, first put forward by Mohl, that the respiratory phenomenon of plants takes the same course as in animals, so far from being antagonistic to it, has been confirmed by Coriander, and is now adopted by leading vegetable physiologists. After a series of very careful experiments Von Pettenkofer concluded that the amount of carbonic dioxide in the Winter Garden in Munich could not be reckoned as telling for or against the hygienic value of vegetation in an enclosed space; and that, so far from giving out more carbonic dioxide at night, and thus rendering the air harmful, plants really give out less of this gas than during the daytime. He also found that the amount of oxygen in the Winter Garden was rather higher than in the open air.

The absorption of moisture by plants is a matter concerning which there has been a great deal of dispute; but the most careful experiments tend to show that while plants do absorb moisture, they do so only when circumstances of absorption by the roots are unfavorable; and hence that growing, including potted, plants absorb no aqueous vapor from the atmosphere, when well watered and supplied with proper soil. On the other hand, under favorable conditions of root-moisture and soil, plants actually exhale watery vapor from all green portions. This has been shown by vegetable physiologists, and more recently and exactly by Dr. Anders, in his "Transpiration of Plants." "In clear weather, the evaporation by night as compared to that which takes place in the day appears to be about in the ratio of 1 to 5. In some cases no loss occurred on dewy or cloudy nights. Under ordinary circumstances, transpiration at night was about the same in-doors as in the open air. The true rate of transpiration during the day showed a very different relation, giving a ratio of 2 to 1 in favor of the open air." The average rate of transpiration may be stated as about one ounce and a quarter *per diem*, of twelve hours, for every square foot of leaf surface. Necessarily, the rate of transpiration varies according to the nature of the leaf. Garreau showed that there is a correspondence between the amount of water exhaled by a plant and the number of stomata in its leaves. It is to be further noted, that while heat causes evaporation from dead organic matters, light is the great agent in transpiration in living plants. Transpiration must of course have an effect upon the dew-point; and Dr. Anders found that "the effects of twenty-four square feet of leaf-surface on the air of a room ten feet long, five and a half feet wide, and eight feet high, would be to increase sufficiently the humidity to raise the dew-point six degrees

Fahrenheit—higher than it would be if there were no plants in the room." "We may justly conclude that during the summer months, when the windows are thrown widely open and the doors kept ajar, the influence of transpiration is quite inconsiderable; on the other hand, when the interchange of air is not too rapid, a sufficient number of growing plants, well watered, have the effect (if the air be not already saturated) of increasing the moisture to any desirable extent. Assuming, furthermore, that transpiration is to a much greater extent controlled by the action of the sun's rays than by the temperature range or the relative humidity of the atmosphere, then this process of nature must in clear weather, including the cold season, be more uniformly operated than evaporation from water or other sources under similar conditions."

This is a point of very great interest to the sanitarian. The temperature is affected to some degree by the amount of water in the air; moistening of the air has the effect of lowering the temperature, and thus changes in the degree of saturation cause variations in the temperature. Applying these facts to the air of our dwellings, the advantage of plant moisture would be to secure a more uniform temperature of the air of our rooms. But what is the quantity of moisture essential to good health? At the ordinary temperature of rooms, from 65° to 70° Fah., "the degree of humidity most conducive to health as well as most agreeable to the average individual is about seventy-five per cent. of saturation." But this proportion is, we may say, never found in our dwellings. It must here be remembered that the relative humidity for the same temperature may be very variable. Now, if in an atmosphere of the proper temperature and with the proper degree of humidity the body-evaporation be just what it should be, it is easily seen that much less moisture will increase the rate of exhalation beyond the health limit, the bodily temperature being lowered at the same time. Again, all artificially heated atmospheres contain far too little moisture, and exhibit marked variations; and these two factors cause excessive and variable evaporation. It may be safely said that most of the colds and inflammations of the upper air-passages are produced by improperly moistened, heated, and ventilated rooms. The most significant bearing of the question of plants in rooms is their application to apartments heated by hot-air furnaces. Dr. Anders calculates that half a dozen plants, each with a leaf-surface of six square feet, would be in a room twelve feet long and ten feet wide, with a ceiling about twelve feet high, ample to bring the hu-

midity of a chamber heated by dry air to that of the external air.

Besides the exhalation of moisture plants possess the important hygienic property of generating ozone. This property is possessed by flowering plants in general, and by odorous flowers particularly; foliage plants do not generate ozone, except scented foliage. "It is highly probable that the function demands the influence of the sun's rays, or at least good diffused light. . . . From the facts brought out by the results of scientific research, it is clearly seen that the cultivation of blooming as well as non-blooming plants giving off perfumes in marshy localities and all other places in which the air is greatly polluted by the products of decaying organic material cannot be, on account of the great energy which ozone manifests to destroy these injurious elements, too strongly recommended. It is equally clear and not less important to observe how decidedly beneficial scented foliage and flowering plants must become in the presence of all public gatherings. . . . they would be of special value in the theatre, in the crowded lecture-hall, the church." Again ozone is not detectable in living-rooms, and when it is remembered that plants generate ozone in-doors in clear weather it is easily seen that here is another way in which they may be of sanitary value; though we may not be able to assert, with the author, that the organic exhalations from the skin and lungs of the patient would be attacked and annihilated by the ozone generated by the plants.

From what has been said it is obvious that there is a place in the sick-room for flowers, and for flowering plants. Especially in cold weather, when the outer air cannot be admitted so freely, the dry air of the artificially heated rooms may be rendered humid by plants; and the value of a moist atmosphere to many cases of disease need not be more than mentioned. Further than this, the normal and æsthetic influence of plants and flowers must be taken into consideration, as this influence is of very great value. One has only to visit the magnificent *Solarium* of the New York Hospital to see that convalescents value growing plants and sunlight. The æsthetic influence of plants is especially to be seen in certain functional nervous disorders. The observations of Eyseline show that ozone has sedative and hypnotic properties, which still further widens the application of those plants and flowers which generate it. It may be objected and admitted that much of this influence would be the result of "faith" or imagination; but what signifies it whether a patient be cured by medicine or faith, so long as he is cured? Dr. Anders gives some

striking information regarding the influence of plant-cultivation on phthisis and the phthisical diathesis; and it will be remembered that an interesting case was recorded by Dr. Ely McClellan, in the *Philadelphia Medical Times*, February 26, 1881, which confirms the views expressed by Dr. Anders.

THE RATIO OF PHYSICIANS TO POPULATION.

A writer on the *Causes of Low Fees* in the November number of the *Provincial Medical Journal*, England, gives the ratio of medical men to the population in different countries as follows (quoting from *La Gazette degli Ospitali*): "France, 2.91 per 10,000; Germany, 3.1 per 10,000; Austria, 3.41 per 10,000; England, 6 per 10,000; Hungary, 6 per 10,000; Italy, 6.10 per 10,000; Switzerland, 7.06 per 10,000; United States, 13.24 per 10,000."

Substantially the same statistical comparisons have been published many times both in this country and in Europe. It will be seen that the ratio of the profession to the population is four times greater in this country than in France, Germany and Austria, and more than twice as great as in Hungary, Italy, Switzerland and Great Britain. Without further explanation, the great apparent excess of physicians in the United States, must cause the inference abroad that the profession here is so overcrowded as to place a large proportion of its members in a state of starvation. And yet it will require but a moderate amount of investigation to show that the members of the medical profession as a whole, in this country, are better paid, and are enjoying more of the substantial comforts of life, than in any one of the countries of Europe. There is doubtless an important error in the comparison of the number of actual members of the profession in this country, with the number in other countries, owing to the different modes of enumeration. The statistics of the profession in this country are derived solely from the general decennial census of the entire population, and depend for correctness entirely upon the verbal statements of individuals to the parties making the enumeration from house to house, and is likely to include all who choose to assume the title of Doctor. The ratio for the United States given above is evidently based on the returns of the census of 1880. On the other hand, in Great Britain, and we think in all the other European countries, the number of medical men taken for the comparison is limited to those legally registered after having completed a prescribed course of medical studies and numerous examinations at prescribed intervals, and received a license or degree from a

University or Royal College. Thus the ratio of six physicians to ten thousand of the population in Great Britain, is fairly deduced from the 25,998 regularly licensed physicians on the "Register" for 1886, and 36,000,000 as the total population of the British Islands. This excludes all irregular and "unregistered" persons who are actually engaged in practice, especially for the poorer classes, and of whom there are many thousand distributed throughout all parts of the Kingdom. By the laboring classes they are employed at low fees, and are freely called "Doctors." While passing a short time in England during the past summer we were assured by some of the best informed men in the profession there, that the number of apothecaries, chemists, and other irregular, unregistered parties engaged more or less in prescribing for the sick in their country was not less than 15,000 or 20,000. Their statements are strongly corroborated not only by the articles concerning the causes of low fees in the recent number of the *Provincial Journal*, but by the frequent references to the number of illegal practitioners in both the *London Lancet* and the *British Medical Journal*, by writers discussing the election of new members of the General Medical Council, etc.

Another circumstance exerting an important influence on the relations of the profession to the population, is the fact that in Great Britain, and indeed throughout the countries of Europe, a much greater proportion of the population belong to the class of indigents who pay no doctor's fees. The aggregate number provided for in the workhouses, infirmaries, hospitals, etc., supported by the Governments, is very great, while in this country the number similarly situated is relatively small. If the number of medical practitioners in each country was compared only with the population capable of paying some fees for medical services, the difference between the ratio in this and other countries would be far less.

SUICIDAL MANIA IN TYPHOID.

The occurrence of suicidal tendencies in the occasional mania of the early stage of typhoid fever is rare, and it may be interesting to know that it was present in the case of the celebrated jockey, the late Frederick Archer. Mr. J. R. Wright, his medical attendant, states that when he was first taken ill it was hoped that the illness was only temporary, and due to a chill; but two days afterwards the enteric condition was recognized, and from his previous exposures and privations there was a prospect of a long and severe attack. There was at first great mental

depression and very high fever, says the *British Medical Journal*, but, under the careful treatment and watching he received, material improvement took place, and the case seemed to be going on better than could have been hoped, when, on November 8, he was seized with one of those suicidal influences which are occasionally noted during the first week or ten days of typhoid fever. This disease is so associated in the minds, not only of the public but of the medical profession, with prostration and low muttering delirium, that the fact that acute delirium with delusions, generally of a suicidal character, sometimes comes on during the early stage, will be new to many. The delirium, indeed, may be so violent as to be mistaken for acute mania, and consultations have even been held, in some cases, to decide whether the patient should be committed to a lunatic asylum. M. Mottet has related a case where this mistake was actually made, and the patient admitted to the lunatic asylum before the true nature of his malady was recognized. Only one consolation can be offered to Mr. Archer's many friends and admirers, and that is, that these maniacal symptoms are of extremely grave moment, and that the majority of patients who present these symptoms succumb to the disease. It is improbable that, under the circumstances, the termination of the case could have been favorable.

CARE IN REPORTING CASES.—A correspondent, alluding to some cases recently published in THE JOURNAL, makes the following important suggestion:

"Articles produced in medical journals are very potent either for good or evil, especially in cases of emergency. Professional men should bear this fact in mind, and confine themselves to true statements in the description, treatment and result of cases. Whether from a desire to draw comments from others, experienced, thereby receiving valuable instructions, or from a thirst for notoriety by striking awe into the readers with the details of some wonderfully complicated case, the bold and original treatment and happy results, I know not; be that as it may, cases are frequently overdrawn and misrepresented with dire effects."

SURGEON-GENERAL OF THE U. S. ARMY.—LIEUTENANT-COLONEL JOHN MOORE, until recently Assistant Medical Purveyor, has been appointed by the President, Surgeon-General of the U. S. Army in place of Brigadier-General Robert Murray, retired on account of age. The new appointee is a native of Indiana, entered the Medical Corps in 1853, and

is consequently one of the oldest in the service. He has been constantly in active service and has made an honorable record for faithfulness and ability throughout, and brings to his new position all the experience, ability, and high character that the office requires.

DIED, November 20, 1886, DR. JOSEPH A. LANDIS, at his residence in Hollidaysburg, Pa., in the 82d year of his age. He was a physician of high standing, and greatly respected by all classes of the community. One of the founders of the Medical Society of the county in which he lived, he was also a member of the State Society and of the American Medical Association.

DIED, November 30, 1886, DR. JOHN P. GRAY, of Utica, N. Y., for many years Superintendent of the New York State Asylum for the Insane, and one of the most eminent of the alienists of our country. A more extended notice will appear hereafter.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, October 20, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

H. M. CUTTS, M.D., SECRETARY.

DR. F. C. FERNALD read a paper entitled
EMPYEMA IN AN ADULT—PLEUROTOMY—RECOVERY IN
THIRTY-FIVE DAYS.

(See page 619.) He also exhibited the *Cabot dressing* as used in the case.

DR. A. F. A. KING complimented Dr. Fernald on his paper and the success of his operation. He thought pleurotomies were not very common in Washington. He mentioned a case in which Dr. J. F. Thompson had aspirated for chronic pleurisy ten years ago. The patient but recently died of tuberculosis. On another occasion he was with the late Dr. Ashford when he failed in two attempts to find pus, on aspiration, in a liver. The patient had chronic dyspnoea and the constitutional symptoms of suppuration. Dr. Ashford, however, did not agree with Dr. King that there was an hepatic abscess. The patient died suddenly with great dyspnoea, which he thought was due to rupture of hepatic abscess into the pleural cavity. He thought that the pus in Dr. Fernald's case was also from an hepatic abscess.

DR. A. Y. P. GARNETT had had a case similar to Dr. Fernald's. It was one of empyema without any previ-

ous serous effusion. The patient was supposed by his attendant in the country to have phthisis, as there was emaciation, hectic, and expectoration of purulent matter. The right side he found filled with pus, as shown by exploratory aspiration. Assisted by Drs. Acker and Hagner, he had done thoracentesis with a large trocar, and then inserted a long drainage-tube. Thirty to forty ounces of pus came away. He thought pleurotomy more dangerous than this proceeding. No antiseptic precautions had been taken, because he did not much believe in their necessity. A silk string was passed through the tube, and this was caught with adhesive plaster. A sponge caught the discharge. The cavity he had washed out, and on first occasion it took two pints of fluid to fill it. Three days afterwards he could only get in one and one-half pints, and in two weeks only two and one-half ounces. The patient made a rapid and complete recovery and is now a farmer. This result is contradictory to Dr. Fernald's views, as he lays much stress on the use of the antiseptic dressing.

DR. R. REYBURN had had a boy of 9 years with empyema of right side. He had aspirated and removed fourteen ounces of pus. This did not stop the hectic, which reached 103° to 104.5° . The irritation still remaining in the cavity, it refilled. He did thoracentesis with trocar and inserted a drainage-tube, retained in place as Dr. Garnett's had been. Sixteen ounces of putrid material came away. He injected iodine water of the strength of 20 drops of tr. iodine to 8 ounces of water. The boy made a rapid and complete recovery without a bad symptom. This he considered due to the removal of the putrid material. He had used no antiseptics. He would just as soon now open an empyema as a common abscess.

DR. A. F. A. KING asked Dr. Fernald if the oedema of the chest walls present or a thickened pleura had made it necessary to go one and one-half inches before obtaining fluid?

DR. GARNETT said he had intended before to ask Dr. Fernald why he had chosen pleurotomy instead of thoracentesis? In his opinion, pleurotomy was admirable in a fibro-serous effusion where there were clots which would not come through a trocar. This was not a chronic lesion which is shown by definite physical signs, such as alternate areas of amphoric resonance and flatness on percussion, etc., but a simple cavity filled with pus. Pleurotomy is usually considered a much more dangerous and complex operation than thoracentesis.

DR. J. F. HARTIGAN said that the case was probably one of so-called "latent empyema" due to some dyscrasia; as, for instance, previous history of liver abscess in this case. Pleurotomy with an incision one to two inches long he thought was always the proper operation for this condition. In the East London Children's Hospital he had seen Mr. Parker do this operation several times. Here they use two large calibre tubes one inch long with a T-piece across them. The opening is made under spray and then covered with antiseptic gauze, which is renewed in forty-eight hours. In two weeks the patient is practically well. He had often made post-mortem exam-

inations on patients upon whom the trocar had been used or where there had been no surgical interference, but never where pleurotomy had been done.

DR. F. C. FERNALD, replying to Dr. Garnett, said that there were no means of knowing the exact nature of the pleural contents until an opening had been made. He thought that a long tube left in the cavity of the pleura delayed cure by keeping up suppuration; moreover, he did not consider pleurotomy at the present day dangerous. To Dr. Reyburn he would say that in this case the pus was not putrid. Dr. Reyburn's patient was a boy at an age when there is an intrinsic tendency to get well. His case was in an adult and a colored man, which race, he understood, were peculiarly liable to a fatal result from such lesions. He thought that Dr. Reyburn had used antiseptics when he used iodine water. It was probable that both the oedema on the outside and a thickened pleura prevented his getting pus before he had shoved the aspirating needle one and one-half inches. He thought that while there may be but a little better percentage of recoveries by the Cabot method of dressing, which he had used and just described, there was no method which produced such quick recoveries.

Meeting of October 27, 1886.

THE PRESIDENT IN THE CHAIR.

DR. JOHN B. HAMILTON reported a case of

TUMOR OF THE ANTRUM, COMPLICATED WITH NASAL POLYPI,

and exhibited the specimen. The patient, W. J. Storms, aged 54, born in Pennsylvania, occupation carpenter, was admitted to the Providence Hospital on May 19, 1886, and was operated upon on the 23d. The tumor completely filled the antrum, and encroached on the orbit and the nasal cavity. There were two polypi springing from the inferior turbinated bone, the right nasal cavity was filled, and the cheek was markedly deformed. The eye projected out of its socket. The tumor had been of slow growth, and entirely painless.

The operation was performed under ether. A curvilinear incision following the curve of the orbit was made at its edge, and met by a similar incision extending vertically alongside of the nose, the flap was reflected and the antrum opened, and the tumor scooped out with the sharp spoon. To my astonishment, no bony wall required removal, for on raising the flap the cavity of the antrum was opened with it; the bone being attenuated anteriorly so as to constitute the thinnest kind of shell. There was then a large opening extending entirely through the superior maxillary bone, and the finger was passed directly into the fauces. Care was taken to scrape out carefully the cavity. Prior to the commencement of the incisions, the polypi were twisted off with stout forceps.

After the operation a carbolized sponge was inserted into the cavity and the flaps closed, a bandage being applied so as to make slight compression. There was no subsequent hæmorrhage. The sponge

was removed on the next day and the flaps carefully adjusted. The wound healed without difficulty, and the patient was discharged recovered June 21, 1886.

DR. I. BERMANN said that tumors of the antrum rarely reached the size of the one exhibited, as they are usually removed when small. He thought that the tumor was a sarcoma, as this is the usual degeneration of such growths.

DR. HAMILTON said that the specimen had been in alcohol since last June, and had changed its external appearance considerably. Nasal polypi usually develop in a capsule. This was an excrescence, and had pushed forward, completely filling the antrum, even pushing the eye out of its socket. The scooping out process had also changed its macroscopical appearance. In a list of nearly 500 tumors of the antrum which he had recently seen, over 50 per cent. were carcinomatous. Sarcomata were, however, very common. There had been no return of this so far as he had learned.

DR. J. F. HARTIGAN said that at present the tumor looked like inspissated mucus.

DR. BERMANN said that when the so-called mucous polypus was punctured there comes out a thick fluid and the tumor flattens so that its appearance is greatly changed. The embryonic cells, when tumor is of slow growth, gradually transform into more solid tissue, and become fibrous with round cells, altogether unlike the original polypus. He thought that this was the case with the exhibit.

DR. HAMILTON said that it was true that mucous polypi vary with age. They are, however, practically cystic in structure, and are classed with the adenomata. When malignant they are myxomatous, or round celled sarcoma—rarely anything else. He had not examined the tumor microscopically.

The Committee on Microscopy reported that the nasal polypi were mucous, and the tumor of the antrum carcinomatous.

CHICAGO SOCIETY OF OPHTHALMOLOGY AND OTOTOLOGY.

Third Annual Meeting, October 12, 1886.

DR. F. C. HOTZ IN THE CHAIR.

BOERNE BETTMAN, M.D., SECRETARY.

The following were elected

OFFICERS FOR THE ENSUING TERM.

President—Dr. E. Holmes.

Vice-President—Dr. Lyman Ware.

Secretary and Treasurer—Dr. Boerne Bettmann.

DR. F. C. HOTZ read a paper entitled

THE RATIONAL TREATMENT OF PATIENTS AFTER CATARACT OPERATIONS.

Though the safety of the eye is of prime importance, we must, in our anxiety for the recovery of this organ, not entirely disregard the comfort of the patient; for we have no right to deprive our patients of any comfort which does not disturb the healing

process. The usual treatment after cataract operations is anything but pleasant to the patient, and many dread the confinement to bed and dark room worse than the operation itself. If it can be shown that such measures are superfluous, they should be abandoned.

When a wound is carefully cleansed and disinfected, and its edges are nicely approximated, it will heal by first union, provided the close adaptation of its edges is not disturbed by external violence or by muscular tractions. Rest of the wounded part is the first condition for kind healing. But to rest the eye ball it is not necessary to put the patient to bed; we can secure the necessary rest for the operated eye, *i. e.*, we suspend the functions of the ocular muscles and immobilize the eyelids, by bandaging *both* eyes. As long as they are closed they remain comparatively motionless. The bandage over both eyes accomplishes this result just as well whether the patient is in bed or sitting in a chair. The confinement to bed, therefore, is irrational; and the recumbent posture is not only of no advantage, but may even disturb the flow of blood to the head; consequently congestion of the ocular tissues is more likely to occur in the recumbent posture than when the patient is sitting up.

The uselessness of darkening the room will be apparent to every one who will bandage his own eyes just in the same manner as we dress the eyes after cataract operations. The bandage shuts off the light so thoroughly that he will be unable to tell whether the room is light or dark. To the patient it is immaterial; but to his attendant it is a great comfort to have light in the room.

In regard to the dressing there is a difference of opinion, the majority of oculists employing the pads and bandage; some closing the eyelids only by strips of plaster, and others discarding all dressings.

If we dispense with the dark room we can not leave the eyes without dressing, because the winking of the eyelids and the constant relations of the eyeball would disturb the wound and cause a good deal of irritation. The plaster strips overcome this difficulty, but they do not give the eye any protection against mechanical insults which might cause a reopening of the freshly united wound. The bandage with padding of absorbent cotton, or any other soft material, secures to the eye rest and protection against accidents, and is therefore to be recommended as the most rational dressing. The flannel roller is open to the objection of being easily disarranged by the movements of the head on the pillow; but a roller of mosquito netting or Swiss gauze, applied wet, forms, when dry, an immobile bandage which does not become loose, and keeps nicely adjusted for any desired length of time.

The sensitiveness of the operated eye to bright light is not due to the bandage; it varies greatly in different persons; some even do not show it at all. When it exists, it only shows that the eye has not completely recovered from the effects of the operation, though the external wound may appear well healed. With the eyes well bandaged my patients are sitting in easy or rocking chairs, in light rooms,

and are even allowed to take an exercising walk in their rooms; they go to bed when they please and get up whenever they like. I have never observed any complication of accident which could directly or indirectly be attributed to this mode of treatment. The recovery was as rapid and the results as good as under the old fashioned régime.

SUFFOLK DISTRICT MEDICAL SOCIETY.

SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

Stated Meeting, October 13, 1886.

DR. V. Y. BOWDITCH IN THE CHAIR.

ALBERT N. BLODGETT, M.D., SECRETARY.

PROF. T. W. SEDGWICK read a paper on

THE FILTRATION OF POTABLE WATERS, WITH REFERENCE TO THE ELIMINATION OF ORGANIC GERMS.

Drinking water is seldom or never free from organic matter. A good quality of deep-well water is probably as free as any other from it, and yet Frankland, by the method of biological examination (gelatine plate-cultures), found rarely more than ten microbes in one cubic centimetre of such water. The same quantity of water taken from the Thames at Hampton contained about one thousand microbes. We shall probably not be far wrong in supposing the same to be true of drinking waters generally. All contain more or less of organic matter, if not when first taken from the well or spring, certainly before they enter the mouth. Some of this matter is living, in the shape of bacteria, infusoria, diatoms, etc., and some is lifeless, being either dissolved or suspended. The entire quantity, however, in what is ordinarily called wholesome drinking water—namely, that from springs, wells, rivers, etc.—is a very small percentage of the total volume of liquid. These waters are by no means necessarily to be condemned on that account, but are still to be regarded as perfectly wholesome.

There is, nevertheless, a *possibility* of danger in this organic matter, and hence the water supply of a community must always be closely watched, and, if necessary, rarely, in times of epidemics, perhaps even abandoned altogether for a while. But this possibility, once recognized and constantly kept in mind, need not cause great anxiety.

We cannot easily get rid of all the organic matters in drinking water, nor is this necessary, except from a theoretical point of view. Most of the microbes present are perfectly harmless, and if all were removed, there would still be abundant opportunities for introducing them into the body through other channels.

There are, however, two ways in which organic matters in drinking waters may be rendered harmless: 1, by removal (filtration); 2, by killing (heat). The latter is an easy, but not a sure method, since the spores of some microbes endure even prolonged boiling. Boiling is, however, a useful, simple, and

inexpensive, though rough and imperfect method of protection. Filtration, formerly a mere straining, has, of late, aspired to *sterilize*, that is, to remove from the water all its living substances, however infinitesimal. In this event the filtrate must be perfectly safe for drinking purposes, even the *possibility* of danger having been removed. Most filters do not claim such perfection, and most which do, fail to reach it. The "Chamberland" filter is said to sterilize, and the micro-membrane filter invented by Breyer, of Munich, is claimed to do the same. [The speaker then exhibited a micro-membrane filtering apparatus imported by Prof. Nichols. An ultra-marine mixture (in water), a fluid which filters with great difficulty, was shown to be perfectly separated by the apparatus.] The essential part of this is a filtering surface of finely divided asbestos. This is made by grinding the mineral in water, then mixing it with crystallized carbonate of calcium, grinding again thoroughly, and adding hydrochloric acid. The sharp edges of the crystallized carbonate seem to penetrate the asbestos, splitting it up—a process which is carried further by the escaping bubbles of carbon dioxide. In this way, fibres of extraordinary fineness are obtained, and, by other steps, made into filtering sheets or "lamels," which are easily arranged for filtration. Prof. Nichols had made some experiments with the filter, but was not convinced that it would sterilize, although he granted its great perfection.

He closed by affirming his full agreement with Prof. Nichols in the following statements taken from a paper by the latter, upon the micro-membrane filter, read before the Society of Arts in April, 1886: "Personally, I am quite content with the efficacy of the filter, and I think, in its larger forms, with attached reservoir, it may serve a good purpose. Of course in this country, these small filters, which take an hour to filter a quart of water, would be quite useless. No one will wait fifteen minutes for a glass of water to filter through; he would rather take his chances for a few more microbes. I do not lay so very much stress upon this matter of "germs" in the present connection. First, because there is no proof that the number of microbes bears any direct relation to the wholesomeness of the water; second, because a water furnished or used for domestic supply ought not to contain *dangerous* organisms requiring removal; third, because, even if it were possible to obtain a germ-free water by carefully sterilizing the whole apparatus, and receiving the filtered water in sterilized vessels, such water would not be obtained in the ordinary use of the apparatus."

DR. S. W. ABBOT, of the Massachusetts State Board of Health, said: There are two things to be borne in mind in the study of filtration of water; one relates to the well-being of the consumer, and is of use only as it modifies the actual condition of the water; while the other relates to the financial success of the company manufacturing the filter. Filters as now made are all more or less defective, and accomplish the objects for which they are manufactured with more or less completeness. If we could have a filter which would adequately protect the consumer of the

water against the contamination which may, and too frequently does, exist in drinking water, we should have a good thing. A filter is a thing which is the subject of many erroneous ideas on the part of the public. All filters containing charcoal, silica, etc., will remove a certain amount of dirt from the water, and the popular idea seems to be that thereby they actually protect the public from the effects of contaminated water. This is a positive mistake, but many people are firmly persuaded that filtration transforms an injurious water-supply to a wholesome one. We cannot put reliance upon any appliance for the mechanical purification of drinking water until it is proved to do more than any filter is now doing. In regard to the micro-membrane filter, it must be remembered that this is a new instrument, and it might not do so good work after a certain period of use as it now does. If it could be enlarged, it would seem to offer the promise of a really good and serviceable filter. It looks as if it might exclude bacteria. If any form of filter could be devised which might be applied to the water at its source of supply, instead of at the end of the service, it would be a vast improvement over any present system.

DR. J. G. BLAKE said that the subject of filters is a broad one, and much misapprehension doubtless exists upon their design and usefulness. A filter is no more than a strainer, and will do the mechanical work of a more or less perfect strainer, and that is about all it will do. The ordinary filter is much too small for useful service, and can do only imperfectly the duty of separating the extraneous matters in water, as is usually seen in the action of most filters. The amount of filtering material is ordinarily far too small to properly strain out the foreign substances or to furnish even an approximately pure water. If the micro-membrane filter can be made practicable and constructed cheaply it would seem to be a good thing.

MR. DESMOND FITZGERALD, of the Cochituate Water Board, said that the whole question of the filtration of water will resolve itself into two propositions. First, does it pay? Second, can the various impurities in water be removed by this means? Can filtration remove the color from impure water? Can it abstract the albumenoid ammonia and other chemical contaminations? Until a filter can be produced which shall answer these demands, this appliance will not come into general use. With respect to the micro-membrane filter, the question to be asked is, will it clog? will it remove chlorine? will it still continue to remove these impurities after a period more or less long of active service? At present all forms of domestic filters are simply strainers. We have not arrived at perfection in the manner of distribution of water-supply, and are farther still from the practicable and reliable means of its purification. Filtration to be most effective should be conducted in such a manner that the water may pass slowly through the filtering medium, and thus allow the detention of deleterious matters. Rapid filtration is not in accordance with the principles of perfect separation of impurities.

In answer to Dr. Blake, Mr. Fitzgerald said that the cost of filtration of water on a large scale would

not probably be so large as to interfere with its practicability, if a useful method could be devised.

PROF. GEO. F. SWAIN, of the Massachusetts Institute of Technology, said: It is not necessary to remove all the germs from the drinking water, even if this were possible. The place for the removal of organic matter is not at the delivery of the water in the house of the consumer, but it is at the source. The dirt in the state of mechanical suspension can be removed by a simple filter at the point where the water is drawn for use. In regard to filtration on a large scale, it is simply straining, and not filtration in any proper sense of the word. Prof. Swain then described the Diamond Filter, for the purification of water for domestic purposes, as follows: This filter is intended to be attached directly to the supply-pipe, taking the place of a faucet, and it consists of a cast-iron enamelled cylinder, to which a top is screwed, the water entering at the bottom and passing out at the top. The filtering material consists of two layers of quartz sand with an intermediate layer of bone charcoal, closely packed between two brass gratings, to which are soldered screens of fine brass wire. The area of cross-section of the filter being very much larger than that of the inlet pipe, the velocity of the water through the filtering medium is very much reduced, and the coarser particles settle below the lower grating or are caught on the wire screen, while the finer ones are intercepted by the lower layer of quartz, very little even reaching the charcoal, which therefore needs renewal but seldom.

The principal peculiarity of the filter lies in the method of cleansing. It is divided internally by a vertical solid partition, and at the inlet a four-way cock is placed. The two upper openings are inlets, and the two lower ones outlets, leading to the discharge-pipe just below the inlet; the inlet and outlet on the right being connected with the right-hand half, and those on the left with the left-hand half of the filter. In ordinary working both inlets are open and both outlets closed, the water entering on both sides and ascending through the whole body of the filter; but if the filter is to be cleansed the outlet valve or cock is closed, and the far-away cock is turned so that the left-hand (upper) inlet, and the right-hand (lower) outlet are closed, the water passing in at the right, up through the right-hand half, down through the left-hand half, and out through the outlet, thus cleansing the left-hand half with *filtered water*, a point upon which the inventor lays great stress. By turning the four-way cock so that the right-hand inlet and left-hand outlet are closed, the course of the water may be reversed, and the right-hand compartment cleansed. Finally, if the water contains such finely divided particles as to be but imperfectly filtered in the ordinary manner, the usual outlet valve may be closed and the water drawn from the lower discharge, after having been made to pass up and down through the filter. The filtering material is renewed by unscrewing and removing the top. The ordinary sizes of this filter, which is made by John G. Avery, in Spencer, Mass., are: No. 1, 4 in. diam., 6 in. high, 4 in. of filtering material, price

\$10; No. 2, 6 in. diam., 8 in. high, 6 in. of filtering material, price \$15; No. 3, 12 in. diam., 15 in. high, 11 in. of filtering material, price \$35. Very much larger sizes, however, have been made in special cases.

DR. HENRY J. BARNES spoke at some length of the desirability of securing the utmost degree of cleanliness in the fluid we use as a drink, and continued as follows: 'The desirability of filtering the water-supply of Boston has been greatly diminished, through the influence of the members of this and the parent Medical Society, exercised chiefly through the valuable services of Dr. John G. Blake, a member of "The Commission of Investigation," since which the storage basins on the Sudbury River have been relieved of a large amount of vegetable mould, the decay and disintegration of which loaded the water with a great volume of organic matter. There has been little to complain of in the character of this water. At the present time these storage reservoirs are practically in the condition of "natural ponds," polluted to a greater or less extent by organic matter both animal and vegetable, dead and alive, washed into the basins with every rainstorm of magnitude, beside no inconsiderable amount of sewage which the praiseworthy efforts of the Water Board and engineer have failed to exclude. Nature strives, and in a manner succeeds, in neutralizing this baneful influence by inhabiting the water with living organisms which devour the dead, prey upon the living, and transform organic into inorganic matter. Insects, fishes, mollusks, crustaceans, diatoms, and other species of animalcules, each and all contribute to this end. And it is therefore undesirable, even if possible, to defertilize it at this point.

The bacteria of putrefaction, consuming oxygen, convert nitrogenous matter into plant-food. Vegetation inhaling carbonic acid and exhaling oxygen, renders it possible for animal life to exist. The algæ selecting food from elements set free by decomposition, the spongella subsisting upon animalcules and the spores of the algæ, are but steps which, if properly balanced, contribute towards purification. The balancing of these organisms, the ideal condition of a water-supply, is not to be hoped for where so many factors interfere with harmony. Unconsumed animal and vegetable material, with the coagula of imperfectly decomposed soluble matter, finds its way into the service pipes, for which we have no means of elimination except by filtration. It is here shown by the working of these filters to be considerable, and I do not believe its consumption conducive to the best hygiene. Nature strains it all out in converting surface into spring water. If we can imitate her by artificial devices it is certainly desirable, and it does seem as if many of these machines do excellent service in this direction. While advocating their use, then, for the Sudbury and Cochituate service, I should deprecate the establishment of the notion that any are capable of freeing water from those noxious elements which go to make up six-sevenths of the pollution where sewage is discharged. The dissolved nitrogenous matter in urine, the almost completely soluble faecal discharge, must of necessity pass through

any mechanical obstruction the mesh of which is capable of transmitting the liquid vehicle. For this reason, water contaminated as in our Mystic supply, with human excreta, washings from tanneries, currying shops, glue-factories, piggeries, etc., cannot be materially benefited by any of these appliances. By chemical treatment, a portion of the soluble matter can be precipitated, but of the great variety of methods employed, but few produce an effluent from sewage which should be discharged even into water not used for domestic purposes. One of the simplest and best plans for this purpose is employed at Stroud, England, and known as the "Bird Process." Impure sulphate of alumina and sulphuric acid are the agents. The acid is added to powdered clay a few days before it is used, from a hopper regulating the discharge, into a current of sewage which goes to the first reservoir of deposit. From this receptacle it runs under another hopper discharging clay mixed with sulphuric acid to a second reservoir, and from thence over three lays of filtering coke. Analysis of the influent and effluent water shows in parts per 100,000 in weight, the water before treatment to contain 53.5 soluble and insoluble matter; after, 48.5.

	Before.	After.
Organic carbon.....	2.289	2.203
Nitrogenous matter.....	2.859	1.779
Ammonia.....	6.000	5.000
Nitrogenous matter in combination.....	7.800	5.887
Matter in suspension, mineral and organic.....	43.000	4.008

This result, though obviously good, cannot be considered satisfactory epuration for domestic purposes. Clay will promote decomposition of nitrogenous matter when brought in contact with the lime it contains, and the alum will cause a precipitation. But this has proved an unsatisfactory method in the treatment of sewage at Tottenham, although complete clarification was secured before discharging in the river Lea. A flocculent deposit collected on the bed of the river of highly putrescible character.

It is obviously impossible to treat potable water with clay even if a more satisfactory result could be attained. The more complicated methods of chemical treatment, such as Hille's, Goodall's, Holden's, Campbell's, and Scott's processes, the A. B. C. process of Sillar, the lime and chloride of iron treatment, afford little assurance of successful epuration, and many of the agents employed would be objectionable in a water-supply. Dr. Frankland wrote a few years ago: "The actual resources of chemistry do not permit the hope that the dissolved impurities in sewage can be precipitated by any appliance of chemical reaction, and unless new chemical laws are discovered, it is useless to attempt the employment of this agency."

Soil purification, though capable of transforming sewage into potable water, opens up a subject beyond the limits set for consideration this evening, and it is not applicable to the purification of water in open sewage basins, except so far as filter galleries will eliminate a certain amount of material in suspension.

DR. HAROLD C. ERNST said that he desired to protest against the view apparently advanced by Prof. Sedgwick, that the indiscriminate and unin-

dered swallowing of bacteria in any and all forms is harmless, not to say wholesome. No person who has ever witnessed the results of the ingestion of the germs of cholera, either in the way of an epidemical outbreak of that disease, or as a means of research in experimental pathology, could entertain such an idea for a moment. The sterilization of water by filtration has been tried in a very thorough manner in the laboratory of Prof. Koch in Berlin. Many different kinds of filters were employed, and the resulting filtrate was tested as to its freedom from germs by means of culture-plates. None of the common forms of filter were found to be bacteria-proof. Only one was found which was capable of arresting the germ contents of water. This was the filter devised by Chambourland, in Prof. Pasteur's laboratory. In most of the filters it was observed that the germs grew rapidly in the filter, and soon penetrated the wall of the filter by direct growth from the other side, and thus appeared in the filtrate in large numbers.

PROF. SEDGWICK stated that he by no means wished to be understood as believing that it was safe or prudent to employ polluted water for domestic purposes. He said that there was no doubt, on the other hand, that a vast number of germs were taken into the human organism every day, and there is usually no serious result from their ingestion. Of course there are microscopic germs, which are harmful or even destructive to the animal body, and these can never be taken except on peril of great disturbance to the functions of the body, but there are also a vast number of germs which may be and are taken into the body without perceptible detriment.

DOMESTIC CORRESPONDENCE

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

New York State Medical Association—Pulmonary Tuberculosis—Puerperal Eclampsia—Officers.

The discussion on "Pulmonary Tuberculosis" on the second day of the meeting of the New York State Medical Association, was of very great interest. It was opened by Dr. Henry D. Didama, of Syracuse, who in his usual attractive style gave an exposition of his well-known views in regard to the causes, prevention and treatment of the disease. The first division of the subject considered was its etiological factors. The *inherited* were discussed by Dr. John Cronyn, of Buffalo, the *acquired* (micro-organisms) by Dr. Herman M. Biggs, of New York, and the *predisposing* by Dr. Henry L. Elsner, of Syracuse. One of the questions handled by the latter was: Is there not satisfactory evidence that some cases of pulmonary consumption are non-tubercular at the start, and that other cases remain free from tubercles throughout their course? and the speaker expressed his positive conviction that there is such a thing as non-tubercular consumption.

The second division was the matter of prophylaxis, and this was discussed by Dr. Wm. H. Flint, of New

York. He spoke of the necessity of removing the children of tuberculous parents from their homes during the period of infancy, and longer in certain cases, and of preventing the association of individuals with cellular impairment with the subjects of tuberculosis. He also advocated the regular disinfection of the sputa and dejections of tuberculous patients. One of the subjects discussed by him was: How can the medical profession most widely diffuse and inculcate the important truth that consumption in children is often the result of parental faults and vices? and he thought that this could only be done by conscientious individual efforts by the members of the profession. The third division, treatment, was discussed by Dr. John Shrady, who in the course of his remarks gave an interesting *résumé* of what had up to the present time been accomplished in the way of local antiseptic therapeutics, including some important experiments lately made by Dr. L. J. McNamara, of the Carnegie Laboratory, which have not as yet been published. While not expressing a positive opinion as to the value of such measures, it seemed to him probable that further investigations would establish their utility, in conjunction with the constitutional and hygienic treatment now generally recognized as appropriate in pulmonary consumption.

On the third day of the meeting there was a general discussion on "Puerperal Eclampsia," and it was opened by Dr. Wm. T. Lusk, of New York, in a paper eminently worthy of his reputation. Dr. James Tyson, of Philadelphia, who, like the gentlemen from a distance who took part in the discussion on laparotomy, came on by special invitation for the purpose of lending additional interest to the proceedings, discussed, in his learned and forcible manner, the connection between uræmia and the eclamptic attack. The questions, Should labor be induced in case of the occurrence of eclampsia during pregnancy? and under what circumstances, in case of threatened eclampsia, shall premature labor be induced as a prophylactic measure? were discussed by Drs. Isaac E. Taylor and T. Gaillard Thomas, of New York.

Dr. Thomas said he thought that the following points would be accepted, as resting even now upon a substantial and enduring basis: 1. That as we have a form of renal disease entitled desquamative nephritis, due to certain causes about which pathologists are pretty well agreed, and another entitled scarlatinous nephritis, due to the blood poisoning of scarlet fever; so have we still a third which should be entitled puerperal nephritis, which commonly attends upon and is undoubtedly due to the condition of utero-gestation. 2. That puerperal nephritis is the great, if not the sole, cause of puerperal eclampsia. 3. That puerperal nephritis accomplishes this result by leaving the blood surcharged with certain noxious elements which the crippled condition of the kidneys causes them to fail to eliminate. 4. That while we are ignorant of the method by which the puerperium induces this form of nephritis, we have abundant evidence of the fact that so soon as utero gestation ceases to progress, the renal trouble, as a rule, diminishes, and soon disappears.

Dr. Thomas said that in all his extended experience he has seen but two cases in which puerperal convulsions were unattended by the unquestionable evidences of renal disease. In both these cases, after the immediate eclamptic seizures had disappeared, albumen in large amount was found present in the urine. He related an interesting case illustrating the point of the disappearance of the renal trouble as soon as pregnancy ceases to progress. He unhesitatingly and in the strongest possible manner advised the induction of premature labor in eclampsia occurring at the sixth, seventh or eighth month of pregnancy, as he had found by long experience that any other course was attended with great danger and was in every way unsatisfactory. He explained, however, that he did not by any means maintain that when a patient is rigid with puerperal convulsions labor should always be immediately brought on. In many cases in which the seizures yielded to appropriate remedies it was wise not immediately to excite the nervous system by the establishment of parturition; but to wait for two, three or four days, until the morbid chain was broken which had registered itself upon the nervous system. It was not such judicious delay as this that he was opposed to; but to that delay which for weeks and months exposed the patient to a reestablishment of all the morbid elements necessary to eclampsia, to the development of which she had already shown herself prone. Under these circumstances parents who were anxious for offspring would often oppose the establishment of premature labor, under the idea that delay would secure for the child a greater chance of life. If the process of gestation had advanced beyond the seventh month, so far from this being the case, the chances of life for the child were much enhanced by interference.

There were three circumstances, and three alone, he went on to say, which would prompt a different line of action from that which he had advocated: 1, the fact that the convulsions were due to some direct and certainly ascertainable irritant influence susceptible of removal by emesis, catharsis, or some similar method; 2, that they were of purely hysterical character, or partook of the form of true epilepsy, to which the patient had long been subject. Under these circumstances the seizures would depend upon no condition which was likely to prove cumulative from the prolongation of utero-gestation. Besides this, it was to be borne in mind that these seizures would not come into the category which was now being considered. 3. If it should be ascertained that the child had lost its life during the existence of maternal convulsions, and the seizures were controlled by treatment, he should, from his own experience, be willing to leave the case to nature, confident that the ending of the progress of gestation would remove all danger for the future, even although a dead child with its secundines still occupied the uterine cavity.

In answer to the query, Under what circumstances, in case of threatened eclampsia, should premature labor be induced as a prophylactic measure? he said: 1. Every obstetrician mindful of his duty will invariably, after the third month of pregnancy, examine the

urine up to the full term, at least as often as every ten or fourteen days. 2. If evidences of puerperal nephritis demonstrate their existence before the end of the seventh month, the period of foetal viability, every effort should be made by daily warm baths, the milk diet, laxatives, and the nightly use of the bromides, to "tide the case over" until that period has been reached. 3. If the amount of albumen, tube-casts and epithelium be plentiful in the urine; if the secretion of urine be scanty; the patient complain of headache, dimness of vision, and decided gastric disturbances, and all these symptoms did not at once diminish under the prophylactic measures already mentioned, we should not hesitate to bring on premature delivery at once. 4. Should the patient have passed through several pregnancies with safety, having at the same time presented the symptoms of puerperal nephritis; should the amount of albumen be moderate, and the secretion free, with a good proportion of solid elements in it; should the evidences of constitutional disturbance be slight, and the effects of prophylactic measures satisfactory, it would not be advisable to induce premature labor, but would be better to await the full term of gestation. "But," said Dr. Thomas, "I should await it as a soldier waits who 'lies upon his arms,' watchful and wary, ready at a moment's notice to meet an issue which threatens night and day."

The third question, What are the most reliable therapeutic agents for the control of the convulsions, and should bleeding be employed in eclampsia? was discussed by Dr. Darwin Colvin, of Wayne County, who strongly advocated bleeding, and Dr. George T. Harrison, of New York, who as strenuously opposed it. After the discussion of the fourth question, In what proportion do the insane in public asylums owe their insanity to puerperal convulsions? by Drs. J. R. MacGregor, of New York, and G. A. Blumer, of the State Lunatic Asylum at Utica, a general discussion of puerperal convulsions and their treatment was participated in by the Association at large.

The following officers were elected: *President*, Dr. Isaac E. Taylor, of New York; *Vice-Presidents*: First District, Dr. L. C. Dodge, of Rouse's Point; Second District, Dr. J. D. Sherer, of Watford; Third District, Dr. G. W. Avery, of Norwich; Fourth District, Dr. Darwin Colvin, of Clyde. The offices of Recording and Corresponding Secretary were united, and Dr. E. D. Ferguson, of Troy, elected to the position. Dr. J. H. Hinton, of New York, was elected Treasurer, and Dr. J. W. S. Gouley was made Director of the Library.

On the first night of the session an interesting and instructive entertainment was held at the Carnegie Laboratory, when Dr. E. G. Janeway gave a demonstration of projections on the screen of representations of Friedlander's pneumo-coccus, the bacilli of cholera, tuberculosis, anthrax and typhoid fever, and other microbes; after which a large number of microscopical preparations and cultures of the various pathogenic micro-organisms were exhibited by Dr. H. M. Biggs. As previously mentioned, the whole session was wound up very satisfactorily with a *conversazione* and supper.

INHALATIONS OF COCAINE IN WHOOPING-COUGH.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—In THE JOURNAL of October 9, page 403, Dr. A. Y. P. Garnett has an article on the treatment of whooping-cough by inhalations of muriate of cocaine, in which he says: "In order to procure it in a form sufficiently volatile to be readily vaporized, I selected chloroform as the solvent. A 6 per cent. solution of muriate of cocaine in chloroform was prepared, and 10 minims poured in a wineglass, made warm by tepid water, was placed under the patient's mouth, whilst the mother was instructed to keep the nostrils closed. . . . It was found by this means many of the paroxysms were arrested or materially cut short," etc.

In reading the paper, the thought at once occurred to me that the relief was derived from the chloroform, the vapors of which passed off, leaving the cocaine. At my request Mr. James Kennedy, Ph.G., investigated the matter and handed me the following as the result:

"Cocaine hydrochlorate does not volatilize at the temperature of the water bath, nor does it rise with the vapor of its chloroformic solution. A 6 per cent. solution of cocaine in chloroform, evaporated to dryness on water bath, yielded as a residue the entire quantity of the salt." T. J. TYNER, M.D.

San Antonio, Texas, Nov. 22, 1886.

BOOK REVIEWS.

Two Comedies: AN ILL WIND; AN ABJECT APOLOGY. By F. DONALDSON, JR. 12mo., pp. 79, parchment, Boston: Cupples, Upham & Co. 1887. Chicago: A. C. McClurg & Co.

Even medical men, matter of fact as most of them are, must sometimes indulge in recreation; and when it is such that amusement or recreation is furnished for their confrères it must be all the more pleasant to them. And really, a non-professional book by a physician has a more than common interest for other (reading) medical men. We may often judge a man very much by his avocation, as by his vocation.

Strictly speaking, however, Dr. Donaldson's two comedies may be said to be the records of some cases of aggravated heart disease, of that peculiar form which affects persons between the ages of 18 and—100 (which we believe to be the limit). In all, five cases are recorded, with three complete recoveries. It is only fair to say that the two cases which are not reported as cured passed from observation. It is a matter of interest that three of the five cases were females, as it is the general opinion that this affection is more common among males. Perhaps it is not best to speak of "recovery" in these cases. The worst cases of the disease cause melancholia of various forms, and the affection may be classified under the general term *philomania*; and this may be subdivided into *gynecomania*, which only affects males, and *andromania*, which is peculiar

to females. While this philomania may often cause great depression of spirits, it is very rarely fatal, unless we include the unauthenticated cases reported by writers of fiction. In the majority of cases the disease runs an irregular course, and may be cured of its worst features by self limitation or by what may be called compensatory cardiac reciprocity. *Philomania acuta* is the less dangerous form of the disease, and is generally of an intermittent type. In the chronic form the unhappy patient may be brought to the verge of idiocy. There is good ground for holding that the disease is often contagious.

As readers we welcome Dr. Donaldson's appearance in that portion of the literary world which we, as medical men, can visit but too seldom. The every day life of some of us is so full of tragedy that his "Two Comedies" are welcome guests.

TRANSACTIONS OF THE TEXAS STATE MEDICAL ASSOCIATION. Eighteenth Annual Session, held at Dallas, Texas, April 27, 28, 29 and 30. 1886. 8vo, pp. 691. Austin; 1886.

The Texas State Medical Association may well be proud of its last volume of Transactions. Some improvements might be easily made in its arrangement. For example, it is difficult to understand why all the papers should be attached as an appendix, and why the publication committee did not do a little more editing. Again, should this volume go abroad some of our European colleagues will wonder why certain French and German names are not spelled correctly. The names of several of our valued contemporaries have also been well disguised in some places. There is another point to which we desire to call attention. One member of the Association reports a case of what seems to have been chronic catarrhal gastritis with some unusual symptoms. It is reported as "A Remarkable Case in my Practice." The first thing to do in writing an article is to give it a proper and descriptive title. We call attention to this now because it is a fault of so many writers to make a title which is descriptive of anything from a ruptured perineum to hay fever. "Cases from Practice" is an abomination which is too frequently seen. The title of a paper should be indexical of the whole paper. All writers may not know this, but a publication committee is supposed to know it.

For all this, however, the volume under consideration is one upon which the members of the Texas Association may congratulate themselves. It is very handsome, and well printed on excellent paper. It contains some good articles, which would be all the better if they were properly indexed. Six hundred and ninety-one pages of book is a good deal to send out without an index. One of the best papers in the volume is on "Boracic Acid in Surgery and Gynecology," by Dr. C. M. Ramsdell, of Lampasas, which will repay careful reading. Dr. O. L. Williams, of Chapel Hill, reports two cases in which electricity acted well in congestive fever (pernicious malarial?). Dr. Q. C. Smith, of Austin, in an interesting paper on the "Treatment of Sporadic Dysenteries," very properly condemns opium, mercury and starvation. Dr. T. C. Osborn, of Cleburne, calls attention to the

usefulness of bimuriate of quinine with urea generally, and particularly in a case of pneumonia. Dr. J. R. Briggs, of Fort Worth, calls attention to the value of *lycopus Virginicus* (bugle weed) in the bites and stings of insects and reptiles. This plant seems worthy of a closer examination than has been given to its physiological action. A valuable contribution to the subject of malaria may be found in a paper by Dr. Henry K. Leake, on "Malarial Irritation of the Bladder in the Female." Those who may be inclined to doubt the wisdom of conservative treatment in gun-shot fracture of the femur would do well to read the report of four cases, all of which recovered, by Dr. J. T. Field, of Fort Worth. Dr. J. G. O'Brien, of Dublin, reports a case of extraction, by tracheo-laryngotomy, of a watermelon seed from the air passages of a child 12 months old, with recovery. Dr. B. F. Brittain, of Jacksonville, records a very curious case of necrosis of the lower maxilla, which began with toothache. The necrosed portion was removed, with a good result. Dr. M. C. Farrar, of Fort Worth, reports a case of amputation of both legs, with recovery, and death subsequently from abscess of the pancreas. Dr. O. Eastland, of Wichita Falls, reports a case of dislocation of the long head of the biceps, which was reduced spontaneously on the fourth day, after ineffectual efforts by the method of Prince. The Prize of the Association was awarded to Dr. J. R. Briggs, of Fort Worth, for a paper on "Physical and Mental Culture," which we hope to notice soon in another department.

MISCELLANEOUS.

INFLUENCE OF MUSIC ON THE SYSTEM.—It has long been a familiar fact that susceptible, or perhaps we ought to say very impressionable, nervous centres, either of brain or cord, or both, may be influenced by music. Whether the influence exerted is not purely physical—perhaps mechanical—and of the nature of vibratory movement of a nature akin to that exemplified by the phenomena of sensitive and musical flames, and obeying the laws of concord or discord, which Newton demonstrated to determining the chromatic and diatonic scales respectively, which Grove further illustrated in the indication of his doctrine of the correlation of forces, and which Tyndall has reduced to practice—may be a moot question, but we cannot doubt that it will sooner or later be settled in the affirmative. However that may be, the fact remains that music does act powerfully on the majority of nervous systems, and there is reason to think that the brain is not alone affected. For example, the movements of the lower limbs both in dancing and marching are distinctly influenced by music independently of the consciousness. When the brain at first participates in the excitement produced, it may become engrossed with other matters, and rhythmical muscular movements of the extremities, and in a lesser degree of the trunk, will be continued automatically in harmony with the music. Direct impressions on the cerebral centres are prob-

ably transmitted through the auditory centre. Thus monotonous and slow music will exert a calming influence, provided that it be not too slow to be in harmony with the nerve habit of the individual, as in that case it may irritate. It is also essential to the success of any endeavor to bring the brain under the control of music, that it should first arrest the attention either by its power or sweetness, and then gradually conduct the organism into harmony with itself. A measured cadence of the sort likely to calm the mind is more likely to augment than to allay irritation, unless it begin with a powerful appeal to the brain in a key which accords with that in which the cerebrum is at the moment itself working. This has not perhaps been sufficiently well understood in some attempts which have been made experimentally to use music as a remedial measure. So with endeavors to rouse the spirits by music, the opening needs to be plaintive, and in the key of melancholy which harmonizes with the brain state of the patient. The attention being arrested and the cerebrum reached through the auditory centre, the key must be gradually changed, and the time quickened in such a manner as to change the brain state. No great progress will be made with the employment of sound, and form, and color, as remedial agents, powerful as these agents really are, until we dismiss the unscientific idea of "mind," and begin to regard the brain as an organ which, like all other parts of the body, obeys physical laws and performs its function by purely physical processes.—*American Musician*, Nov. 27, 1886.

DR. SHAKESPEARE'S RECENT INVESTIGATION UPON CHOLERA.—On the 18th instant a special meeting of the College of Physicians of this city was held in order to hear a lecture upon Cholera by Dr. E. O. Shakespeare, who has recently returned from a tour of investigation by special appointment of the United States government. During his stay abroad he made personal visits to those whose labors have rendered them distinguished in this field; not only in several countries in Europe, but also in India. In commencing his review of his work, at the College, Dr. Shakespeare gave brief accounts of recent epidemics of cholera in the different countries where it had been studied, and illustrated his remarks by diagrams of morbidity and mortality. The connection between the outbreaks of the disease and infected water-supply was clearly shown in nearly every instance.

Although the proof of the statement that the comma-bacillus is the active and efficient cause of cholera Asiatica was not entirely satisfactory to his mind, the lecturer felt no hesitation in declaring that Koch had conferred an inestimable boon upon the race by placing in the hands of every practitioner an infallible means of diagnosis of this disease from cholera morbus and other diseases resembling cholera. He expressed the opinion that a health-officer or physician who, in the presence of suspected cases and before the prevalence of the malady as an epidemic, should fail to employ this means of deciding whether or not the disease is genuine cholera, would be guilty of criminal negligence.

After a personal visit to Ferran, in Valencia, and an examination of his methods of investigation, he was prepared to endorse the verdict of the French Commission with regard to the condition of his laboratory, but as to Ferran himself he arrived at a different conclusion. He was impressed by his modest bearing, and believed him a cultured gentleman, possessed of no mean skill as a bacteriologist. In his laboratory Dr. Shakespeare found as pure cultures of the comma-bacillus, and as handsomely mounted and stained specimens, as could be found anywhere in Europe. A few of these slides, made in his presence, were exhibited after the lecture was finished.

With regard to the result of Ferran's inoculations, Dr. Shakespeare demonstrated by the official returns made by the Government officers, who are not friendly to Ferran, that there was a sudden and marked reduction in the number of cases and in the mortality in several villages after the inoculations were begun—this measure apparently having about six times the value of ordinary hygienic precautions in checking the epidemic. The facts concerning inoculation, so far as they have been reported officially, seem to indicate the importance of making in future epidemics, this method the subject of a searching scientific investigation, such as it has not received up to the present time.—*Philadelphia Medical Times*, November 27, 1886.

THE INTERNATIONAL MEDICAL CONGRESS.—Among the foreign physicians who are expected to attend the Congress, and to read papers, are the following: Mr. W. D. Spanton, of England; Dr. E. Landolt, of Paris; Dr. A. Strubens, of Brussels; Dr. Julius Althaus, of London; Dr. A. Cordes, of Geneva; Dr. P. Ménière, of Paris, ("The Treatment of Fibrous Tumors of the Uterus"); Dr. T. M. Madden, of Dublin ("Laparotomy in Relation to Modern Gynecology"); Dr. W. U. Whitmarsh, of England ("Vaccination and the Pasteur Method"); Dr. Léon Petit, of Paris; Dr. A. Hegar, of Freiburg ("The Diagnosis, Origin, and Surgical Treatment of Tuberculosis of the Genitalia"); Dr. G. H. Savage of London ("Some Relationships of Syphilis to General Paralysis of the Insane"); Dr. W. Macewen, of Glasgow; Mr. Edmund Owen, of London; Mr. Lawson Tait, of Birmingham ("The Pathology and Treatment of Tubal Pregnancy"); Dr. J. Veit, of Berlin ("Tubal Pregnancy"); Dr. D. Perruzzi, of Bologna ("In the Cases of Cæsarean Section in which Porro's Hystero-oophorectomy is not absolutely indicated, what is the best manner of Suturing the Wound of the Uterus?") Dr. E. Ehrendorfer, of Vienna* ("The Prophylaxis of Puerperal Fever"); Dr. J. A. Doléris, of Paris; Dr. Gusserow, of Berlin; Dr. A. Charpentier, of Paris; Dr. G. Braun, of Vienna; Dr. L. Casarti, of Florence ("The Origin and Causes of Sterility in Women"); Dr. J. Korosi, of Budapest ("New Observations on the Preservative Power of Vaccination"); Dr. E. H. Kirch and Dr. A. Olendorff, of Prague; Dr. H. Power, of London ("Microbes in the Development of Ophthalmic Diseases"). Dr. A. Eulenburg, of Berlin;

Dr. W. Murrell, Dr. B. W. Richardson, and Dr. J. L. W. Thudichum, of London; Dr. Dujardin-Beaumetz, of Paris; Dr. G. P. Unna, of Hamburg; and Dr. Eustace Smith, Mr. Christopher Heath, and Dr. H. Charlton Bastian, of London, are also expected.—*N. Y. Medical Journal*, Nov. 13, 1886.

DEATH OF M. PAUL BERT.—In the death of M. Paul Bert, which occurred on November 11, science has lost a master whose place cannot be easily filled. He was born at Auxerre, on October 17, 1833, and was licensed as a Doctor of Medicine in 1863. His work in physiology is so well known that it need not be more than referred to. He was elected to the National Assembly in 1872, and was appointed Minister of Public Instruction in 1881–82.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY. FROM NOVEMBER 20, 1886, TO NOVEMBER 26, 1886.

Lieut.-Col. B. J. D. Irwin, Asst. Medical Purveyor, relieved from temporary duty in New York City, and of the charge of the Medical Purveying Depot in that city, and ordered to San Francisco, Cal., to take charge of the Medical Purveying Depot in that city. S. O. 270, A. G. O., Nov. 19, 1886.

Major F. L. Town, Surgeon, ordered from Ft. Clark, Texas, to Post of San Antonio, Texas, to relieve Surgeon J. P. Wright. S. O. 159, Dept. Texas, Nov. 15, 1886.

Major Joseph R. Gibson, Surgeon, ordered for duty as Post Surgeon, Ft. Sayon, Col. S. O. 134, Dept. Mo., Nov. 20, 1886.

Capt. J. L. Powell, Asst. Surgeon, ordered for duty as Post Surgeon, Ft. Supply, Ind. Ter. S. O. 134, Dept. Mo., Nov. 20, 1886.

First Lieut. Freeman V. Walker, Asst. Surgeon, assigned to duty at Ft. McIntosh, Tex. S. O. 159, Dept. Texas, Nov. 15, 1886.

First Lieut. Paul Clendenin, Asst. Surgeon, recently appointed, ordered to report to commanding general Dept. of Texas, for assignment to duty. S. O. 271, A. G. O., Nov. 10, 1886.

Capt. Henry Johnson, Medical Storekeeper, will, in addition to his present duties, assume charge of the Medical Purveying Depot in New York City as Acting Asst. Medical Purveyor. S. O. 270, A. G. O., Nov. 19, 1886.

APPOINTMENTS.

Lt.-Col. John Moore, Asst. Medical Purveyor, to be Surgeon-General of the Army. Nov. 18, 1886.

Ball, Robert R., to be Asst. Surgeon, with the rank of First Lieut. Nov. 19, 1886.

PROMOTIONS.

Major Joseph C. Bailey, Surgeon, to be Asst. Medical Purveyor, with the rank of Lieut.-Col. Nov. 18, 1886.

Capt. Chas. L. Heizmann, Asst. Surgeon, to be Surgeon with the rank of Major. Nov. 18, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY. DURING THE TWO WEEKS ENDING NOVEMBER 27, 1886.

Nash, Francis S., P. A. Surgeon, ordered to special duty at Smithsonian Institution. Nov. 26, 1886.

Rhoades, A. C., U. S. N., Medical Inspector, ordered to special duty attending officers and families, New York City.

Law, Homer L., Surgeon U. S. N., ordered before the Retiring Board, Dec. 2, 1886.

Lippincott, George C., P. A. Surgeon U. S. N., ordered before the Retiring Board, Dec. 6, 1886.

CORRIGENDUM.

In THE JOURNAL of November 27, p. 597, in third line from last of Dr. Gaston's remarks on Dr. Smith's paper, for "pus" read *fæces*.

ESSENTIAL VERTIGO.¹

BY L. BREMER, M.D.,

OF ST. LOUIS, MO.

Impairment of equilibrium, accompanied by strange sensations of varying kinds and degrees, is met with as a symptom, not only of cerebral but of a great many other diseases, especially those of an exhausting and debilitating character. Besides the physiological vertigo produced by rapid rotatory movements or by a sojourn in high places, temporary pathological giddiness or dizziness is not uncommon with many persons enjoying, in other respects, good health. In fact, there is scarcely an adult but has not, at one or the other period of his life, experienced vertigo of some kind. Whereas, then, vertiginous sensations may be said to fall within the boundary lines of health, they may constitute a well-marked disease and rise to the dignity of a pathological entity, if they are severe or persistent enough to interfere with the comfort or occupation of the individual so affected.

I will remark here that the moral effect of the same degree of vertigo varies much with the individual moral and mental disposition of the patient, and that to the one an attack of vertigo of a certain intensity will appear of the gravest importance, which by another would be ignored, nothing thought of and easily forgotten. Thus the psychical, and consequently physical, effect of such an attack will tell more on the excitable than the phlegmatic. Children seem less disposed to the trouble than adults; or, perhaps, are less likely to speak about it than adults who have an idea, however vague, of its seriousness. The English expressions: giddiness, dizziness, lightheadedness, all of which are comprised in the term vertigo, signify a number of totally different affections; they are often used promiscuously by physicians and patients, and may mean loss of balancing power, simple fulness or pressure in the head, faintish feelings, temporary confusion of thought, or bewilderment and strange and undefinable sensations in the head in general.

The kind of vertigo which is the subject of the present paper shows a tolerably well defined and cir-

cumscribed clinical picture. I have chosen for it the term, essential vertigo, as suggested by Nothnagel.² It is the form which by others has been described as "idiopathic," or a "simple" vertigo. This affection must, in the present state of our knowledge, be classed with the neuroses; I therefore exclude those cases that are due to disturbances of vision, hearing or digestion, to the gouty diathesis, epilepsy, malaria, cardiac trouble, acute infections, and organic diseases of the brain, intracranial tumors, atheromatous condition of the cerebral arteries; in short, all the so-called organic, *i. e.*, coarse pathological lesions of the central nervous system.

Although there are many variations of the disease and, since the symptoms are chiefly subjective in character, ever changing according to the individuality of the patient, the following may be said to be an average representation of the symptoms of essential vertigo:

The patient, generally, though not always, more or less anæmic-looking, debilitated and nervously exhausted by overwork, disease or excess, experiences, at greater or lesser intervals, a strange sensation in the head, a feeling of emptiness accompanied with loss of balancing power. The attack may come on suddenly or after certain premonitory signs, while walking, sitting, or lying down, during day or night; often in the midst of apparent perfect health, at other times on the supervention of slight ailments, acute catarrh, indigestion, etc. The victim of the attack feels as if his whole strength were to drop away from him, as if the ground were drawn from under him; he is at sea, unstable on his legs and, as if on board a ship, he straddles in order to enlarge his base, or grasps the nearest support. In severe cases he actually falls to the ground; but this is done in a coördinated manner, unlike an epileptic attack, care being taken by the patient not to injure himself by the fall. There is no loss of consciousness, though there may be a warning of it, *viz.*: dimness of vision and hearing and other signs premonitory of fainting. If the attack be a severe one and the patient be not yet accustomed to vertiginous feelings, a very striking symptom is the intense terror, a vague fear of becoming paralyzed, of dropping suddenly out of existence, of utter annihilation. For hours and sometimes for days this terror vibrates in the nerves, and leaves the victim in a depressed and demoralized condition. Generally speaking, essential vertigo comes on by short spells, the whole attack lasting only a few seconds or minutes, but there are cases in which a status

¹ Read in the Section of Materia Medica and Therapeutics, at the Thirty-Seventh Annual Meeting of the American Medical Association.

² Vertigo, Ziemssen's Handb. d. Spec. Path. u. Therap. Supplement C, p. 102, ff. Nothnagel proposes this name for those forms which arise repeatedly in some persons without the slightest etiological trace. "As a matter of course," he adds, "this name is only a preliminary cover of our ignorance."

vertiginosus, analogous to the status epilepticus, is developed, incapacitating the patient for the ordinary duties of life and for business. I have known such patients to remain in this state for weeks, day and night.

The objective signs of an isolated attack are pallor of the face, often of the whole surface of the body, cold extremities covered with clammy perspiration, uneasiness and restlessness, a desire to move about, to change place, as if any other locality offered greater security from an impending catastrophe than just the spot where the patient happens to be at the time. Meanwhile the heart's action, especially in persons who are, in a measure, used to the attacks, remains normal, whereas in others it is considerably slowed by fear or quickened by excitement. Again, these disturbances may be present independently of any emotion. A gentleman under my treatment counted during some of his attacks thirty-six beats a minute, whilst in others, especially when they occurred in rapid succession, the pulse would run up to 120. A distressing form is the nocturnal vertigo. The patient wakes up suddenly with a strange sensation of oppression in the region of the heart, great fear, and loss of balance. This form is often observed after errors in diet.

After the vertigo has ceased, relief may be complete, the patient remaining free from the trouble for days, weeks or even months, but the rule is recurrence in short intervals. In many cases the attack leaves a psychical depression and great anguish behind it, the patient being in constant fear of a reappearance of the trouble. In this state of mind even slight vertiginous sensations, the most insignificant aura, will frighten the unfortunate patient and predispose him to another spell. This distrust and fear is in some cases carried so far that an occasional misstep on the street, or staggering over an object on the ground, a leaning to one side or a quick movement will make him think of a new attack; there is immediately set up a precordial anxiety, and the imaginary vertigo may be turned into a real one. Thus a vicious circle is established, in which cause and effect are intimately blended, and cannot be distinguished the one from the other. The same interweaving of cause and effect may be said to exist between vertigo on one hand, and visual, aural and pneumogastric disturbances on the other. It is very rare that vertiginous patients are not affected, however slightly and transiently, with functional disorder of the auditory or visual apparatus, and especially of the stomach and heart. The pneumogastric seems to play a similar mysterious and important part in vertigo as in epilepsy. It would be erroneous, though, to classify such cases as visual, aural, cardiac or stomachal vertigo, the chief trouble being an instability of the vasomotor centre or centres, an instability which is greatly increased by the peripheral complications mentioned, and which in its turn is capable, probably, of generating them if not yet existing, and aggravating them, if already present.

A lowered tone of the whole nervous system, presenting often unequivocal neurasthenia in its manifold manifestations, is met with in all cases of confirmed vertigo, either as a cause or a result, or both.

The following case will illustrate some of the preceding remarks:

S. C., a lawyer, æt. 32, who had for five or six years lived a rather irregular life, working very hard at times at his profession and indulging in liquor and tobacco at others, coming of a neurotic family (father dipsomaniac, mother slightly hysterical), was, while crossing a public square, suddenly taken with strange sensations in the region of the heart, and in the head. He found himself making several steps in a different direction from the one intended, and, being in great fear lest he might fall, took hold of a tree which happened to be near by. He was at the time in good health, and had not touched a drop of liquor or smoked a cigar for months. In order to get over this alarming sensation he stamped with his feet and shook his arms. His extremities felt cold, and there was a clammy perspiration on his forehead and in the palms of the hands. In a few moments the attack was over, and he walked on without further difficulty. The spell, however fleeting, left him nervous and had a very depressing effect on his mind. He felt gloomy and morose, lost confidence in himself and had all kinds of dismal forebodings as to his future, especially his professional career. Although the vertigo did not repeat itself in the degree he had experienced the first time, he felt, when walking on the street, an almost constant warning of another attack, which it seemed to him he could ward off by walking briskly or shaking his arms in order to accelerate the circulation of the blood. With the greatest diffidence he attended to his business in the court-room; the excitements incident to his avocation, the mental efforts he had to go through, and the close atmosphere in the court-room, invariably made things worse. In crossing the place where he had had his first attack he instinctively tried to avoid the tree, but, seeing how ridiculous this fear was, he made it a point to pass the scene of his first spell as often as he had an opportunity, and by dint of great efforts, succeeded in overcoming his apprehensions. His physical condition, and especially his state of mind, were at times desperate. The recumbent position or, if this was not feasible, an ounce or two of whiskey, would keep the worst symptoms in abeyance, whereas the alcohol increased the trouble when indulged in even slightly in excess of his accustomed quantity.

By leading a regular life, carefully attending to his diet and his clothing, by bathing in cold water and discreetly using whiskey (one ounce twice daily), the vertigo gradually disappeared, although every little ailment, such as taking cold, a touch of malaria or a slight excess in alcohol, was apt to bring on an aura. Theaters and crowded places in general he had to avoid, even after he considered himself well, owing to ill-defined sensations of uneasiness. He managed, however, to pursue his business without betraying his peculiar affection, although while pleading in a case the idea would sometimes harrass him, that his vertigo would return and a public sensation result. With these exceptions, nothing reminded him of his old trouble, and he was in every sense of the word a healthy man, when one day, while inspecting the roof of his house from the street below, he had a

fresh and very severe attack, owing, no doubt, to the continued abnormal and strained position of his head. This spell was followed by a series of milder ones. By strict hygienic measures they disappeared within three weeks, when he regained his former good health.

This individual had been of a nervous disposition from his early youth, and subject to vaso-motor disturbances. During the years of puberty he had fainted on several occasions, and all his lifetime he had been greatly annoyed by a tendency to blush on the slightest occasion. He had, after the first few attacks of vertigo, a pronounced fear of softening of the brain, an idea which, by a good deal of reasoning, he finally got rid of. He is now, one year and a half after his relapse, free from all vertiginous sensations, and in full possession of his former self-reliance and energy. This case is one of essential vertigo *par excellence*. There were no disturbances of vision, audition, or digestion. The psychical impression of the first attack, the fear of the tree near which this occurred (topophobia), the general diffidence and demoralization, deserve special mention. The strained position of his head by which a fresh outbreak of the trouble was brought on is also of significance. It is the prolonged upward gaze which is peculiarly apt to lead to an attack. Hence picture galleries and museums are to be avoided.

The following case is not so simple as the preceding one, but none the less characteristic, owing to the large collateral train of strange and ever-changing symptoms:

F. S., æt. 37, a merchant, presents himself at my office in August, 1884. He is anæmic, greatly emaciated; his face almost lead-colored. His mother is subject to megrim; his father died at an advanced age from phthisis, having ailed for a great number of years. He, too, suffered from vertigo for years, and is said to have been cured of it by cupping of the nape of the neck. Patient has been in his younger days "on the road" as a traveling salesman for fourteen years, and undergone all the hardships and irregularities incident to such a life, and has committed excesses of various descriptions. Three years previous to his coming under my treatment he was suddenly, while in the act of defecation, taken with violent vertigo, which afterward repeated itself in such a degree and with such frequency that he was forced to temporarily abandon his business. After various modes of treatment had failed to improve his condition, he sought relief in traveling, and finally went to Hot Springs, where, in addition to warm bathing, he was, on a vague suspicion, subjected to an antisiphilic treatment both by inunction and the administration of the iodide of potash, which soon made a perfect wreck of him. A trip South during the winter did not improve him; he lost flesh rapidly, becoming weaker from month to month, and was almost driven to utter despair by the permanent vertigo which at times was so severe that he could not cross the street.

At the time I saw the patient he weighed about 116 pounds, his usual weight, when in good health, being 135 pounds. Beside the vertigo, he complains of shifting pains, their principal seats being the regions

of the heart, spleen, left shoulder and nape of the neck. The head is exempt. The pain around the heart and the spleen has a vicarious relation with the vertigo. Whenever there is an exacerbation of the pain, the vertigo is lessened or entirely disappears; whenever the pain is gone the vertigo is at its worst. There is also pain in the lumbar region and slight twitching of the muscles of the left side of that region. He has night sweats and occasionally polyuria, which produces great exhaustion. The urine at such times is limpid and of low specific gravity. At such periods, too, his vertigo is gone, to set in again on the disappearance of the "nervous urine." His appetite is capricious, his tongue furred, and has been so for a number of years, his stomach often distended with gases, the expulsion of which by the œsophagus affords generally relief to the pericardial pain. He sometimes complains of fulness in the left ear; which is, however, transient. One day he noticed that he could not hear with his right ear. This deafness lasted only three hours. He grinds his teeth at night, sometimes so loudly that his wife is awakened by the noise. In consequence of the constant friction, the crowns of the molars are completely ground off. The vertigo is often attended with cold extremities and clammy perspiration, but never with nausea.

The symptoms of the patient are ever varying, and sometimes surprising to him on account of their novelty. There is no stability in any of the pathological manifestations except the vertiginous sensation, and even this is sometimes varying in character; thus, instead of there being a disturbance of equilibrium, a tendency to fainting sometimes predominates, and these are the times when the patient's sufferings are greatest and when he is most alarmed. Nor is the vicariousness of the symptoms invariably observable, there being times when he suffers both from excessive pains and vertigo. When in this condition, the patient is unable to get up from bed.

Errors in diet, colds, malaria, and excitement of all kinds, invariably aggravate the trouble. This patient was very much improved by cold sponging every morning, dry diet, Carlsbad salts in the morning, and from 6 to 7 drops of muriatic acid three times a day after meals. At bedtime, and whenever threatened by an attack of vertigo, he took 30 grains of bromide of potassium in one teaspoonful of the elixir of the valerianate of ammonia. Besides, patient was allowed two ounces of whiskey daily, one at 10 A.M., the other at 4 P.M. Under this treatment all the symptoms, except the shifting pains, disappeared. His weight ran up to 142 lbs., being more than he ever weighed in his life. His spirits, too, were considerably improved, his hopelessness yielding to a more cheerful mood, which made him bear the pains with comparative facility. These pains appeared generally in the evening; during business hours he used to be free from them. He felt best on getting up in the morning, and worse as the day advanced.

I look upon this case as one of outspoken neurasthenic vertigo. It might be mistaken for stomachal vertigo, and, indeed, the treatment consisted chiefly in combating the catarrh of the stomach complicating the trouble. But this condition of the stomach, the

furred tongue, etc., had made their appearance a long time after the commencement of the vertigo, and may therefore be considered as a consequence rather than a cause of the nervous debility of the patient. Again, the absence of nausea speaks against stomachal origin. To prove that the case was one of nervous dystrophia, it suffices to say that all the various pains would disappear during business hours, when the patient was actively engaged, to set in immediately when neither mind nor body were occupied. A dose of the bromide, an ounce of whiskey, and sometimes a 10-grain dose of quinine, would terminate an attack of vertigo as if by magic.

The good effect of the treatment lasted about eight months, when, in consequence of a great excitement caused by a severe accident in his family, the old symptoms manifested themselves with renewed vigor. Loss of sleep, irregular diet and change of season (spring) brought on a complete relapse. There was irritability of the heart, the pulse running up to 100 a minute and more; at other times it was normal and even below normal. His face was at times of a dark purple color; at others deadly pale. The symptoms now were extremely intense and alternating; palpitation of the heart, throbbing in the left side of the head, vertigo, faintishness, and pain, especially in the nape of the neck, appearing and disappearing in wild and rapid succession and demoralizing the patient. None of the remedies employed, among which amyl nitrite, caffeine and digitalis may be mentioned, gave satisfactory relief; whiskey alone in greater quantities seemed to be capable of alleviating the symptoms. During this stage the patient became a "rounder," going from one doctor to another to have his heart examined, believing, in spite of my assertions to the contrary, that he had an incurable heart disease.

In the preceding two cases the impairment of equilibrium was very marked, but there are others where this feature is less pronounced, the higher centres being chiefly affected. The following case will illustrate this point:

H. P., æt. 28, of temperate habits, nervous temperament, slim build and rather hectic appearance (one sister is consumptive), presents himself in May, 1885. He has never indulged in alcoholic excesses, but has, up to three years ago, danced whole nights to complete exhaustion. He finally became so debilitated that he had to give up dancing altogether. In November, 1884, he was suddenly taken with dizziness in the head, which has persisted, with intervals of various duration, up to the present date. The trouble consists more in mental confusion, incoherence of thought, temporary impairment of memory, and slight paraphasia, than in equilibrial impairment, although the latter element is also present in his attacks. These come on principally while writing letters, and by mental efforts of a similar kind, but at times the strange and alarming sensation is constantly on him. At one time a "status" was developed, lasting, without any appreciable intermission, for two weeks. An injury of his thumb resulting in suppuration put an end to the trouble as long as the suppurative process was going on; it reappeared on the

healing of the wound. Patient complains of numbness and heaviness of the left arm. There is a very slight mitral stenosis, which does not, however, prevent him from executing rapid movements such as running up and down stairs. There is also slight nervous dyspepsia, the tongue clean, the stomach bloated after meals, with heaviness in the epigastrium. The dyspeptic symptoms showed themselves some time after the appearance of the dizziness. Patient is afraid of having softening of the brain, and finally losing his memory and mind altogether. His skin is abnormally dry. The same treatment as in Case 2 was instituted, the Carlsbad salts and muriatic acid being substituted by Fothergill's pills (strychnine and ipecac). The improvement was prompt, but the relief obtained was again lost two weeks afterwards by a night's dancing. The relapse finally yielded to the old treatment, but not with the same promptness. The patient, although greatly improved, has occasional attacks of vertigo; the numbness of the arm is entirely gone, his disposition has become more cheerful, and he can, without any difficulty, perform his duties as a bookkeeper and manager of a tailoring establishment. Great benefit was derived from the administration of 5 drops of Fowler's solution three times a day.

In this individual the circulatory trouble affected, doubtless, more the anterior and, perhaps, middle portions of the brain (numbness of arm, mental confusion, paraphasia and loss of memory); whereas in the first two cases the principal site of the trouble lay in the posterior portion of the cerebrum and in the cerebellum. The disappearance of the vertigo during the existence of a suppurating wound is particularly instructive.

A fourth case is interesting from its attendant symptoms and a possible organic lesion of the central nervous system. A. R., æt. 47, a preacher, over six feet high, rather fleshy, with good family record, absolutely abstemious from alcohol all his lifetime, is afflicted ever since his childhood with a slight trembling of the hands which he formerly could control by his will; his handwriting used to be firm and neat. No history of chorea during childhood. Two years ago, when officiating at the altar, he suddenly became giddy and had to be led out of church. Ever since this time he has an invincible fear of appearing before his congregation and in public generally. During a visit to this city he was asked to make a few remarks to the children of a Sunday-school. In spite of a supreme effort to comply with the request he was, on trying it, completely at a loss to utter a single syllable. He cannot approach the scene of his first attack of vertigo, the altar, without immediately experiencing a giddy sensation or a morbid fear of the same. His appetite is good. Being very fleshy before, he lost during the affection twenty lbs. All events relative to himself or his family, whether sad or joyful, excite him very much. The birth of a little son, a long hoped for event, threw him into a state of extreme nervousness lasting several days. The trembling has increased considerably since the beginning of the vertigo; he cannot drink a glass of water without spilling a portion of it. In spite of

this *tremblement intentionnel*, there are no other symptoms of multiple sclerosis. The tremor is confined to the upper extremities, head and legs being exempt. He claims that he became hypermetropic within eight days after the beginning of the vertigo. This defect is completely corrected by wearing proper glasses. Ophthalmic examination is negative. He has no pain anywhere. The patellar tendon reflex is somewhat exaggerated. His chief complaint uncertainty of gait and mental anxiety. Excepting the loss of weight his physical condition is, on the whole, the same to-day as it was when the vertigo commenced. The topophobia (fear of the place where the altar stands) and the fear of appearing in public after twenty years of a clerical career, are conspicuous and noteworthy symptoms in this case. The trouble is engrafted upon and superadded to a previously unstable nervous disposition. I saw the patient only once and have no further record of the progress of his case. I speak of it as one of essential vertigo because, in spite of certain symptoms indicating coarse lesions, its clinical picture does not fit the frame of any typical lesion of the central nervous system.

Vertigo and Neurasthenia.—It may be fairly urged that in the cases described above I have simply related instances of neurasthenia manifesting itself by equilibrial disturbances. Further, Cases 3 and 4 might seem improper for illustrating essential vertigo, since in the former there is a slight lesion of the heart, and in the other there is suspicion of organic disease of the central nervous system. My reasons for citing them in connection with the subject are merely clinical ones. As to the neurasthenic character of the trouble, I perfectly agree with those who class essential vertigo among the many symptoms composing the mottled clinical picture of nervous exhaustion. But, accepting the two principal divisions of neurasthenia into cerebraesthesia and myelasthenia as proposed by Beard, the form just described and illustrated by me would rather deserve the name of meancephalasthenia, since it is the mid brain, the recognized seat of the equilibrial centre or centres, where the nervous instability chiefly manifests itself. But the localization of perverted nerve action in the mid brain is not perfect, bulbar and hemispheric symptoms generally being present, as shown by the cases detailed above, and as will be dwelt on more fully further on.

Physiological Researches.—The experimental researches instituted to establish an equilibrial centre in animals have not been conclusive enough to be of great value in the explanation of essential vertigo. All such experiments have of necessity a direct bearing on objective vertigo, or that form in which there is an appreciable and visible loss of balancing power, such as a drawing or falling to one side, circus movements, etc. But essential vertigo partakes more of the subjective kind; there is a psychical element in it, is often of a purely mental or hallucinatory character and cannot, therefore, be rendered intelligible by results of vivisection.

Equilibrial Centre.—But even the mechanism of purely objective vertigo is far from being understood. "We cannot, at present at least, define a coördinating

centre in the same way that we can the vaso-motor or respiratory centres" (Foster). Since the famous investigations of Flourens it seemed to be a settled fact that the cerebellum was the chief, if not the exclusive equilibrial centre. But pathological observations disproved this doctrine. Lesions of considerable extent were found in the cerebellum of patients who, during life, had not betrayed the slightest symptoms of ataxy or vertigo. Nothnagel believed that this could be explained on the ground that the lobes of the cerebellum were not essentially concerned in maintaining the equilibrium of the body, but that the vermiform process was the chief coördinating centre, an injury of which was, under all circumstances, followed by incoördination.

But even this restriction does not seem to suffice, and recent investigations assign to the cerebellum an office altogether different from coördination. Luciani² was the first to succeed in almost completely removing the cerebellum of a dog and keeping the animal alive for a considerable time. The dog operated upon lived eight months. Luciani found, when the dog had recovered, that the peculiar state of the muscles known as cerebellar ataxy was not due to a deficient coördination, nor to an impaired muscle sense, but that the ataxy was caused exclusively by a deficient muscular tone and the insufficient energy exercised by the nerves on the involuntary muscles. It is, according to Luciani, a general dystrophia that results from the abolished cerebellar innervation, and it is this dystrophia that gives rise to the supposed ataxy.

Before Luciani similar views have been expressed by Schiff,³ according to whom there are in the cerebellum "certain apparatus which *reinforce* all muscular actions necessary for complicated movement."

One of the most indefatigable workers on the subject of coördination and equilibration has been, of late, Bechterew. By a number of experiments upon animals detailed in a comprehensive treatise,⁴ he comes to the conclusion that in the higher animals there are three centres presiding over the maintenance of equilibrium: the cerebellum, the central gray substance of the third ventricle, and the olivary body of the medulla oblongata. All these central organs are in connection and correspond with as many peripheral equilibrial apparatus: the semicircular canals, the visual organ, and the tactile nerves of the skin.

Iandois⁵ looks upon the tactile nerves, the nerves of the muscular sense and the ampullary fibres of the auditory nerves, as being the peripheral organs concerned in maintaining the equilibration.

The Mechanism of Equilibration.—There can be no doubt that our body is properly balanced by means of a number of afferent impulses which in their turn react on certain efferent nerves to call into action muscles or groups of muscles. Instead of one single coördinating or equilibrial centre, there is a complex

² Linee generali della fisiologia del cervello. Publ. del R. A. di stud. sup., in Firenze, 1884.

⁵ Eulenburg's Realencyclo., art. Vertigo.

nervous machinery composed of very different and specialized nerve elements, the harmonious coöperation of which constitutes the balancing power. In short, there are a number of equilibrial centres corresponding to a number of equilibrial peripheral nerves.

Encephalic Origin.—An injury or functional impairment of any part of this equilibrial mechanism, central or peripheral, will be followed by incoördination, by vertigo. There is, consequently, a vertigo of peripheral and one of central origin. It is the latter which, in the absence of coarse lesions, constitutes essential vertigo. It probably depends primarily on vaso-motor disturbances which, secondarily, give rise to weakness and irritability of the cells of the equilibrial centres. These centres being situated in the mid-brain (cerebellum, corpora quadrigemina and pons), are nourished by branches of the basilar artery. A spasm of this artery or any of its branches determines impairment of nutrition, and consequently of function of the equilibrial cells. By repeated attacks of such angio-spasms there is set up a permanent irritable weakness of the centres, which finally may be disturbed in their function by trivial irritations of the peripheral equilibrial nerves (ampullary branches of the acoustic, retina, pneumogastric) without the intervention of the vaso-motor centres. Hence the apparent aural, ocular and stomachal vertigo in the nervously exhausted who are free from organic aural, ocular or gastric disease.

But the starting point of the disturbance may be lower down, in the medulla oblongata, especially in such cases where faintishness is a complication. We know that attacks of outspoken syncope are more frequently observed in organic affections of the bulb, and the inference is admissible that partial or abortive fainting spells may result from simply functional derangements of that part of the nervous system.

Again, vertigo is one of the commonest symptoms in structural diseases of the cervical portions of the spinal cord, whereas it is absent in the lesions confined to the dorsal and lumbar portions.⁶ This observation simply means that in the cervical affections the medulla oblongata, with its centres, is functionally deranged owing to a neighboring focus of disease. Again, the "neurasthenic" pains sometimes observed in the nape of the neck (see Case No. 2) in vertigo patients, also point to the medulla oblongata as a possible seat of the trouble.

The concomitant disturbances of respiration, of the heart and stomach, so often observed in vertigo, also speak in favor of this view, and are easily explained by the close proximity of the respiratory, heart, and pneumogastric centres, to the vaso-motor centre which plays so prominent a part in vertigo.

Morbid Fear.—As to the morbid fear so common in persons suffering with vertigo, we know that it is a prominent symptom in organic bulbar disease, "in which it means that life is in immediate danger" (Wernicke). This morbid fear, then, may also be referred to a functional derangement of the medulla oblongata, although there is no valid reason why it should not be brought in connection with and find

its analogon in those cases of anguish that precede the bursting of cerebral arteries or the formation of abscesses. This morbid fear has a tendency to attach itself to or concentrate itself upon certain objects, places, or conditions. After one or a series of intense attacks of vertigo, the whole psychical stamp of the patient undergoes a profound change. The most resolute man may become an effeminate and vascillating weakling. There is a stain on the brain that disappears only with the general improvement of the whole nervous system. This condition is described by some authors as male hysteria; by others as hypochondriasis.

The most common form of these morbid fears is topophobia (Beard), or fear of a certain place or places. The scene and incidents of the first severe attack of vertigo impress themselves indelibly on the mind and memory of the patient, who shuns those places and fears to approach them. Thus, one patient who had the first attack in the water-closet in his store, would neither use it or go near it ever afterwards; another could not sit in a rocking chair, and a third could not pass a tree for similar reasons.

By the preceding remarks I do not mean to imply that topophobia is invariably the result of vertigo. It may be a manifestation of neurasthenia in general, or hypochondriasis. The same is true of agoraphobia, or the fear of open places or squares. Although I have found it associated with vertigo, it is not, as has been pointed out by other authors, a form of vertigo, although it is a matter of daily experience that vertigo patients do not like to cross places where there is no chance, in case of an attack, to sit down, lean against a tree, etc.

Finally, dinophobia or fear of vertigo is very common among the majority of the cases under consideration. It leads to mental vertigo, that condition in which the patient is constantly on the alert.

If the chief vaso-motor centre in the medulla oblongata be the centre of functional disturbance, there will be, in addition to a diffuse cerebral anæmia giving rise to vertigo and faintishness, a general arterial spasm producing pallor of the skin, chilliness and cold perspiration, most marked in the palms of the hands. In some cases, however, the arterial spasm and consequently the anæmia, is more of a local character, and confined to the central nervous system or parts thereof. Under these circumstances there are no external objective symptoms accompanying the vertigo. The nature of the latter will vary with the subsidiary vaso-motor centres acting on certain circumscribed portions of the brain. Thus, if the cerebellum be the principal seat of ischæmia, there will be actual staggering and reeling (cerebellar vertigo, Immermann); if the posterior half of the large hemispheres be chiefly attacked, abnormal sensations in the extremities, numbness, tingling, formication, etc., may be looked for; whereas anæmia of the frontal lobes will manifest itself by confusion of thought, aphasic symptoms etc., and the implication of the basal ganglia will be followed by disturbances of hearing and vision. Generally, however, there is not a distinct line of demarcation between these forms. It would be a mistake, though, to assert that

⁶ Cp. Girardeau, Des accidents vertigineux et apoplectiformes dans le cours des maladies de la moëlle épinière. Gaz. Méd., May 3, 1884.

all kinds of vertigo depend upon circulatory changes in the central organs. In ocular and aural vertigo proper the ganglionic cells of the organs of equilibration or reinforcement may be directly affected by essential nerve-vibration starting from the peripheral terminations of the optic and auditory nerves, without the intervention of vaso-motor influences. Assuming this to be true, loss of equilibrium would find its analogue in certain forms of reflex paralysis. On the other hand, it is a one-sided proposition advanced by some otologists, and among others Woakes, that all kinds of vertigo are due to disease of the auditory apparatus. Nobody will deny the great importance of the internal ear as being the chief peripheral organ of equilibration, and clinical observations of changes in the intralabyrinthine pressure proves it every day, but in many cases of vertigo there is not the slightest trace of ear disease discoverable. In these the impairment of hearing, or tinnitus, is, like vertigo, of central origin, the auditory trouble is not the cause, but merely the accompaniment, of giddiness.

Minor Epilepsy and Vertigo.—Although essential vertigo has never been known to pass into epilepsy, and though the vertigo under consideration has nothing to do with epileptic vertigo so-called, which, as is well known, is a misnomer, there are some traits that are common to both affections. What has been said of epilepsy (Gowers), that every fit is the result of those that have preceded it and the cause of those that follow it, is also applicable to vertigo. It is not only the peculiar mental state, the anxiety and fear that predispose to and produce a vertiginous spell on the slightest provocation, but an instability, a want of resistance of the nerve cells themselves is set up by a number of repeated attacks, paving the way for and facilitating future spells. This instability may concern the anatomical elements of the common vaso-motor centre in the medulla oblongata, the nerve elements of the superior or inferior cervical ganglions (the local vaso-motor centres of the brain), or the ganglionic cells of the various equilibratory centres of the brain. Like epilepsy, vertigo occurs with and without warning, sometimes in the midst of good health, like an explosion. In some of the severer forms I even saw twitching of the facial muscles, especially the orbicularis oris, and gritting of the teeth at night.

Etiology.—Essential vertigo is preëminently a disease of the middle period of life; it generally occurs between 35 and 50, *i. e.*, that period in which most of the nervous affections are developed. The remote and most important cause of vertigo is a neurotic disposition and a general defective nutrition of the brain. Individuals liable to vertiginous attacks are generally very impressionable, bluish and change color on the slightest provocation, are easily frightened, and give other evidences of an instability and irritability of the central nervous system, and of the vaso-motor centres in particular. In short, the victims of vertigo are recruited from among that ever-increasing class of neurasthenics who have been so graphically depicted by the master hand of Geo. M. Beard in his classical treatise on "Nervous Exhaustion."

I differ, however, from the eminent author when he considers this trouble as peculiarly American. Wherever civilization has taken a foothold, with its attendant evils of over-work and under-rest, of strife and struggle, of unbridled ambitions, passions and excesses, neurasthenia will be found to exist.

Among the immediate causes, exhausting diseases and excesses of all kinds, exposure to the rays of the sun, overheated and badly ventilated rooms, indigestion, mental emotions, and malaria may be mentioned. The latter is, at least in our section of the country, responsible for the often observed recurrence of vertigo in predisposed individuals, and occasionally an attack of intermittent fever may be ushered in or substituted by a spell of vertigo. It is preëminently malarial cachæmia that accompanies or gives rise to the most obstinate cases, and if it is true that nervous exhaustion prevails to a greater extent in the United States than in other countries, the greater prevalence of malaria with us is one of the responsible factors. Next to hereditary predisposition there is no more fertile soil for the neuroses to grow and develop upon than malarial cachæmia.

Influence of the Seasons.—General nervous debility makes the body a pretty reliable barometer. This is particularly the case in those neuroses where vaso-motor disturbances predominate. Some of my patients could, by an increase of vertiginous sensations, foretell a change of the weather, and Romberg mentions that vertigo is more frequent in the spring and fall than during the other seasons. This means that sudden changes of temperature may bring on or aggravate vertigo. In our latitude, however, there is no season more trying to vertigo patients than the hot summer months. A moderately cold winter and the months of May and June are, in our part of the country, the most favorable to the patients.

Treatment.—It has been well said of neuralgia that it is a cry of the nerve for better blood. The same is true of vertigo. It is a warning that the equilibratory centres are not supplied with the necessary amount and proper quality of blood. Indeed, neuralgic pains are very frequently associated with vertigo, so that we are justified in concluding that both are due to the same cause, *viz.*, anæmia; although the clinical manifestations are different. The plan of treatment, then, is clearly the reëstablishment of the vaso-motor equilibrium, and the normal quality of blood. The former can be accomplished only by the latter, for it is the condition of the blood in the first place that calls into action and regulates the principal centres in the medulla oblongata, the respiratory and vaso-motor centres.

Hence, therapeutical measures must be of an essentially reconstructive character, and the stomach and food must be the chief objects of our attention. Without a strict régime or neglect of the physiological requirements of the digestive tract all therapeutical measures become nugatory.

Gastric Complications.—I venture the broad statement that there is no case of essential vertigo without a more or less disordered digestion. A simple assertion on the part of the patient that he has a

good stomach, is without value; on closely questioning him it will be found that he suffers from one or another form of dyspepsia. It may be mentioned here that "a good stomach," or "a good digestion" are only relative conceptions. One of my patients told me that he had an excellent digestion, "because he was in the habit of passing a great amount of wind." The getting rid of his flatulency with him was a sign of a normal digestion. Dyspepsia, then, permanent or intermittent, functional or organic, existing in spite of dietetic precautions or brought on by periodical excesses in eating and drinking, will be found in the majority of vertigo patients. This, of course, does not mean that every case of vertigo is one *a stomacho læso*. In this latter affection we have generally to deal with a catarrhal condition of the stomach, and although there may be a blending of the two forms, of the essential and the stomachal, in many cases, they are etiologically and clinically distinct.

Diet.—As a *sine qua non* of treatment in severe cases I order the dry diet. Fluids in the form of water, or in intense dyspepsia, a very weak infusion of tea, is allowed in quantities to suit in the intervals between meals. During the hour preceding or the two hours following a meal no fluid is allowed. Soft boiled eggs, lean meat well done, and stale bread, especially the crust of bread, are recommended. Soups, fat meats and fresh bread are, above all, to be shunned. Vegetables in small amount are admissible in cases where there is not a catarrhal state of the stomach, and where the dyspeptic symptoms are more of a nervous character.

In the catarrhal condition Carlsbad salts in the morning, and five or six drops of muriatic acid after meals; in the nervous variety of dyspepsia, Fothergill's pills (strychnia and ipecac) do good service. It is sometimes astonishing to see under such a régime all the vertiginous symptoms disappear, as if by magic. I have known cases in which the beginning of this plan was marked by the absolute disappearance of the whole trouble, to make its reappearance only when the patient thought that he might return with impunity to his former habits of eating and general mode of living.

Clothing.—If there is any affection in the whole range of nosology peculiarly more influenced than another by variations of temperature, it is essential vertigo. Colds play even a more important part in bringing on a fresh attack than they do in cases of nephritis in aggravating the disease. This is easily understood by taking into consideration the vaso-motor nature of the disease, and the fact that exposure to sudden changes of temperature is the most fruitful cause of disturbing the vaso-motor centres, both general and local. Hence the great importance of proper clothing, upon which not enough stress can be laid. Wool is that material which offers the best safeguard against the sudden changes in the atmosphere. I recommend, therefore, to my patients the substitution of the woollen shirt to the fashionable white shirt. This, as it leaves the laundry with the starched bosom, is an abomination and an opprobrium to common sense. Impermeable

like rubber, it puts a considerable portion of a person's body under the same disadvantages as the latter material does when used as wearing apparel. I am not an advocate of the cranky notions of certain fanatical dress reformers, nor do I believe in any specific virtue of wool, but if we look around us we will observe that those persons who, in consequence of their occupations, are most exposed to the changes of temperature, shun cotton and linen almost instinctively. In the Rocky Mountains the woollen shirt is worn almost to the entire exclusion of the cotton and linen shirt. I would not insist upon this point, which to some may appear a trifling one, were I not firmly convinced that it is often overlooked and ignored, and that vertigo cannot be successfully treated without a strict attention to a rational mode of clothing.

Alcohol.—The great palliative remedy is alcohol. Without it the difficulty of treating vertigo would be a considerable one. The effect is usually prompt and uniform. It not only puts a stop to the vertiginous sensations, but reassures the patient and prevents or does away with the usual psychical depression. I need hardly remark here that over-indulgence in this affection of necessity leads to more baneful consequences than in almost any other. As a curative agent, too, it is of paramount importance. There is scarcely a case of vertigo in which I do not prescribe the moderate and strictly regulated use of whisky, as a rule from $1\frac{1}{2}$ to 3 ounces a day. Owing to the great danger of stimulants in the neurotic, and to the fact that they often jump right into confirmed inebriety, great discretion must, of course, be exercised in its administration.

The Bromides.—The bromides, in 30 or 40 grain doses, especially when combined with the valerianate of ammonia, are very serviceable. In cases accompanied with irritability of the heart they are almost indispensable. The action of the drug is probably similar, but perhaps superior, to that of quinine. Its well known power of steadying the ganglionic cells in the spinal cord, and increasing their resistance to peripheral afferent impulses, thus checking and controlling reflex movements, is equally well observable in vertigo, where it exerts a regulating influence either on the vaso-motor centres or on the equilibrial ganglionic cells direct. Digitalis, which I employed in cases where the irritability of the heart was very marked, never gave satisfactory results as to the vertigo, and often made it worse, although it did mitigate the heart symptoms. Arsenic, as a general nerve tonic, has a good effect where the gastric disturbances are slight or absent.

Iron.—Since almost all vertigo patients are more or less anæmic, it would seem, *a priori*, that iron is indicated in the treatment. It is not well borne by these patients as a rule, and is apt to do more harm than good. I discontinued it in all cases in which I yielded to the temptation of trying it. Aside from its tendency to aggravate the dyspeptic troubles, and thus adding to the peripheral disturbances apt to produce vertigo, it seems to influence the vaso-motor centres in a direct way, inciting them to perverted action.

Quinine is almost, if not entirely, as efficacious in temporarily preventing or dispelling vertiginous attacks, whatever their cause may be. A judicious use of this drug may accelerate a cure considerably, not only in cases of malarial origin or complication, but also in the forms of essential vertigo, pure and simple. Quinine, in spite of its tremor producing qualities, seems to have the power of steadying the vaso-motor, and perhaps the equilibrical, centres, as is shown by its great value in the treatment of that most uncontrollable of all forms of vertigo, Menière's disease.

Electricity.—From the fact that vertigo, objective as well as subjective, may be produced by passing a galvanic current through the brain, the patient experiencing some or all the symptoms of essential vertigo, cerebral and especially sympathetic nerve galvanization suggested itself at an early date of electro-therapy. But the results of competent observers have not answered to their expectations. Moriz Meyer, probably the most enthusiastic author on electro-therapeutics, does not mention in his treatise a single case of vertigo treated by electricity. Erb had negative results. Beard and Rockwell saw vertigo arise from faradization of the cervical portion of the sympathetic. Acting on the anatomical fact that the cerebral vessels are innervated by the sympathetic fibres starting from the superior and inferior cervical ganglia: acting, furthermore, on the physiological experiment that the medium pressure is due, according to G. Fischer, for the most part to an irritation of the vagus and sensitive nerves, and assuming, finally, that vertigo is due to a disturbance of intracerebral circulation, the most rational procedure would, indeed, seem to be the application of the electric current to the cervical sympathetic. But there exists the well known difficulty of applying electricity to the nerve without, at the same time, affecting the depressor nerves of the vagus, the brain itself, and the spinal cord. After having seen some very unpleasant symptoms arise, such as increased vertigo and threatening syncope, I like others, abandoned galvanization in the treatment of vertigo. In one case which recently came under my treatment I obtained a surprising result with static electricity, the electric wind, so-called. Here a status vertiginosus which had lasted for more than two weeks, and had refused to yield to the usual remedies, the first application gave prompt relief and the patient improved rapidly on the continuation of the treatment. I will say, however, that the patient, who was a strong believer in electricity, and who took at first sight a deep interest in my static machine, had suggested the remedy himself, and his implicit faith may have played the principal part in his cure.

Traveling.—If all remedies have been exhausted, if the patient has found that the most diverse plans of treatment and a host of remedies have failed to give him relief, he is generally told by his physician or friends to travel, and to try this or that watering place. But as a rule it will be found that neither benefits him, and he returns home more vertiginous and disheartened than ever. The excitement incident to travel, the crowded depots of large cities,

the whistling of locomotives, the jarring on the cars, the irregular meals and improper food, will, together or separately, deleteriously influence the nervous system of the sufferer. It is true that very often home influences which are constantly at work, petty annoyances, insignificant in themselves, but cumulative in their action, will prevent the patient from getting well. Business cares will, of course, be particularly prejudicial. Under such circumstances separation from home, a sojourn on a farm, a monotonous, solitary, and simple life will have the same beneficial effect on vertigo as on some forms of hysteria.

Decidedly injurious is warm bathing. Hence it is one of the most baneful mistakes for vertigo patients to try the effect of Hot Springs, as is often done in this part of our country. I do not know of any form of nervous disease which could possibly be benefited by warm bathing except those depending on a rheumatic diathesis. Much more rational is the use of cold bathing and of cold springs, although it is not the intrinsic remedial value of the water as such, but the employment of hydro-therapeutic measures in general, that is apt to work a favorable change in the patient's condition. Cold water and pure air are among the most powerful remedial agents to control vaso-motor disturbances, to calm and cure those forms of neurasthenia of which they constitute the predominant symptoms. Hence the discreet use of cold water ablutions, followed by gentle rubbing, and sleeping with the windows open, are prerequisite for success. That a fanatical abuse of these measures will have the contrary effect, is unnecessary to say.

Massage, the fashionable hobby and cure-all with some neurologists of the present day, was never, in vertigo, followed by any conspicuously good results in my experience.

From the fact that in some cases of injury and suppuration vertigo is suspended, the conclusion is justified that a seton may do good. I never tried this remedy.

Prognosis.—Life is rarely compromised by essential vertigo, and some patients grow old with it. Yet it cannot be denied that the often-repeated alarm experienced by the patient may set up psychical and physical ailments of greater or lesser gravity. On the whole it may be said that, as in neurasthenia in general, the prognosis is good *quoad vitum*, but dubious *quoad validitudoinem completum*. An ominous symptom is loss of memory and confusion of thought. These are symptoms, however, that are not frequently met with in the vertigo under discussion.

Those cases are most promising of success in which malaria is the proximate cause, although vertigo thus induced may last for years even after the disappearance of all malarial symptoms. When the stomach keeps in a fair condition the prognosis is also favorable. It would be a comparatively easy task to successfully combat vertigo were it not for the fact that we have, in most instances, to deal with bad habits (alcohol and tobacco), unwholesome surroundings and adverse circumstances of a social or financial nature.

However complete the success of treatment in a

given case may seem, there always remains a tendency to relapse. Like the sword of Damocles, vertigo hovers over the head of the predisposed, ready to descend on its victim when least expected.

SALICYLATE OF AMMONIUM IN THE TREATMENT OF TYPHOID AND SEPTIC FEVERS AND INFLAMMATIONS.¹

BY J. R. BARNETT, M.D.,

OF NEENAH, WISCONSIN.

For some two years I have been employing the salicylate of ammonium in some of the affections in which we have been accustomed to place our main reliance upon quinine, and I desire to submit the results of such experiments and my own conclusions.

Before doing so it may not be amiss to speak of the leading motive of such an investigation; its development, step by step, will appear later on. Briefly, the inadequacy of quinine in typhoid and remittent fevers and other grave affections to which it is commonly addressed, nay, its not infrequent harmfulness, raised the question in my mind years ago, whether it were not desirable to supersede it as an antipyretic by some other of at least equal power and free from its disadvantages and dangers. That many physicians have entertained the same question is amply attested by the multitude of substitutes that have been submitted during the last few years, some of them of the cinchona series and closely allied to quinine, as if it were not safe to get far away from the parent tree. Others derivatives of coal tar, as if it were better to get entirely away, and still others quite remote from both.

I speak of typhoid and remittent fevers together, not from their pathological but from their clinical relationships. The former would involve questions outside the scope of this paper. Still I may remind you of the spirited discussion of this question by this society three years ago, which settled only one thing clearly, which was that the typhoid of one observer was quite liable to be the remittent of another, and *vice versa*, the treatment of both, however, displaying the closest similarity. It seemed to be the general experience that cases of fever possessing all the clinical features of typhoid often occur side by side with those distinctively remittent, and that the two classes shade so insensibly together as to puzzle the most experienced in making a differential diagnosis. It is this clinical relationship of those fevers which renders the name "typho-malarial" convenient if not accurate, and which justifies the rather narrow line of routine treatment addressed to both.

For my purpose it is not necessary to particularize this, but to refer only to the one indispensable agent, quinine; indispensable because few physicians had the hardihood to disregard the canons of the Fathers which required its use, whatever they did with the collateral treatment that might be associated with it.

I felt myself so bound for years, an unwilling subject, for it was my fortune to see but few cases where the quinine treatment was of marked benefit, while I saw many in which it did unequivocal harm as long as its use was persisted in. I never knew it to abort the fever, given in any safe quantities and at the earliest moment. It never distinctly shortened it, at whatever stage its administration was begun, in whatever quantity given, and to whatever length of time. Given early it often seemed to hasten the occurrence of delirium and adynamia, and to accentuate the character and degree of each. Dryness of the mouth and sordes, absent before or slight in degree, would promptly follow its use, irrespective of its effect upon temperature, which was by no means uniform, and the more distinctive typhoid phenomena later on would be favorably modified only exceptionally, and then, as it would usually seem, only when these phenomena approached those of a genuine septicæmia. I am far from saying that there is no stage or condition of those fevers where quinine can be employed with tolerably uniform advantage, but that it is seldom found earlier than the end of the second, or the beginning of the third week and, except in sepsis from intestinal lesions, only in tonic doses.

The antipyretic salicylic acid and its salts, so fortunate in their earlier application, raised the extravagant hope that at last something approaching a specific in fevers had been discovered. Their experimental use, as such, became so general as to at least demonstrate the general belief in the inadequacy of former remedies; but, unhappily, it failed to convince the profession that anything better had come to take their place. Such experiments were generally, if not always, limited to the acid and its salts of soda and potassa. Generally the soda salt was the one used, doubtless because of its superior success in the pyrexia of rheumatism, and because of the general acceptance of the theory that both the acid and its different salts are at once changed in the system into the sodium salicylate. Some still adhere to this as superior to the classical antipyretics, a conclusion which my own experience with it does not sustain.

At the meeting of the American Medical Association in Washington, Dr. S. K. Jackson, of Norfolk, Va., submitted a paper on the "Ammonia Treatment of Typhoid Fever" remarkable in its record of successful cases, and still more so for the startling theories of the author concerning the pathology of the disease and the rationale of a successful treatment. Forgetting these theories—vagaries, I had nearly said—and remembering only their substantial fruits, because in harmony with what I had myself recently observed, I was, and still am convinced that his paper was the most valuable contribution to the therapeutics of typhoid fever that has appeared in recent years. The ammonium salts he employed were the nitrate, the acetate, the carbonate and the hydrochlorate, each in its appropriate stage of the fever, and in its well marked indications, and he did not hesitate to affirm that, one and all, they constituted the sole necessary treatment.

The year before this paper appeared I had seen a

¹ Read before the Wisconsin State Medical Society, at its Annual Session, June, 1886. From report of Committee on Materia Medica and Therapeutics.

number of cases of an exceedingly malignant type of the fever in consultation with a medical friend. Five adult members of a family had been stricken in succession; three had died, and the other two seemed in the last extremity. One of these had intercurrent pneumonia and gangrene of the lung. The treatment had been strictly orthodox in all particulars, in one case embracing the cold pack and cold affusion, with free alcoholic stimulation in all. In the remaining two cases it was determined to discard all former remedies with the exception of opiates in moderate quantities, and to rely upon the carbonate of ammonia for stimulation, as advocated by Stokes. These cases recovered.

Two years ago quite an endemic of remittent fever occurred in Neenah, the malady often assuming a distinct typhoid type, attacking several members of a family. Two of my earlier cases died under the classical treatment. My own son, a lad 8 years old, sickened and rapidly grew worse until his condition became grave in the extreme. I dared not depart from the old ways with him, although a trusted colleague and friend was in almost hourly attendance during the worst. I felt bound to them by fear and hope until the last moment. There were suppression of urine and uræmic coma in his case, and I feared to give carbonate of ammonia as a stimulant, for has it not been said that uræmia is not *uræmia*, but *ammonæmia*? Moreover, as a condition consequent upon this, there was œdema of the lungs, and surely I could give ammonia only at peril of strangulation. At last in desperation I administered it cautiously, 2 grains every two hours. It did no harm, but it seemed to do no good, and the time shortly came when it seemed to my faithful colleague that the boy was dying. His extremities were cold; his finger nails were blue, his lips livid, his face leaden, and the rattle that precedes death was in his throat. Death seemed inevitable and imminent. But he was my only boy, and I had the desperate courage to strangle him if need were, in the frantic effort to do something for him as long as he should live. I gave him the ammonia every fifteen minutes, with what difficulty you can imagine. The boy lived, but had he been any other on the wide globe, and under my care, he would have died.

This is how I came to venture upon the ammonium treatment of typhoid fever. But I also ventured upon a radical departure at the outset. I reasoned that the rational remedy must be the ammonium salicylate, for reasons which need be only alluded to. Its germicidal properties, possessed in common by all salicylates and its antipyretic and antiseptic powers, would at least give promise of effectiveness in modifying if not aborting the course of a fever. It would certainly avail in hyperpyrexia, it ought to fortify against systemic contamination from intestinal ulcerations, and whether or not it were to be decomposed in the body, and thus produce a nascent ammonium carbonate, it should, in common with all ammonium compounds, serve as a stimulant, which could be strengthened at will by the addition of ammonia in excess.

I had cases enough for a guarded, and finally a

confident trial. In the first one, that of a young man with all the symptoms of commencing remittent fever, I had the good fortune to be called on the first day of high temperature, 104°. A drachm of the ammonium salicylate in divided doses brought this down to 100° within twenty-four hours. A day later he was out on the street. Several similar cases followed at intervals, with the same result, so that I saw them but two or three times. Often patients with prodromic symptoms of fever would call at my office, and after prescribing I would lose sight of them and not learn the result. Probably this was not uniformly good, and it is within the bounds of possibility that not all of them needed medical advice. I saw some others where the same opportunity for abortive treatment presented, but without the same happy result, although a mild run of short duration was secured in all. Others, seen perhaps after a week of fever, ran the usual course with a medium temperature, with general symptoms of extreme mildness, and with uniform recovery. Two only reached the danger line, passing perilously beyond, but they also got well. Several of these cases were complicated with pneumonia. To them I gave the remedy with ammonia in excess, as I also did to the grave cases already mentioned. Some of them received a small Dover's powder two or three times a day, but there was far less frequent need of it than there usually seems to be. Of all of them, and of others occurring subsequently, only the two seemed unresponsive to the treatment. Most of them answered surprisingly, and all of them satisfactorily. The effect upon temperature was very uniform. Not seldom this was found as high as 105° at the beginning, but whether high or moderate at this stage, it nearly always came down promptly to 100°, to reach normal within a day or two more, in cases recovering at this point, and varying from 100° to 102° in cases reaching the third week.

A case of puerperal septicæmia occurred about this time, developing pelvic cellulitis and pneumonia. The latter seemed to involve one entire lung and the base of the other. The temperature when those complications arose was 106°. The patient's pulse was feeble and irregular, her face livid. The prognosis was grave enough. A drachm of the salicylate of ammonia given through the night reduced the temperature to 101°, and it never rose but one degree higher. The patient's recovery was rapid and complete. Excepting digitalis the salicylate was the only remedy given, opium being contraindicated by the deficient and labored respiration.

The next case of the same nature, without the pneumonitis, did not fare as well. Her temperature was 104½°, but it fell off three degrees within twelve hours. Twelve hours later it remained the same. The patient looked and felt so comfortable and well that I told her that I would wait to hear from her before calling again. Two days later I was sent for to find her as bad as ever. She had felt so well that she thought it unnecessary to renew her medicine after it was all taken. I directed an immediate return to it, but it did not avail. She grew rapidly worse and died a few days later. I have never felt wholly

blameless for this death, although recovery might have been impossible at best.

Something like a dozen cases have come under my care since, including those, a majority, following early abortions. In nearly all, cellulitis was present; in some peritonitis and in a few inflammation of the lung or pleura. With one exception they all recovered promptly, and this one after a dangerous run of more than two weeks. In all of them a prompt reduction of temperature followed the administration of the salicylate, with or without the help of opium, and nearly always without the use of the hot or the antiseptic injection.

In ordinary attacks of pelvic cellulitis, arising often from indeterminate causes, all of the salicylates have proved of value, and are probably unsurpassed by other remedies.

A case of gangrene of the lung following entire hepatization of one side came to my care in the second week. I employed quinine with the ammonium salicylate, but several times tried the effect of suspending one and then the other of the remedies. The quinine was not missed, but high temperature and hectic ensued when the salicylate was omitted for even a few hours. Whisky was also given for prudential reasons, as the patient had been a hard drinker. He recovered completely and is still, after nearly two years, in excellent health.

In a case of pulmonary gangrene attending tuberculosis the salicylate proved far superior to all other agents, but, of course, could not avail to save life. Death by asthenia was evidently deferred for many weeks, the patient's comfort being promoted unmistakably.

In the septicæmic state of the last stage of tuberculosis it has often mitigated the fever and other distressing symptoms where quinine failed or could not be borne. It has even served to lessen the cough, or at least to promote the action of other agents addressed to that symptom.

Its favorable effect in the pneumonitis complicating other affections, led me to employ it in idiopathic pneumonia, as its indication was also clear from the well-known benefit of both the chloride and the carbonate. In all these cases a varying excess of ammonia was given. They all terminated in recovery after the usual course, characterized, however, by unusual mildness. It is not to be forgotten that pneumonia is a self-limited disease, with a tendency to spontaneous recovery. Nevertheless, recovery does not always occur, and sudden death from embolism is an event of sufficient frequency, even among cases of a mild character and with a hopeful prognosis. Bearing in mind the possibility of this accident in all cases, we may turn with favor to any agent that promises to guard against it more effectually than those hitherto employed, and this, it seems to me, the ammonium salicylate does. With me it has largely superseded all others except opium.

Since beginning this paper last week I have been afforded the opportunity of employing it in the high temperature of cerebral meningitis. I used it because two recent cases of the same age ended fatally under the customary treatment. This one, a child

4 years old, had been ill a day, with intense headache, delirium, and almost constant vomiting. Her temperature when I first saw her was 105° . Three grains of the salicylate every hour and a half or two hours, and the ice-cap to the head, reduced this four degrees by the next morning. The vomiting was greatly lessened, but delirium was more pronounced and constant. The pupils were contracted and insensitive, and the urine was discharged involuntarily. The temperature rose one degree during the next day, then fell to normal, when it seemed that convalescence was assured. But this hope was illusive. On the sixth day the temperature rose suddenly to $103\frac{1}{2}^{\circ}$. The ice-cap, which had been left off for two days, and the salicylate, which had been practically abandoned, were restored, with the effect of reducing the temperature to 101 and 102° , between which points it still—on the eighth day—vacillates, while there is absence of delirium and a general condition which affords a very favorable prognosis.

A case in which I gave the salicylate through an initial error in diagnosis will serve to point out one of its probable dangers. It was that of a man about 35 years old, who was taken with chills and high fever, severe headache and uncontrollable vomiting. It seemed to be a commencing remittent. He lived a long distance in the country, and as it was late at night I gave such remedies as I had with me and prescribed the salicylate of ammonia for the next day. The next evening I found him in a semi-coma, with urine suppressed, and all symptoms of the gravest omen. Then I elicited from his wife a history of Bright's disease of some two years' duration, and discovered, when too late, that this was an acute exacerbation. It is presumable that the case might have ended fatally under any treatment, but I am inclined to think that the action of the agent employed was unfavorable, and now I should never give it when there were undoubted renal lesions, either acute or chronic, and should watch its effect with solicitude where there was a tendency to anuria from any cause.

In concluding this report I desire to say that I have not attempted to present to this society a panacea for the various affections it enumerates. Probably this will never be discovered. But I fully believe that the results already obtained will justify further investigations upon a much larger scale. My own cases have been far too few to establish definitely the superiority of the salicylate of ammonia, in the line of treatment to which it has been addressed. The clinical material afforded by a country practice during so short a period is necessarily too limited. Still, it does not seem too much to say that the following conclusions may be provisionally accepted:

The salicylate of ammonium is to be ranked among the most efficient of the antipyretics.

As an antipyretic in all fevers characterized by extreme adynamia it ranks among the safest, owing to its ammonium base.

It is stimulant as well as antipyretic, and thus of itself fulfils indications otherwise only met by a combination of remedies.

It is an agent of wide germicidal powers, being promptly efficient in affections of great etiological

and pathological differences, each confessedly arising from its own proper specific infecting micro-organism.

As a remedial agent in typhoid and remittent fevers it is unsurpassed, aborting them at the outset, under favorable conditions, and greatly mitigating their severity and danger under circumstances less favorable.

It is entitled to confidence in the treatment of pulmonary inflammations, either idiopathic or septic, and probably eliminates the dangerous factor, embolism, with greater certainty than any other prime curative agent.

It is the most efficient known remedy in puerperal septicæmia and probably also in most septic inflammations of non-puerperal origin.

It is worthy of a trial in non-tubercular cerebral meningitis, as it gives some promise of relief in an affection which has hitherto resisted, if not resented all modes of medical treatment.

Since the submission of the foregoing report the clinical material at my disposal has enabled me to fortify its conclusions by additional data.

The case of cerebral meningitis referred to recovered completely, partial deafness, however, continuing several weeks.

Another case convalesced at end of second week, the symptoms during four or five days denoting great danger. Among the earlier of these were repeated convulsions. In this case the ice-cap could not be employed, and evaporating lotions had to be used instead; which, it seemed to me, could have afforded but little help to the constitutional treatment, either in the control of the cerebral circulation or the high temperature.

Some twenty five or more cases of typhoid or allied fevers have been under my care during the present autumn. At least this number, had they been left uninfluenced by medical treatment, would have pursued, with substantial fidelity to the clinical history of these fevers, the usual course.

With one exception they were subjected to the salicylate of ammonia treatment only, and uniformly without alcoholic stimulation, and with the exception noted they all recovered. Of these cases all were convalescing by the close of the second week. To speak more definitely, three showed entire absence of fever on the twelfth day, three more on the ninth; all the rest were convalescent at the end of the first week or earlier.

The case in which the ammonium treatment was not strictly adhered to died on the ninth day of the fever, two days after the occurrence of an enormous nasal hæmorrhage. Epistaxis had occurred several times before I saw the case, and it was an almost daily phenomenon throughout. Thinking that the salicylate of ammonia might contribute in some degree to the existing hypinosis, I substituted quinine for it, without, however, improving this condition in the least. The prognosis was extremely favorable up to the day of the severe hæmorrhage. After this the decline was phenomenal in its rapidity.

In the cases recovering after but few days of fever there was, not seldom, a tendency to relapse or return of high temperature, where the antipyretic was

prematurely withdrawn. It seemed analogous to the recrudescence of rheumatism frequently observed in the too early abandonment of salicylic acid. I soon learned from them the necessity of continuing the remedy in reduced quantity and at lengthening intervals during several days of normal temperature. With this precaution, when the fever leaves it ends definitively.

MEDICAL PROGRESS.

PASTEUR AND FRISCH.—Among the vast number of criticisms to which M. PASTEUR's prophylactic treatment of rabies has been subjected, none has been more often repeated than the contention that in attempting to treat human beings after the infliction of the bite, he was going beyond the warrant afforded by his experiments on dogs. M. Pasteur had indeed said that even when he inoculated the first human being, on July 6th, 1885, he was not performing an experiment entirely new to him, but there was a great deal of obscurity on this point, and when Frisch, of Vienna, published certain experiments tending to show that dogs could not be protected by inoculations made after infection by trephining, many writers were ready at once to draw the conclusion that M. Pasteur's method was not applicable to human beings, who, of course, would never be inoculated except after a bite. In his paper at the Académie des Sciences on November 2, M. Pasteur admits that Frisch's results are correct, but does not accept the conclusion that his method in its application to man, is thereby put out of court. With, perhaps, a truer scientific instinct than has been shown by his critics, he at once proceeded to vary one of the terms of his experiment; he altered the method of inoculation so that the protective influence, if such existed, might be earlier exerted. With this object he began the preventive inoculations on the day following infection, and repeated them rapidly, so that the whole series of cords was used in one day, instead of during a week or ten days as previously; then on the next day the treatment was recommenced, and inoculations made every two hours; the course might even be repeated a third time. In this way M. Pasteur has succeeded in preventing the development of rabies in dogs inoculated with virulent material by trephining. "The success of the preventive inoculation of animals after infection by trephining, depends," he says, "on the rapidity and the intensity of the vaccination."—*British Medical Journal*, Nov. 13, 1886.

NEW METHOD OF DILATING THE UTERUS.—DR. VULLIET, professor in the Medical Faculty at Geneva, communicated at the meeting on April 6, 1886, of the Academy of Medicine in Paris, his new method of dilating the uterus, and its application in the diagnosis and treatment of uterine disorders. The following is a summary of the communication. His method (1) renders possible the direct inspection of the whole uterine cavity; (2) permits the dil-

atation to be continued whatever, be its degree, as long as desirable and necessary; (3) affords at the same time the most efficient antiseptic dressing. Professor Vulliet dilates the uterus by plugging the cavity with iodoform tampons, which he leaves. Eight to ten pluggings, repeated every two to eight hours with gradually enlarged tampons, will on the average suffice to render visible the cavity, the patient being in the genu-pectoral position. A dilatation of sufficient degree as to open to view the whole interior, facilitates the diagnosis and treatment of all affections of the cavity. Professor Vulliet has employed it in the treatment of cancer, of submucous and parietal fibro-myomata, and of chronic endometritis. He has obtained, within eight months, complete cicatrization in four cases of uterine cancer, and is hopeful about these local cures. Time, however, must prove whether they be permanent. In parietal fibro-myomata, this method, without endangering the layer of tissue which separates the tumor from the cavity, permitted incisions to be made in order to transform the parietal neoplasm into an easily removable polypus of the cavity. In endometritis, the dilatation facilitates the scraping of the mucous membrane by means of the curette, and a consequent energetic typical treatment. Without pushing dilatation to its extreme possible extent, Vulliet's method will prove very useful on account of the long duration of the dilatation, and that especially in strictures and deviation of the cervical canal, and in all operations which require the repeated and frequent introduction of the finger or of larger instruments. Moreover, this method—by its very principle, the plugging with antiseptic substances—is applicable in every case in which virulent processes are evolved in the uterus—viz., puerperal, catarrhal, and blennorrhœic infections. Professor Vulliet, requested by M. Léon Labbé to demonstrate his method in the Hôpital Beaujon, succeeded within twenty-four hours in dilating the uterus sufficiently to permit full inspection of the fundus. He has since frequently operated after his method for cancer of the uterus in private practice, and, by invitation, in several hospitals.—*London Medical Record*, October 15, 1886.

ANTAGONISM BETWEEN ATROPINE AND MORPHINE.—At a recent scientific meeting in Berlin, HERR LENHARZ, of Leipsig read a paper (*Prager Med. Wochenschr.*, No. 42) on the alleged antagonism between atropine and morphine, considered both clinically and experimentally. He had come to the conclusion that no such antagonism existed, for the following reasons: Firstly, the antidotal doses of atropine have far too wide a range. As a rule, enormous doses are given, often without success, while, at the same time, recoveries from morphine-poisoning are recorded after merely nominal doses of atropine (.015 grammes, and even less than this); secondly, the uncertainty of the indications. Johnston, of Shanghai, would resort to atropine in all cases, in spite of a weak irregular pulse, whilst Wood makes the condition of the respiration the criterion, and Binz discards the use of atropine if the pulse be

rapid and small; finally, atropine does direct harm. Binz had recommended atropine on experimental grounds, but Binz's experiments had not been sufficiently complete, that is, only enough morphine had been given to make the animals sleep, but not enough to give them convulsions. Animals killed by large doses of morphine did not die from lowered blood-pressure, nor from embarrassed breathing, but from the exhausting convulsions. Of 132 cases of morphine-poisoning, collected by the author, fifty-nine were treated with atropine, with a mortality of 28 per cent.; of the other seventy-three only 15 per cent. died. In eight experiments with morphine on animals, atropine made no difference—the animals died just as soon as without it.—*British Medical Journal*, November 20, 1886.

CAFFEINE IN HEART DISEASE.—DR. OTTO SEIFERT (Würzburg) undertook, in the course of last year, a series of researches on Citrate of Caffeine. All the patients to whom he administered it were suffering from organic affections of the heart with imperfect compensation. In one case there was chronic nephritis, with generalized oedema. The caffeine was given in seven cases, sometimes in repeated doses, in others all in one dose. According to Lepine, the daily quantity should be from 1 to 2 grammes. The principal advantage which has been claimed for it is that it quickly improves the action of the heart and regulates the cardiac beats. It is also a diuretic, and has no cumulative action. One to 2 grammes of caffeine should be given in twenty-four hours. Opinions as to the value of the drug are conflicting; the principal drawback to its use seems to be that, owing to its speedy elimination, its action only lasts for a short time. In those cases where compensation has been reëstablished, the action of caffeine may be as prolonged as that of digitalis. The general condition is influenced in a striking manner; the palpitations, the dyspnoea, and, as a rule, the insomnia also rapidly disappear.—*British Medical Journal*, November 20, 1886.

LANTANIN, a new alkaloid with antifebrile properties has been discovered and examined by Buiza and Negreta in Lima. It is obtained from a verbenaceous plant, *L. Brasiliensis*, and its effects are retardation of the circulation and tissue-changes, and considerable lowering of the temperature. It is well tolerated where quinine cannot be taken, and in doses of 15 or 20 grains daily cured 95 per cent. of intermittent fever cases treated by it.—*London Medical Record*, October 15, 1886.

CHLOROFORM has been found very efficient against tapeworms. Doses of 2 grammes have been given, repeated after twenty or thirty minutes, but troublesome cardiac symptoms may be avoided by giving much smaller doses (a few drops) every few minutes for a few times. Thompson successfully prescribed chloroform ʒj. (by weight), simple syrup to ʒj., to be given in three doses, at intervals of two hours, in the morning, fasting, with castor-oil to follow.—*London Medical Record*, October 15, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

SATURDAY, DECEMBER 11, 1886.

FIBRINOUS OBSTRUCTIONS OF THE VASCULAR SYSTEM.

It is now thirty-six years since DR. B. WARD RICHARDSON revived the neglected study of diseases in which the circulation is arrested by what the older authors called "polypi," and which we term fibrinous deposits. In the last number of *The Asclepiad* Dr. Richardson again calls attention to this clinical condition in a paper entitled "Some Practical Notes on the Diagnosis and on the Ammonia Treatment of Fibrinous Obstructions in the Vascular System."

In regard to the diagnosis, Dr. Richardson says that in at least eighty per cent. of the cases he has seen that the seat of obstruction has been in the right cavities of the heart; in eleven per cent. the obstruction has been in the large veins, the iliac and the femoral; in six per cent. the obstruction has been on the left side of the heart; and in three per cent. the symptoms of obstruction were simulated—"they were hysterical in character, and although very embarrassing, were not cases presenting the really dangerous indications of vascular obstruction. The diseased conditions under which obstruction takes place in the right cavities of the heart are usually acute and are what is commonly called inflammatory. They are cases of puerperal fever, surgical fever and erysipelas, pneumonia, croup, diphtheria, peritonitis, septic fever." All his acute cases, constituting the large majority of the whole series, may be included under this group, with the exception of one case, which occurred during the later stages of pregnancy, without any preliminary stage of inflammatory character. "In the acute inflammatory cases the symptoms indicating obstruction from fibrinous separation

on the right side of the heart are usually rapid in the manifestation. They may be reduced to the following seven indications: 1. Apnoea. 2. Fulness of the veins. 3. Failure of the arterial pulse. 4. Reduction of animal temperature. 5. Pallor of the general surface of the body. 6. Collapse of the physical and mental powers. 7. Symptomatic physical signs."

Taking these symptoms in order, the first, which is subjective and objective, and most apparent and distressing, is apnoea, the want of breath—a breathlessness with open air passages, with perfect freedom from pulmonary obstruction, and with freedom of respiratory mechanism; and to this condition Dr. Richardson has given the name *cardiac apnoea*. It is not due to the failure of the air to reach the air-cells of the lungs, but to the fact that the blood does not reach them in sufficient quantity, and the respiratory effort is made to no efficient purpose, since the blood is arrested on its way to the lungs through the right cavities of the heart. The respiration is rapid, heaving, and sighing, and the patients, when they can describe what they feel, always refer the difficulty to the heart: in the words of a patient: "I can breathe freely enough, but it does me no good." The second symptom, fulness of the superficial veins, is especially seen in the veins of the neck, and sometimes in the veins of the extremities. If one of these veins be compressed by the fingers it does not fill more than it is already filled on the side farthest from the heart. We know that this is a useful point in the diagnosis of other forms of disease, but in these cases it is singularly characteristic, as showing that the right side of the heart cannot freely receive the blood which should flow into it. In some cases the observer may detect a regurgitant movement of the blood in the veins of the neck. In this connection we may refer to the editorial article on "Hepatic Pressure, and the Condition of the Right Side of the Heart," in THE JOURNAL of July 24, based on an article by Dr. W. Pasteur in the *Lancet*, of May 15, 1886, in which he shows that in cases which give evidence of great over-distension or failing compensation in the right heart, there is a distension or over-filling of the external jugular veins, apparently from below, with or without pulsation or undulation, which takes place when pressure is exerted in the right hypogastric or epigastric regions with the flat of the hand, the direction of pressure being backwards and upwards.

In regard to the third symptom, failure of the arterial pulse, it may be quick or slow, but it is always thin and feeble; and except at the time of death it is rarely, if ever, intermittent or ir-

regular. This peculiar pulse is all the more noticeable as the action of the heart is often forcible, and even bounding, from the fact that the heart, though contracting on a diminished current, is excited by the pressure of the semi-fluid, mass which is retained in its cavities, into quick contraction. Cardiac overaction with diminished arterial tension thus run together diagnostically in these conditions of life. The fourth symptom, reduction of animal temperature, may take place very suddenly. Dr. Richardson alludes to a case in which the temperature fell from 105° to 98° F. in one hour, and to another in which the temperature was reduced to 96° F. some hours before death. The reduction begins in the extremities, usually in the feet, and extends towards the trunk; though the patient rarely complains of it. We are all, perhaps, familiar with this sudden decline in temperature, to the extent of one or two degrees below the normal when the certain signs of obstruction are fully developed. The *pallor* which overspreads the body is also of a familiar symptom—not a strictly anæmic pallor, but one tinged with a bluish shade, producing lividity. This sign is especially noticeable on the cheeks, where the normal red or reddish color is replaced by the lividity.

The physical and mental collapse is a marked symptom. "The muscular prostration is marked by restless tossing and failure without convulsion. After a time the muscles themselves collapse, the abdominal muscles are drawn in deeply with each respiration, and the power of the voluntary muscles to perform any resolute act subsides. The mental prostration is equally marked. There is no apparent desire to effect anything except to breathe. The mind does not wander, neither does it sleep. A patient who recovered told me she knew everything that was going on all the time, but in such a listless way that she had no real interest in the anxious plans which we were carrying out to save her life, for which listlessness she said, in apology, that 'she hoped she should be excused, because she was only half alive.' To the end of life there is no active convulsion: the mind loses its consciousness before the respiration ceases, and death, when it comes, is usually by a kind of coma, with asthenic or slow syncope." The *symptomatic physical signs* yielded by auscultation are not such as would be at first suspected. Cardiac murmurs are not heard, as a rule, since the soft mass of fibrine acts as a damper or muffler of the sounds produced by valvular tension, or holds down the valves by becoming attached to the cords, and crossing their free margins. The most diagnostic physical sign, then, is a deficiency in the fulness of the first

sound in the early stage, to which we must add the differentiation of the sounds proceeding from the two sides of the heart. With a differential stethoscope and a little careful practice one may easily make out this point. "With one mouth of the stethoscope over the seat of the tricuspid, the other over the seat of the mitral valves, we listen for the sound produced by the combined tension; raising the mouth of the tube over the mitral, we find that the sound is all but lost; then putting down the mouthpiece over the mitral, and raising that over the tricuspid, we hear the stroke nearly, if not quite, as perfectly as when both mouthpieces are down in their respective places. "In very extreme cases, the physical diagnosis may extend to the second sound of the heart. The second sound may be differentiated as reduced or lost on the right side. This tells that the coagulum extends beyond the pulmonary semilunar valves; and after death in such instances, the clot will be found impressed with the figure of the valves as distinctly as such an impression can be made on plastic material."

These, then, are the seven distinctive signs, and are sufficient to establish the diagnosis as clearly as any kind of physical diagnosis, as known at present, can determine any diagnosis. But with these there are sometimes certain pulmonary symptoms—exceptional, it is true—which are also strikingly diagnostic. One is a sharp, dry respiratory murmur. The most significant, however, is emphysema, which may be extreme in infants and young children in whom the right heart is obstructed by fibrin. It may be so extreme as to raise up the anterior wall of the chest into a rounded prominent form, almost immobile. This emphysema is "produced by the forcible efforts of the patient to inflate the lungs, at a time when the vascular plexuses surrounding the air vesicles are so deprived of their blood that the balancing blood-pressure is reduced."

We now come to the diagnosis of obstruction of the left side of the heart. The most common positions of fibrinous deposits or concretions on the left side of the heart are the ventricle, the infundibulum, and the ascending portion of the aorta. The general symptoms of this particular condition differ from those of the preceding in many respects: "There is suffocative dyspnoea, with expectoration of mucus, sometimes mixed with blood; the surface of the body is of a leaden color, and the body is cold. The muscular perturbation lapses into powerful convulsions, and coma precedes dissolution. These symptoms may extend over many hours; or, as in the preceding class of cases, they may also occur in a sudden manner. The patient, in moving or making a straining

effort, may suddenly fall back, may be seized with a sudden convulsive fit, and so expire." But the cardiac physical signs of obstruction of the left heart do not differ materially from those found in obstruction on the right side, as regards the systolic and diastolic sounds: "for, if the right side of the heart is free, the two sets of valves on that side are all-sufficient to produce the two sounds; so that a mere reduction in the intensity, or rather the fulness, of the normal sounds, is the only probable modification." But there is a distinction in the action of the heart when the concretion is on the left side: the heart's action is much more violent, irregular and tumultuous. The difference in the physical signs on the part of the lungs is found in the fact that the lungs are not made emphysematous. They are always congested, and the congestion is decided and extensive. The dyspnoea is of the pure pneumonic type, and not the syn-copic dyspnoea of the previous condition; the oppression is in the lungs, and is so recognized by the patient.

When masses of fibrin are precipitated in the blood-vessels the diagnosis of the condition may be difficult or very easy. In large superficial vessels like the femoral vein the deposit may be detected by the touch, being felt in the line of the vessel as a firm, large, perhaps knotted mass; the vein is dilated, and pressure, however gentle, usually causes pain. The condition may cause oedema below the seat of obstruction. When such deposit occurs in a vein within a cavity, such as the abdominal, the diagnosis is more difficult; though it may sometimes be felt by careful manipulation when the body is well flexed, and if there be no distension or swelling over it. This deposit of fibrin within the veins is usually sudden, generally occurring in connection with one of the forms of pyrexial disease already mentioned, and especially with fever following parturition. Obstruction on the arterial side of the circulation is evinced by coldness and numbness in the parts from which the blood-supply is cut off, and is usually announced by sudden symptoms, which disappear when anastomosis is established, if the vessel blocked be not of such size as to cause gangrene of the limb below by complete obstruction of circulation.

Dr. Richardson says that his long experience has shown him that the only rational means of treating these cases is by the free use of ammonia, carried to the point of causing re-solution of the obstructing fibrinous masses; and this method was proposed by him in 1854. Alcohol, opium, ether, and other antispasmodics are useless; and he gives the following rules for treatment: 1. The ammonia is best administered

either in the form of the strong aqueous solution or of the saturated alcoholic solution. More than five minims at a time cannot be easily swallowed. The best menstruum for the ammonia is milk, and if the milk be chilled by ice the patient takes the mixture with great facility. 2. The ammonia must be relied upon exclusively. Sedatives of all kinds are to be avoided as fraught with danger. Wine and spirits are most injurious; they produce a danger of movement of the fibrinous masses, they excite, and, in time, exhaust the heart. 3. The diet should be, as nearly as possible, of pure milk, with an occasional change to gravy soup or minced cod-fish, with bread or toast. Other solid substances do not digest readily; they create flatulency, and cause a restless movement of the body, which is detrimental. 4. With the medicinal and dietetic treatment thus enjoined there must be combined the most perfect rest of the body in one position. The secret of success consists in producing solution of the obstructing mass while it lies sufficiently out of the course of the circulation. If it loosen from its hold and be carried into the pulmonary artery while it remains semi-solid, however small it may be, it will be a source of fatal danger. 5. Together with this physical rest every mental comfort, must be supplied. The patient must be harassed with no unnecessary fears, agitated by no unnecessary comments. Much of the success of the treatment depends on the gentle firmness with which the practitioner enforces that the greatest advantage is secured by absolute repose of the mind as well as the body. 6. When the secondary changes indicate the solution of the fibrin and its distribution over the vascular system, the administration of the ammonia is not to be withdrawn. The alkali is indeed as important under these circumstances as in those which precede them. 7. The conditions warranting the withdrawal of the solvent are: entire subsidence of the difficulty of breathing; relief of the tension of the veins; returning fulness of the pulse; normal temperature; restored mental and physical power; and steadiness of motion of the heart, with perfect clearness of the sounds. When these favorable conditions are proclaimed it is fair to infer that no obstruction is present in the circulatory canals, and that the ammonia may be withdrawn. But inasmuch as the ammonia, however far it may, with reason, be carried, does no injury that is not quickly recovered from, there exists no cause for hurry in withdrawing it. It may, therefore, be continued in less frequent doses for a few days when every danger appears to have passed away.

MONUMENT TO DR. BENJAMIN RUSH.

Partly by liberal appropriations of Congress and partly by State action, statues and monuments have been placed in the Memorial Hall of the Capitol and in the numerous parks that adorn the city of Washington, commemorative of many of the patriots, warriors, statesmen, jurists, scientists and philanthropists of our country, but thus far no member of the medical profession is found among them. And yet, history shows that the medical profession of our country has furnished examples of as ardent patriots, as brave warriors, as wise statesmen, as profound scientists, and as enlightened philanthropists, as have been furnished from the ranks of any other profession or calling. The defect is not from the want of meritorious names highly worthy of commemoration, but rather from the failure of the profession itself to initiate the movements necessary to secure the proper visible monuments commemorative of their own illustrious dead. Attention was directed to this subject during the annual meeting of the American Medical Association in Washington in 1884, and a Committee was appointed to consider and report some practicable plan of procedure. The Committee, through its Chairman, Albert L. Gihon, M.D., U. S. N., subsequently submitted an interesting report recommending the erection of an appropriate statue of Dr. Benjamin Rush, of Pennsylvania, at an estimated cost of \$40,000, the money to be contributed in small sums by members of the medical profession in all parts of the United States. The report was approved by the Association, and the Committee continued, with the addition of one member from each State and Territory, to carry the enterprise to its final completion.

To make the pecuniary interest in the monument as general throughout the profession as possible, the Committee decided to solicit subscriptions of \$1 only from each individual, though larger sums will not be refused. The member of the Committee in each State is expected to solicit and receive contributions of the profession of the State or Territory he represents, and transmit the same to the Treasurer of the Committee. The officers of the Committee are Albert L. Gihon, M.D., Chairman; George H. Rohé, M.D., of Baltimore, Secretary; and Joseph M. Toner, M.D., of Washington, Treasurer. When it is remembered that Dr. Benjamin Rush "was not only a great physician, teacher, and investigator in medicine; a philosopher, philanthropist, elegant lecturer and accomplished writer; but also a fearless patriot, a founder of the Republic, a member of the Conti-

mental Congress and one of the Signers of the Declaration of Independence, the first Surgeon-General of the Army of the Revolution for the Middle Department and Physician-General of Military Hospitals, and a member of the Convention for the adoption of that Federal Constitution under which we now live," and, of not less importance, a man of pure and Christian life, every American physician should feel a just pride in contributing his *mite* to ensure the erection of an enduring monument to his memory in an appropriate position among the many already adorning the Capital City of our country. Indeed, we think no physician should wait to be called upon, but enclose his *dollar* direct to the Treasurer of the Committee mentioned above.

SOCIETY PROCEEDINGS.

CHICAGO MEDICAL SOCIETY.

Stated Meeting, Nov. 15, 1886.

THE PRESIDENT, EDMUND J. DOERING, M.D.,
IN THE CHAIR.

DR. LESTER CURTIS read a paper on

THE ABSENCE OF THE PATELLAR TENDON REFLEX,

in which he enumerated a number of cases of persons in apparently good health in whom the patellar tendon reflex cannot be elicited, such being the case with the author himself. He quoted from authors who had made similar observations, and who had also found the patellar tendon reflex present in diseases in which it is not expected. These variations in the presence and absence of the patellar tendon reflex were so frequent that he was inclined to question its absence as an important sign of nervous disease. He believed it to be a sign that had received undue attention.

DR. D. R. BROWER, in opening the discussion, said: I have been very much interested in Dr. Curtis's paper. I have found the patella tendon reflex occasionally absent in health, but very rarely. Since the suggestion was made by Jendrassik that an effort be made to increase the general muscular tension by having the person pull upon the fingers of one hand linked into those of the other, which was brought to my attention about a year ago, I have been able to elicit the patella reflex in healthy persons when otherwise I would have failed. I think it is necessary in doubtful cases that the blow be struck upon the naked limb. I think it is occasionally absent in health, and it has been my habit in teaching to always say in regard to the patella tendon reflex that it is the loss and not the absence—we have first to know that the person had patella tendon reflex before we can regard its absence as pathological. I have taken that view of the matter for a long time.

As to the presence of tendon reflex in locomotor ataxia, the President will remember one of the patients that I saw three or four years ago in whom patella tendon reflex was present and in whom all of the other symptoms of locomotor ataxia were present in a marked degree, and I have met with that condition in one or two other cases. I think that in these cases the degeneration has not commenced in the usual place. At the meeting of the American Medical Association an interesting paper on this subject was read by Dr. Zenner, of Cincinnati, who has made very extensive observations upon healthy people as well as upon the insane, with a view of determining the real value of this sign. And his opinion is in accord with my own, that if all precautions are taken it is a remarkable thing for it to be absent in a healthy person. In the case cited by the author there would seem to be a part of the spinal cord that was not entirely destroyed, possibly enough to admit of the passage of the stimulus from the sensory nerves.

DR. H. N. MOYER said, regarding the manner of eliciting the patella tendon reflex: Unless very great care is exercised in determining that the reflex is absent the observation has very little value. In testing this reflex I prefer to have the leg rest across the back of the wrist, by which means we easily detect any tension of the hamstring muscles, which greatly interferes with the reaction. As to the manner in which the tendon should be struck, I do not believe that the surface of the ulnar side of the hand is the proper thing to elicit it, and the ordinary rubber hammer is not quite heavy enough for that purpose. The best thing is a steel hammer with a small rubber tip. In doubtful cases care should be taken to percuss the tendon over its entire surface. I have seen a number of cases in which I supposed the patella tendon reflex was absent in undoubtedly healthy persons, but since this new manner of increasing muscular tonicity by lessening the inhibitory power of the brain over the lower spinal centres has been adopted, have never seen a case in which the patella reflex was absent in a healthy individual. There is one other point, in regard to the difference in the amount of the reflex obtained when this procedure is employed and when it is not. There are certain qualitative variations which have not been pointed out. I have under my observation at present two cases of chorea in which there is only the slightest evidence of patella tendon reflex on percussion in the ordinary way, but when the patients are required to clasp the hands and the patella is then struck the reflex is markedly exaggerated. I think in some cases this procedure will enable us to diagnosticate between the neurasthenia of cerebral and of spinal origin. I have one undoubted case of locomotor ataxia in which the patella tendon reflex is present. In the two cases of Westphal which have been recently published, the microscope revealed the morbid processes in the lumbar portion of the cord to be largely confined to the points of entrance of the posterior roots, and also to a slight extent involving the lateral columns. This probably obtains in the cases reported to-night.

DR. J. J. M. ANGEAR said: I do not know that we can come to the conclusion that our patient is suffering from locomotor ataxia when we find the patella tendon reflex absent. I have in mind a patient who was under my care about two years ago, in whom the patella tendon reflex was entirely absent. There was unsteadiness in gait, a little wavy motion when attempting to stand erect, with eyes closed and feet close together, and the patient walked with a cane. There were symptoms of congestion of the cord, a feeling of a heavy weight at the feet, that peculiar sensation known as girdle feeling, which improved on lying down. The patient improved somewhat under the use of mercury and iodide of potash (I learned afterwards that when a young man he had syphilis, but it has not shown itself since). This was two years ago, and the patient is no worse to-day, but it seems to me that he ought to be a great deal worse if it was locomotor ataxia. If we fail to elicit the reflex by simply striking the tendon, we can get it, if it is present, by engaging the patient in conversation about something foreign to himself and then suddenly strike the tendon. In regard to cases where it is absent in apparent health, I think we should emphasize *apparent*, for we have no positive evidence that the nervous system is in a normal condition in such cases, and I should be a little skeptical with regard to the patient's perfect health if I had taken all the precautions for securing this action and then found it absent.

DR. ROBERT TILLEY said: I wish to bear testimony to the truth of Dr. Curtis's observations. I certainly have seen a small number of persons that I considered average healthy individuals in whom I have not been able to elicit the patella tendon reflex. I have not caused the patients to bare the leg, but I have employed other devices to satisfy myself that if the tendon reflex was not absolutely absent it was certainly diminished in its activity. I would like to emphasize the fact that it seems under certain circumstances to be obtained when struck upon one side or the other when it cannot be obtained by striking the tendon in the centre. On several occasions it has struck me as desirable in post mortem examinations to have a microscopic examination of the tendon itself, and see if some peculiar changes might not be visible in it. I would ask Dr. Curtis if he knows of any histological investigations in that direction. I recently saw an article giving an account of a case where the tendon reflex seemed to be absent, but on the administration of a small dose of morphia it was elicited. No mention has been made of what may be called a normal tendon reflex, although the exaggerated form has been referred to, and I do not know whether any one here would venture to give a definition of a normal tendon reflex in opposition to an exaggerated one. I am certainly disposed to take exception to Dr. Curtis's explanation of the tendon reflex, that it is most likely to be found in individuals who are a little scary, are easily frightened, easily thrown off their guard, or persons of that character. I may instance myself. I do not think I should be easily thrown off my guard, but in my case the tendon reflex is markedly present, so

much so that those who would distinguish between the forms would say that mine was an exaggerated form.

DR. J. FRANK said: I have a theory as to why the tendon reflex might be absent in a healthy person. In order to get the reflex the tendon must be put on the stretch, and there are such things as abnormal patella tendons. If the ligamentum patellæ is abnormally long when the leg is flexed the tendon is not put on the stretch; if lax and cannot be made tense, it might be struck all day without any result. I think this will explain why in some people the tendon reflex is absent. When I was a student my preceptor tried it on me but could not get any tendon reflex; it seems that at certain times my tendon answers to the blow and at other times it does not; still I have been in good health all my life. Where the tendon reflex is absent without other symptoms the tendon should be examined.

DR. JAMES JEWELL said that in tendon reflex, when the muscle is struck a shock is given to the sense nerves. He had met with a large number of cases in which the patella tendon reflex could not be obtained by the ordinary impulse, but which he had been able to elicit by other means. He thought locomotor ataxia did not depend so much upon loss of sensibility in the muscles themselves as in the great numbness of the feet. He had had cases of locomotor ataxia in which the only symptom was acute sensibility to temperature, and another who had no sensibility on the right side except in the nates.

DR. JOSEPH ZEISLER read a paper on

THE USE OF ICHTHYOL IN THE TREATMENT OF SKIN DISEASES.

Dr. Zeisler gave his clinical experience with ichthyol in the treatment of over one hundred cases of skin disease. The strength of the salves varied from 3 to 30 per cent.; frequently other drugs were added as adjuvants according to the requirements of the case. All the usual ointment bases mix well with it. Ichthyol soap was found very useful for acne rosacea and sycosis. The physiological effects of ichthyol; its regenerative power, when used in a mild form, its resolvent action when used in full strength; its contracting influence upon blood-vessels, were explained from its chief quality, to draw oxygen from the tissues. In about twenty-five cases it was used internally in the form of capsules (0.10 pro dosi), three to ten of which may be taken daily. In this form Dr. Zeisler found it very useful in chronic cases, and thinks that it may frequently be preferable to arsenic. Very good results were obtained in eczema, fifty-six cases of which, comprising nearly all forms and stages of that disease, were treated with it; its effect and the mode of its application in the principal form is described and illustrated in the history of two cases.

In sycosis (eleven cases) and psoriasis (two cases), it was found to be a very good adjuvant. Excellent results were also obtained from internal and external use of ichthyol in acne rosacea (seventeen cases). In acne vulgaris (ten cases) it did not result beneficially except when used internally. In several other

cases, herpes tonsurans, prurigo and acne varioliformis, it was used in too few cases to allow of any decided conclusion.

DR. G. C. PAOLI said there is no one remedy that we can positively rely on in the treatment of skin diseases. This new remedy, ichthyol, was used by Dr. Unna, of Hamburg, but he combined it with other ointments. We cannot treat all the stages of skin diseases with the same remedy. Ichthyol has a fetid odor, and he should think it would be obnoxious in use. He has not had an opportunity to try it.

DR. E. J. KUH said: Not enough time has elapsed to express either a final condemnatory or laudatory opinion on ichthyol. The physiological experiments by Baumann and Schotten are entirely insufficient, and the conclusions reached are practically no conclusions at all. Our clinical knowledge has been sufficient to show its value in skin diseases. And as Dr. Zeisler has confined himself to a discussion of its use in his specialty, a few words bearing on the application of ichthyol in other diseases may not be out of place. Lorenz and Unna are its chief recommenders. The former in the beginning applied it in acute and chronic articular rheumatism, and to judge from the experiences of others (including myself) who have used it in this direction, there can be no doubt that it is a very strong adjuvant in this disease, and that the exhibition of salicylates is promoted in its efficacy when used in conjunction with ichthyol salve. Lorenz extended its use to gout, muscular rheumatism, contusions, gastric troubles, etc. Unna, whose enthusiasm is so unbounded as to inspire distrust, barely finds a limit to its usefulness. It is a mild anti-tuberculosum, has cured asthma in an eczema patient, will cause immediate demarcation in erysipelas, etc. It is a malicious characteristic of new remedies that they are wonderfully multiple in their therapeutic action. Time, the great enemy of the Pharmacopœia, is their surest test. Let us hope that it may deal gently with ichthyol.

DR. JEWELL thought a great deal of attention should be paid to the constitutional conditions, and especially to the neurotic aspect of cases of eczema. He had met with success in the treatment of skin diseases by a current of large quantity and mild intensity from an electric battery.

DR. JOHN A. ROBISON said that the literature on the subject of ichthyol is very meagre except what is found in foreign and special journals. He was sorry that Dr. Zeisler did not give a fuller description of the drug, in order that general practitioners might become more familiar with it. Undoubtedly many of the members present thought it a proprietary preparation, and therefore will not investigate its merits more closely. During the past year a large number of new remedies have been introduced which unfortunately bear a foreign patent, although the manner of manufacture is known. While opposed to prescribing secret proprietary preparations, he believed the therapeutical action of such drugs as ichthyol, antipyrin, thallin, etc., should be studied.

DR. R. TILLEY said that it was to be regretted that the author did not present some cases that were treated solely by ichthyol; for instance, the case that

went to so many physicians, the salicylate given would be likely to exert quite as much influence as the ichthyol, and the same might be said of the case treated by hydrarg. ammoniatum. It is really difficult to form an estimate as to what we can expect from ichthyol by the result of the combinations which the author found it necessary to use.

DR. JOSEPH ZEISLER, in closing the discussion, said that he did not think of recommending ichthyol as a panacea; on the contrary, he was afraid that it would be overestimated, and that some would use it in cases where it might not be beneficial. As to the remarks of Dr. Kuh, the physiological effect of ichthyol was not tested by experiments on animals, but was inferred from clinical observations. He was very much interested in Dr. Jewell's suggestion, and referred to the well known forms of neurotic eczema. Ichthyol has been found in Tyrol, Austria, in some bituminous rocks. He was unable to tell anything about its manufacture; Mr. Sargent gets it directly from Germany. In reply to Dr. Tilley, he said it was true that in some cases he could not say how much of the benefit was due to internal and how much to external treatment, how much to ichthyol and how much to other remedies. But his observations on ichthyol might still have some value when compared with other cases where *ceteris paribus* it is not used.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday, November 4, 1886.

THE PRESIDENT, B. F. BAER, M.D., IN THE CHAIR.

W. H. H. GITHENS, SECRETARY.

DR. JOSEPH PRICE exhibited specimens from two cases, and Dr. M. PRICE exhibited specimens from one case of

PYOSALPINX OF GONORRHOEAL ORIGIN.

Those by Dr. J. Price were removed from prostitutes. That exhibited by Dr. M. Price was from a married woman who had been infected by her husband. The tubal disease manifested itself soon after childbirth. The menstrual period had always been very painful and had kept her in bed from eight to ten days.

DR. HOWARD A. KELLY exhibited a

SARCOMA AS LARGE AS A MAN'S HEAD, REMOVED FROM THE ANTERIOR ABDOMINAL WALL.

It had its origin at the transverse tendinous band of the right rectus muscle, just below the umbilicus. The mass was about eight inches by ten, and hung pendulous under the greatly thickened skin of the right umbilical, inguinal and iliac regions. The great point of difficulty was in determining before operation whether the mass did not spring from a small hernia slipped through the umbilical ring; which was greatly drawn out on one side over the tumor, and deep in which the fibre-like cords of attachment could be felt. The tumor was very vascular, but was readily removed, and the patient made a perfect non-febrile recovery.

DR. KELLY also exhibited a specimen upon which

he desired a report by the Microscopical Committee. The case was one

OVARIAN PREGNANCY.

The patient, a German woman, who had had one child by forceps delivery two years ago, in Germany, had since been regular in her menstruation until October, when she went two weeks over time, and was then roused in the night by sudden and violent pain in the right leg and groin, extending obliquely down the right ovarian region. With the pain came a profuse uterine flow which lasted for two weeks with intermissions. From excellent health she was immediately prostrated and became miserable, with elevated temperature and quick pulse. She had no organic disease, but a small tumor at the extremity of the right Fallopian tube. The tumor was about two and one-half or three inches in diameter, softish, not sensitive, freely movable in the pelvis. In front of this a sharply defined round ligament could be traced out to the brim of the pelvis, and above this the flatter cover of the Fallopian tube could be felt. The ureters were enlarged, as Sanger has noticed, and the speaker has frequently verified in pregnancy. The uterus was of a size approaching two months pregnancy and the cervix was remarkably soft for the early stage of pregnancy. Dr. Kelly sent invitations to Drs. R. P. Harris, J. G. Allen, Freemann, John and Frank Haynes, Jos. Hoffman, Geo. Horn and Wm. Ferguson to be present at an abdominal section for extra-uterine pregnancy, and in their presence the operation was carried out. (The patient up to date of publication has made uninterrupted progress toward recovery). Dr. Kelly exhibited a chorionic membrane from a uterus, with a four weeks fœtus attached.

DR. BEATES remarked that the lining membrane of the cyst was easily separated from the wall and he thought the specimen was most probably a parovarian cyst.

DR. JOS. PRICE thinks the cyst could be entirely shelled out. He thought that it had none of the characteristics of a tubal pregnancy.

DR. KELLY in closing the discussion, demonstrated in the extra-uterine and in the uterine specimens an identical membrane which could be detached and which was the amnion. He demonstrated ovarian tissue completely surrounding the cyst, thus proving that it was not parovarian in its origin. The lining membrane underlying the apparent amniotic membrane is a soft tissue, never seen in an ovarian cyst. The specimen was referred to a committee.

DR. LONGAKER exhibited a

FIBRO-MYOMATOUS SUBSTANCE EXPELLED FROM A UTERUS TWENTY-THREE DAYS AFTER NORMAL LABOR.

The placenta came away entire; there was a post-partum hæmorrhage on the second day. In the third week a rise of temperature occurred. The temperature became normal after the expulsion of this mass.

DR. KELLY said that, judged by the macroscopic appearance of the specimen alone, and with great

certainty in view of the history, this flat, elongate mass, with one semi-circular rounded edge, and with long shreds hanging to it, was a portion of a retained placenta. A question is by this brought up upon which it is of the utmost importance that every member of this Society should have positive convictions, and that our practice should be uniform, and that is, What shall be done in the case of a puerperal woman who has an elevated temperature and a foul smelling discharge from the vagina? Where other manifest cause was absent every such patient should be placed in a convenient posture and the uterus thoroughly gone over with a dull curette, followed by a swabbing with an antiseptic solution. Thousands of women are to-day suffering from neglect of this simple precaution of removing stinking shreds of decidua and pieces of placenta, which remaining have caused sub-involution, chronic endometritis and cellulitis, lingering for years, or even a more acute and rapidly fatal septic process. Dr. Kelly prefers the lateral semi-prone position for convenience of exposure and manipulation, considering the objections which have been urged against this as purely theoretical.

DR. BAER would prefer the patient on her back for scraping or washing out the uterus after labor, using tincture of iodine or bichloride solution.

DR. BEATES has made it a rule whenever the temperature rises after labor to introduce the finger or curette into the uterus and remove any adherent masses.

DR. LONGAKER, in closing the discussion, said that he had not the slightest doubt that the specimen had been a fibroid tumor buried in the tissues of the lower portion of the uterus; the contraction and involution of the uterus cut off its supply of blood and partly enucleated it. Time was required for this process. The rise of temperature did not excite immediate suspicion, as the case was a hospital one and the wards overcrowded at the time.

DR. BEATES, on behalf of the committee, stated that the microscopic examination of the

OVARIAN FIBROID

presented by Dr. Baer at the October meeting, showed it to be a neoplasm developed from the epithelium of the ovary; it was a true scirrhus, with nothing ovarian about it except its origin.

DR. HOWARD A. KELLY read a paper on "Hysterorrhaphy," written for the Society in the spring of this year upon a new operation which he called

HYSTERORRHAPHY, OR THE SUSPENSION BY SUTURE OF A VICIOUSLY POSED UTERUS;

that is, an organ prolapsed or retroflexed, which it is impossible to relieve by any line of treatment applied *per vaginam*.

The speaker first applied this method on April 25, 1885, upon a patient who had been under the care of several other specialists, and under his own care for nearly three years. The uterus had been acutely retroflexed, with a large soggy fundus in Douglas's pouch, below the level of the cervix. Months of rest in bed, combined with careful packs and counter irritation, and for a long time applications to the

endometrium, failed to cure the flexion even temporarily. The patient had been operated upon a year previously, removing a very tender ovary *per vaginam*. On this occasion the left tube and ovary were removed, and as the right tube could not be felt it was concluded it had atrophied. The uterus was then raised and a sharp band of cicatrix-like tissue felt half encircling it in the angle of flexion, when the futility of any attempt to relieve the condition from the outside was at once evident. Silk sutures were passed through the left horn of the uterus and the body suspended from the anterior abdominal wall, about one and a half inches above the pubis to the left of the incision. The suspensory sutures were passed between two ligatures encircling the horn and the base of the pedicle, to avoid the dangers of tearing out and of bleeding.

The uterus thus suspended remained in place one year, when the right tube enlarged to a hydro-salpinx, and just before operation for its removal dragged the fundus over.

Dr. Kelly urged that in future both cornua be utilized and attached between one and a half and two inches above the pubis, to allow room for free expansion of the bladder; and again, that while in most instances the disease will have been of such long standing as to involve chronic incurable disease of the appendages necessitating their removal, yet in some cases the good effects of drainage of these latter, which are raised with the body, should be tried. The operation is to be urged where the long retroflexed, infiltrated uterus is unable to stand up straight alone after removing diseased ovaries and tubes, and if adhesions bind the fundus down they should be carefully removed. He also insisted that the operation for shortening the round ligaments was not admissible for retroflexion alone, as owing to enormous mechanical disadvantages the slightest degree of relaxation would allow a reproduction of the deformity.

While in simple prolapsus, if a supra-pubic operation of any sort were ever necessary, which the speaker doubted, he would prefer a simple, aseptically made, abdominal incision and direct support by attaching the fundus to the anterior abdominal wall, to an operation which has a doubtful and possibly a high rate of mortality, and of which the ratio of success is even more problematical.

The operation has been devised and performed independently by a number of prominent gynecologists in various parts of the world, among whom are Koeberlé, Bardenheuer, of Cologne, Hennig, of Leipzig, Czerny, of Heidelberg, a surgeon in the north of Italy, and Lawson Tait, probably Keith, and two cases not published which Dr. Sänger, of Leipsig, kindly gave the writer during the past summer.

DR. DRYSDALE remarked that he had performed a second operation upon a lady upon whom, eighteen years previously, Dr. Atlee had performed ovariectomy for the removal of an ovarian tumor; at the first operation the uterus was found prolapsed. In this operation Dr. Atlee had used the clamp to secure the pedicles, and at the second operation the uterus was found attached to the original wound. The pro-

lapse had been effectually cured. He thinks both cornue should be secured to the abdominal wall. He had never met with a case of retroversion that could not be relieved by pessary after curing the accompanying endometritis. Many years ago, a lady who had been for eight years under the care of Dr. H. L. Hodge for retroversion, and in whom the presence of a pessary excited such expulsive efforts that it could only be worn a week at a time, came under the care of Dr. Drysdale; he treated the endometritis first, and when it was cured a pessary could be retained and complete relief was secured.

DR. JAMES PRICE remarked that Tait considers it dangerous to stretch the fundus uteri to the abdominal wound, and has abandoned it. In some operations he introduces sutures to draw the uterus high up that he may more readily remove the tube close to the cornua.

DR. BAER thought it seemed the most natural method to stitch the fundus to the abdominal wound. He asked for what reason Mr. Tait considered it dangerous? He thought the field of Dr. Kelly's operation would be small, as, when the endometritis was cured, a pessary or other support would relieve the retroversion or flexion. After laparotomy or removal of the uterine appendages it might be advisable in some cases to draw the uterus up. He has had no experience with such a procedure. He does not like the Alexander operation; he considers it unscientific, and in many cases it has failed to cure the displacement.

DR. LONGAKER feared that, granting that anteversion could be secured by Dr. Kelly's method, the bladder would not be allowed to expand. A fixed anteversion would itself be pathological. He would hesitate to stitch the fundus to the abdominal wall even after removal of the appendage. Retroversion does not necessarily produce discomfort, as some cases have no symptoms to call attention to the condition.

DR. HARRIS recalled the case of Mrs. Keybold, whose uterus was suspended for fifty years. She died at eighty. The senile organ was drawn out into a tongue-shape; the uterine attachment was one and a half by three-fourths inch at time of death; the uterus was four and a half inches long, and the vagina was lengthened and cord-like. There had always been a tender spot in the cicatrix, probably from tension.

DR. KELLY stated, in reply, that he considered the main points which had been raised had been already answered in the paper. He considers these cases *rare*, and by no means recommends a resort to section and suspension without first trying every other known expedient likely to relieve, and then only in those cases in which the local disorder causes such pain or disability as to render life a burden. He considers the operation established, however, in those cases in which, after removal of the appendages, the flexed organ fails to remain upright when lifted into position. An occasional resort to hysterorrhaphy will not affect the table of recoveries from operation, but will affect the list of patients *cured*, which is not always made so prominent after abdominal section.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, November 3, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

DR. BLACKBURN, of the Government Hospital for the Insane, presented a specimen of an

ENLARGED SPLEEN AND OF A COLLAPSED LUNG.

Mr. N., æt. 48; married; publisher; nativity, New York, was admitted to the Government Hospital for the Insane, September 2, 1886, suffering from acute mania, induced by malarial poisoning of many years' duration, claimed to have originated during the late war. Six days previously he had an attack of acute maniacal excitement of four or five days' duration, during which he was violent and destructive, and threatened his own life and that of his wife.

At the time of his admission he conversed coherently, but still showed traces of excitement and great nervous prostration from the maniacal attack. He had been taking, for three or four years, large quantities of morphia, alcoholic stimulants and chloral (the morphia by hypodermic injection), and to the immediate effect of these drugs was attributed the maniacal excitement. The causes assigned for the use of the narcotics and stimulants were insomnia, distress in the epigastric region, and mental anguish due to his knowledge of the existence of an enlarged spleen, of which he had made a complete study. He was pale, emaciated, sallow but not jaundiced. His voice betrayed mental and physical weakness, and he had to be assisted by the nurse.

A specific history could not be proven, but was suspected, as depression of nasal bones, some periosteal nodes, and scars from dermal lesions existed. He craved stimulants and opium, which were given him in moderate quantities. A tendency to constipation was present and had existed for years (the alvine discharges were indicative of this condition only). The urine was natural in color, but considerably increased in quantity; examination revealed no indication of renal disease.

About two weeks before his death, which occurred September 28, 1886, some pyrexia appeared as the first indication of change in his condition. The urine became highly colored, the alvine discharges pale, and the skin and eyes deeply jaundiced. One week after delirium supervened, with anorexia, nausea and occasional vomiting. This condition continued, with gradually increasing dyspnoea and nervous prostration, until his death. Death occurred apparently from exhaustion and inanition.

The specimen of enlarged spleen which I exhibit was removed from the body of the patient whose clinical history I have read. Its dimensions are as follows: Length $23\frac{1}{2}$ inches; breadth 7 inches; weight 5 lbs. $14\frac{1}{2}$ ozs. This size, although great, is much exceeded by splenic tumors of various origins examined and recorded by others. Gray gives eighteen to twenty pounds as weights of enlarged spleens, and other writers mention enormous increase

in size. Of the several causes of chronic splenic hypertrophy this is from the most frequent—malarial poisoning. The capsule was firmly adherent to the surrounding structures, especially to the diaphragm, and the organ had to be dissected out. It extended from the fifth rib to the anterior superior spinous process of the ilium, and laterally to within an inch of the median line. The capsule was thickened, and the color was a reddish brown; the pulp was firm and tougher than normal. The small supernumerary spleen has apparently been enlarged also. The other organs presented nothing of especial interest.

The liver was somewhat enlarged, and within the gall-bladder were several small calculi, none of which obstructed the duct. The left kidney was oedematous and flattened at the upper part from pressure by the enlarged spleen; the oedema probably caused by pressure upon the renal vein. Slight contraction of the renal tissue had occurred.

The extreme variation in weight of spleens may be seen by comparing the small specimen, which weighed $1\frac{1}{2}$ ozs., with the enlarged one, which weighs about sixty times as much.

The patient conversed freely about his ailments, and as he had "suffered much of many physicians," he expressed a desire that the organ—of which he was not a little proud—should adorn some medical museum or grace the collection of some medical college. Agreeable to this request, I have brought it before you this evening.

The lung was removed from the body of a man æt. 50. Disease, chronic mania with chorea. History previous to admission unknown. The right lung extended far beyond the median line, and was emphysematous at its margins. The heart was also displaced upward and to the left. The left pleural cavity contained a moderate amount of fluid, and at first sight seemed to be empty, but underneath its thickened pleura, firmly bound to the chest walls by adhesions, was found the remnant of the left lung. It was impossible to remove it without detaching the parietal pleura. Section of the lung revealed some small, partially collapsed cavities, fibrous bands and pigmented, and calcareous masses of tubercular tissue. The right lung showed some hypostasis, but was crepitant throughout and showed no trace of tubercular disease. The clinical history was that of moderate cough and expectoration, probably bronchial to a great extent. It appears to have been a case of arrested tubercular disease.

On motion of Dr. S. S. Adams, the specimens were referred to the Microscopical Committee.

DR. S. C. BUSEY remarked that he hoped a full report would be made by the Committee, and that a discussion would follow. He asked Dr. Blackburn if he thought that the malaria and large spleen had anything to do with the mania. It seemed more likely to him that the morphia, chloral, etc., taken were the causes.

DR. BLACKBURN replied that the tubercular origin of the mania was the patient's own idea—that himself and the other medical gentlemen at the hospital thought that the drugs were causative. In reply to Dr. Hartigan, he said that the brain was all right.

DR. C. E. HAGNER said that he could not quite agree with Dr. Blackburn that the collapsed lung exhibited was tuberculous. He thought it much more likely that it was a complication caused by pleuritic effusion which had been absorbed, or a fibroid degeneration of the lung. He believed that tuberculous disease would have shown itself in some other viscera as well, and he would be surprised to find tubercles in this lung.

DR. D. S. LAMB reported

A CASE OF ACUTE GENERAL TUBERCULOSIS SUPERVENING ON ENLARGED AND CHEESY MESENTERIC GLANDS—DEATH FROM MENINGITIS.

The patient was a girl, light mulatto, 3 years and 9 months old at death. There is no family history of tubercular disease. The child had good health, escaping even the ordinary eruptive fevers, etc., of childhood. In the latter part of June of this year, she had what seemed to be a "bilious" seizure, lasting a few days. From that time she never appeared to be entirely well. There were dark rings under the eyes; she lost flesh somewhat; was disposed to be continually at her mother's side; had a habit of tying up her head in a handkerchief, saying she had headache, which was supposed by her mother to be simply childish play. Her skin had somewhat of a yellowish tinge, more marked at times, and she frequently complained of itching, especially of the back, and would wake her mother up at night to have her back rubbed.

During the last week in September, her appetite was not as good as usual. October 1, while at supper, she had a paroxysm of vomiting, and afterwards slight fever. Vomiting recurred next day, and at night she had severe frontal headache, jerking of arms and hands, biting of fingers, and intense itching along back and legs. Dr. Mary A. Parsons saw patient on the 5th of October, I was asked to consult on the 10th, and Dr. Garnett a few days later. When first seen by Dr. Parsons, the child complained of pain in the abdomen; there were an irregular form of fever, and loss of appetite; she sighed frequently and said she was tired; pulse 80; respiration 18; no recurrence of the vomiting; tongue slightly coated; constipation.

On the night of the 9th she had again severe frontal headache, and cried out sharply. The pain in the abdomen continued till the 12th. On the 14th she had epileptiform convulsions with strabismus, apathy, restlessness, mild delirium, grinding of teeth, sighing; pupils contracted. These symptoms continued till the 17th. On the 16th the conjunctivæ were red. On the 17th the temperature rose to 104° ; pulse to 160; spasms ceased; coma diminished so that her eyes followed the movements of her mother. On the 18th the body, especially the face, became cyanosed. On the 19th she died; nearly three weeks from the first paroxysm of vomiting. The complaint of abdominal pain, which continued till October 12, aroused a suspicion that the case might be one of typhoid fever. The pulse was 80 to 85 till the 10th, then rose to 102 and thereafter remained frequent. The respirations continued to

be 18 to 20 until a few days before her death; but there was "sighing" from the first and lasting throughout. The temperature ranged from 100° to 102° until a few days before death when it rose to 104°. There were general apathy and somnolence from the beginning, deepening into coma when convulsions set in. The fever was quite irregular, the heat of the skin rapidly increasing and diminishing. The vomiting recurred only a few times. The sharp outcry occurred only from the 9th to the 12th. The pupils were contracted most of the time; sometimes dilated and then reacted to light. Constipation throughout.

Treatment may be summed up as follows: Two small blisters placed behind the ears; iodoform ointment rubbed into the scalp; ice bag to head; calomel to open the bowels; opium and bromide of potassium for the convulsions. For several days she was nourished by enemata.

There being some doubt as to diagnosis a necroscopy was made by me October 20, with the following results: Nutrition of body fair. Dura mater and pia mater congested; sinuses full of dark blood and soft clots; thin lines and small patches of pus along blood-vessels of pia mater; [lymph in space of circle of Willis and along Sylvian fissures. Lateral ventricles dilated and contained serum and lymph]. Heart normal. Both lungs showed abundance of minute tubercles, mainly peripheral; in the right lung were also two hæmorrhagic infarctions, one in the upper and one in lower lobe. In left lung also, upper lobe, was a whitish mass the size of a pea, "solitary tubercle." Brownish mucus in stomach. Small intestine generally normal; but lower part of ileum showed slight prominence of solitary bodies and Peyer's patches. I would be inclined to consider this physiological except that the lowermost patch showed at its lower edge a small abrasion, and the adjoining segment of the ileo-colic valve showed a square-shaped ulcer through mucous membrane nearly half an inch in width. There is also what appears to be a large deeply ulcerated solitary follicle a short distance from the valve; it looks, however, like a *healing* ulcer with contraction. The colon contained feces. The mesenteric glands mostly normal, but there were three in the ileo-colic position which were enlarged, one to the size of an almond; they were not soft as if recent, but firm and contained thick purulent-looking matter. The liver and spleen showed many minute opaque spots in the periphery. Pancreas and kidneys normal. Bladder empty. Uterus and ovaries normal.

In brief, the case clinically was one of meningitis with a strong suspicion of typhoid fever. The post-mortem examination shows what I believe to be acute tubercular disease of pia mater, especially of base of brain, and of lungs, liver and spleen; and consequent upon extension from a focus of inflammation in the mesenteric glands.

FOREIGN CORRESPONDENCE

LETTER FROM PARIS.

(FROM OUR OWN CORRESPONDENT.)

Retirement of Professors Hardy and Sappey—Pasteur's Method.

The law compelling hospital physicians and surgeons and Professors of the Faculty to retire after a certain age, has just been applied to three eminent Professors whose teaching was so much appreciated not only by the natives of the country, but by foreigners from all parts of the world who resorted to Paris to study French medicine. The names of these Professors are familiarly known to the present generation: Professor Hardy, who was greatly valued as a clinical teacher, but before his appointment as Professor of clinical medicine he was accustomed to lecture on skin diseases at the Saint Louis Hospital, where he had been physician for many years, and where he had acquired his reputation as a dermatologist of the highest order. This did not prevent his becoming famous in general medicine, and as a clinical teacher he has hardly been surpassed. The same inexorable law affects Professor Sappey, the well-known anatomist, who has devoted almost his whole life to the study of this science, and which he taught with so great advantage at the Paris Faculty. His lectures, which were a model of their kind, will for a long time be engraved on the memory of those who attended them. Professor Gavarret had for some years past virtually retired on account of failing health and the infirmities of old age, but he was replaced *pro tem.* by Dr. Gariel, who is likely to succeed him in the Chair of Medical Physics. He was a very popular lecturer, and although physics was the subject he had to lecture on, he almost always diverged into the science of biology, which gave a great impetus to that most important branch. He may be regarded as one of the founders of biology. The vacancies caused by the retirement of these three eminent Professors will probably remain unfilled for some time, as the Minister of Public Instruction, with whom these appointments lie, will doubtless find some difficulty in obtaining successors.

At a recent meeting of the Academy of Sciences, M. Pasteur made a new communication on the results of his method against hydrophobia. This he did in person, but subsequently at the Academy of Medicine, being indisposed, his paper was read for him by the Permanent Secretary. In this report there are two arguments apparently of some value. According to M. Pasteur, there have been during the last year 1,700 French persons (the author abstains from saying anything about other nationalities) bitten by dogs supposed to have been mad, and who had been inoculated. Of this number there have been ten deaths from rabies, or one in 170. On the other hand, there is reason to believe that a few French persons who have been bitten during the year, did not go to the Pasteur Laboratory for treatment; of this small number seventeen died from hydrophobia. Another argument in favor of the method is, that in five years,

there died from rabies, in the hospitals of Paris, sixty persons, or an average of twelve per year. During the last year there have been but two deaths, and these two persons had not been inoculated. M. Pasteur's reports, however, have not escaped severe criticisms both in the medical and lay press. One shrewd observer remarked with reference to the above report that, notwithstanding the successes therein referred to, M. Pasteur, who, on the 26th of October, 1885, affirmed to have discovered an infallible method for the cure of rabies after a bite, also affirmed on the 2d of November, 1886, that the method employed during the last two months was insufficient, and that he was now employing a new method, "*la méthode intensive*," as he terms it; consisting of repeating the treatment three times a day, in employing for the inoculation spinal marrows, beginning with the oldest and ending with the most recent. For instance, on the first day, the spinal marrows of twelve, ten, and eight days are inoculated at 11, 4, and 9 o'clock. On the second day, those of six, four, and two days at the same hours. On the third day, that of one day. The treatment is resumed on the fourth day by inoculations of eight, six, and four days; on the fifth day by those of three and two days; on the sixth by that of one day. On the seventh the marrow of four days; on the eighth that of three days; on the ninth of two days; on the tenth that of one day. Three treatments are thus made in the course of ten days, each terminating in the inoculation with the freshest virus. Another curious fact in this communication is the cure by the inoculation of animals inoculated by trephining. If spinal marrows dissolved are injected into the brain, the animals become rabid; but if after this first operation one continues to inject into the same animals the rabic marrow, but this time in the abdomen, rabies does not declare itself.

A. B.

STATE MEDICINE.

GEORGIA ANATOMICAL BILL.

The following is an abstract of the bill, introduced by Hon. C. M. Candler, of DeKalb, and referred to the General Judiciary Committee, has been returned to the House by them with recommendation that it pass.

A BILL to be entitled An Act for the protection of cemeteries and burying places in this State, and to prevent and punish the unauthorized uses of and traffic in dead human bodies, and for the promotion of medical science by the distribution and use of unclaimed dead human bodies for scientific purposes through a Board created for that purpose, and for other purposes.

SECTION 1. The General Assembly of the State of Georgia do hereby enact:

That the professors of anatomy, the demonstrators of anatomy, and the deans of medical and dental schools and colleges of this State, which are now or may hereafter become incorporated under the laws

of this State, shall be, and are hereby constituted a Board for the distribution and delivery of dead human bodies, hereinafter described, to and among such persons as under the provisions of this Act are entitled thereto.

SEC. 2. That all public officers of this State and their assistants, and all officers and their deputies, of every county, city, town or other municipality, and of any and every prison, chain-gang, morgue, public hospital, penitentiary company in this State having charge or control over any dead human body or bodies *required to be buried at public expense*, are hereby required to notify the said Board of distribution, or such person or persons as may, from time to time, be designated in writing by said Board, or its duly authorized officer, whenever any such body or bodies come into his or their possession, charge or control, and shall, without fee or reward, deliver such body or bodies, or permit and suffer the said Board and its duly authorized agents, who may comply with the provisions of this Act, to take and remove all such bodies, *to be used only within this State, solely for the advancement of medical science.*

Provided, that no such notice shall be given, nor shall any such body or bodies be delivered, if any person claiming to be and satisfying the authorities in charge of said body or bodies, that he or she is of any degree of kin, or is related by marriage to, or socially or otherwise connected with and interested in the deceased, shall claim the said body or bodies for burial, but it or they shall be at once surrendered for interment to such person, or shall be buried at public expense at the request of such claimant, if a relative by blood or a connection by marriage, provided he or she is financially unable to supply such body or bodies with burial.

And Provided Further, that such notice shall not be given or such body be delivered if the deceased person was a traveler who died suddenly, in which case the said body shall be properly buried.

And Provided Further, that such body or bodies shall in each and every instance be held and kept by the person or persons having charge or control of it or them at least twenty-four hours after death, before delivery to said Board or its agent or agents, during which period notice of the death of such person or persons shall be posted at the court-house door of the county in which said body or bodies are so held.

SEC. 3. That the said Board or their duly authorized agent, may take and receive such bodies so delivered as aforesaid, and shall, upon receiving them, distribute and deliver them to and among the aforesaid schools or colleges for lectures and demonstrations by the said schools or colleges, the number assigned to each to be based upon the number of *bona fide* students in each dissecting or operative surgery class, which number shall be reported, under oath, by said schools or colleges to the Board at such times as it may direct.

Provided, that said schools or colleges, upon receiving them, and before any use is made of them, and without any dissection or unnecessary mutilation thereof, shall cause them to be properly embalmed and decently kept and preserved for the period of sixty

days after their reception, and shall deliver them properly prepared for burial to any person mentioned and described in section 2 of this Act, who shall claim such body within or before the expiration of said body of sixty days, and satisfy the authorities of said schools or colleges that he or she is such person as is entitled to said body under said section 2.

If, at the expiration of said period of sixty days, said bodies have not been claimed for burial, in the manner and by the person or persons herein described, said bodies shall then be used for the purposes specified in this Act by said schools or colleges.

And provided further, that all of said bodies which have been so used and are no longer needed for the objects herein mentioned shall be decently interred by the said schools or colleges.

SEC. 4. The said Board may employ a carrier or carriers for the conveyance of said bodies, which shall be well enclosed within a suitable encasement, and carefully deposited free from public observation. Said carrier or carriers shall obtain receipts by name, or if a person be unknown by a description for each body delivered by him, and shall deposit said receipts with the Secretary of said Board, who shall record and preserve the same.

SEC. 5. No school or college shall be allowed or permitted to receive any such body or bodies until a bond shall have been given to the Governor of this State, and his successors in office, etc.

SEC. 8. Neither the State, nor any county or municipality, nor any officer, agent or servant thereof, shall be at any expense by reason of delivery or distribution of any such body or bodies, but all the expenses thereof shall be paid by those receiving the body or bodies, in such manner as may be specified or fixed by said Board.

SEC. 9. That any person having duties enjoined upon him by the provisions of this Act, who shall neglect, refuse or omit to perform the same as hereby required, shall be guilty of a misdemeanor, and on conviction thereof shall be punished as prescribed in section 4705 of the Code of this State.

HEALTH IN MICHIGAN.

For the month of November, 1886, compared with the preceding month, the reports indicate that bronchitis, pneumonia, and influenza increased, and that diarrhoea, cholera infantum and cholera morbus decreased in prevalence. Compared with the preceding month the temperature in the month of November, 1886, was much lower, the absolute humidity and the night ozone were less, the relative humidity and the day ozone slightly more. Compared with the average for the month of November in the eight years 1879-1886, intermittent fever, pneumonia, typhoid-malarial fever, remittent fever and diphtheria were less prevalent in November, 1886.

For the month of November, 1886, compared with the average of corresponding months for the eight years, 1879-1886, the temperature was lower, the absolute humidity was less, the relative humidity was the same, the day and night ozone were more.

Including reports by regular observers and others, diphtheria was reported present in Michigan in the month of November, 1886, at sixty-three places, typhoid fever at thirty-five places, measles at eleven places, and small-pox at one place.

Reports from all sources show diphtheria reported at the same number of places, scarlet fever at four places more, typhoid fever at eight places less, measles at five places more, and small-pox at the same number of places in November, 1886, as in the preceding month.

NECROLOGY.

JOHN PURDUE GRAY,

one of the founders and an ex-president of the New York State Medical Association, died after a long illness at Utica, N. Y., November 29, 1886, aged 61 years. He was the Medical Superintendent of the State Lunatic Asylum at Utica, having assumed the duties of that position in September, 1850, and it is no exaggeration to say that he made this institution the most favorably known in the world. As an alienist he was accepted as an authority, and almost invariably appeared as an expert in all cases of importance. His testimony is credited with being lucid, analytical and eminently impartial. When Guiteau was tried for the assassination of President Garfield he was chief of the experts summoned to Washington by the prosecution. His testimony followed that of all the other experts, in order that a careful review of the case might go to the jury at the close with all the weight of his ability and reputation. He did not see "the slightest shadow of insanity" in Guiteau, and with this conclusion the nation fully coincided.

On March 16, 1882, an unsuccessful attempt was made to assassinate Dr. Gray in Utica. He was in his office reading his mail, having just returned from Washington, when Henry Reimshaw entered and fired one shot at him from a revolver. The ball struck the doctor's left cheek bone, passed through the right cheek and lodged in the wall. The wound was not a serious one and the doctor soon recovered. Reimshaw was employed in Bagg's Hotel, and for eighteen months had been under the delusion that he was an ambassador sent from Heaven to shoot Dr. Gray. He had never been a patient in the asylum, but had taught Dr. Gray's children to swim.

As a man Dr. Gray was an enemy of sham and pretence, possessed of a judicial mind, and master of himself in the most trying situations; was thorough in the investigation of all medico-legal points bearing upon the particular case in hand, and always commanded the respect of his judges for the honesty of his opinions. He was active in the profession, defending its best interests; broad and liberal in his views, very approachable, and an especial friend to the meritorious, struggling practitioner. In the relations of life he was beyond censure, and died regretted in the community where he was best known.

BOOK REVIEWS.

THE DIAGNOSIS AND TREATMENT OF DISEASE OF THE EAR, by OREN D. POMEROY, M.D., Surgeon to the Manhattan Eye and Ear Hospital; Ophthalmic and Aural Surgeon to the N. Y. Infant Asylum; Consulting Surgeon to the Paterson Eye and Ear Infirmary; Member of the American Ophthalmological and Otological Societies, etc. Second edition, revised, with Additions; 8vo. With 100 illustrations. New York: D. Appleton & Co. 1886.

The appearance of the second edition of this work soon after the issuing of the first is a sufficient indication of the high value placed upon it by the medical profession. The author has in this, as in the first edition, omitted the usual chapter pertaining to the anatomy and physiology of the ear. We regret this omission; a cursory reference to its construction and action would enhance the value of this otherwise creditable work.

Dr. Pomeroy has incorporated in his book the latest researches, and shows by numerous citations and references to recent publications his thorough familiarity with current aural literature. The chapter on "Treatment of Purulent Otitis" contains the newest means of medication, based on the revolutionary methods of antiseptis. We fail to notice, however, any allusion to peroxide of hydrogen, which, although not universally employed, is considered a valuable adjunct to the aurist's armamentarium. The description of the naso-pharynx and its diseases is brief, but to the point. The book is of special importance to the student and general practitioner, directing their attention, as it does, to the necessity of treating these parts in conjunction with the ear.

HENKE'S ATLAS OF SURGICAL ANATOMY. A series of Plates Illustrating the Application of Anatomy to Medicine and Surgery. Translated and edited by W. A. ROTHACKER, M.D. Cincinnati: A. E. Wilde & Co.

This work consists of eighty-one large plates, which are carefully and clearly drawn. That which makes the work practically valuable is the exposition of structures, not in systems, but just as they are laid bare by dissecting. The introduction of numerous plates of sections adds very greatly to the value of the work. Sections of the head and brain made in different directions and at different points are given, also two transverse sections of the neck; several transverse and longitudinal sections of the thorax, and a number of sections of the pelvis in both males and females. The contents of the abdominal cavity is shown by a number of plates representing the organs as they appear when portions are removed in longitudinal layers.

A feature which adds much to the utility of the book is noticed in the placing of the names of parts along the margin of the pages.

A book of this kind is always useful to physicians

and surgeons in enabling them, at a glance, to see the relationship of parts. The drawings are sufficiently large and so well made that no difficulty is experienced in using them.

MISCELLANEOUS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM NOVEMBER 27, 1886, TO DECEMBER 3, 1886.

Major Daniel G. Caldwell, Surgeon, granted twenty days' extension of his leave of absence. S. O. 278, A. G. O., Dec. 1, 1886.

Capt. E. B. Moseley, Asst. Surgeon, relieved from duty as attending surgeon in San Francisco, Cal. S. O. 99, Div. Pacific, Nov. 19, 1886.

Capt. Edw. B. Moseley, Asst. Surgeon, directed to take charge of the Medical Purveying Depot, San Francisco, Cal., until the arrival of a proper bonded officer. S. O. 99, Div. Pacific, Nov. 19, 1886.

Capt. Louis S. Tesson, Asst. Surgeon, granted leave of absence for four months, to date from Nov. 13, 1886. S. O. 278, A. G. O., Dec. 1, 1886.

First Lieut. Peter R. Egan, Asst. Surgeon, assigned to duty at Ft. Clark, Texas. S. O. 162, Dept. Texas, Nov. 22, 1886.

First Lieut. Wm. J. Wakeman, Asst. Surgeon, leave of absence extended three months. S. O. 274, A. G. O., Nov. 26, 1886.

First Lieut. W. D. McCaw, Asst. Surgeon, granted leave of absence for two months, to take effect when his services can be spared. S. O. 274, A. G. O., Nov. 26, 1886.

First Lieut. C. L. G. Anderson, Asst. Surgeon, recently appointed, ordered for assignment in Dept. Arizona. S. O. 277, A. G. O., Nov. 30, 1886.

First Lieut. Robert R. Ball, Asst. Surgeon, recently appointed, ordered for duty in Dept. of the Missouri. S. O. 278, A. G. O., Dec. 1, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING DECEMBER 4, 1886.

Farwell, W. G., Surgeon, detached from the "Kearsarge," proceed home and wait orders.

Gatewood, J. D., P. A. Surgeon, detached from the "Kearsarge," proceed home and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE FOR THE TWO WEEKS ENDED NOVEMBER 27, 1886.

Williams, L. L., Asst. Surgeon, granted leave of absence for twenty-four days, to take effect when relieved. Nov. 15, 1886.

McIntosh, W. P., Asst. Surgeon, granted leave of absence for twenty-seven days. Nov. 26, 1886.

Norman, Seaton, Asst. Surgeon, when relieved to rejoin station (New York); granted leave of absence for twenty-three days. Nov. 27, 1886.

CORRIGENDA.

In THE JOURNAL of November 27, p. 611, the title of the paper read by Dr. E. M. Moore, before the New York State Medical Association, should be "Subluxation of the Radius Downward, by Elongation at the Elbow, in Young Children."

In THE JOURNAL of December 4, article of Dr. Schenck, on "Hygiene of Periodic Fevers," p. 623, 2d column, 5th line from bottom of 2d par., for "mighty chill" read *nightly* chill. On p. 624, 11th line, 1st col., for "toxic doses" read *tonic* doses.

ORIGINAL ADDRESS.

RHINOLOGY IN THE PAST AND OF THE FUTURE.

*An Address Delivered before the American Rhinological Association, on October 5, 1886, at
St. Louis, Mo.*

BY CARL H. VON KLEIN, A.M., M.D.,
OF DAYTON, OHIO.

No subject can present a higher interest than an inquiry into the past and future of rhinology. What ever tends to correct error or introduce improvement into science must affect the comfort of the profession. No research on such a subject can be accounted too minute, no labor too long. Progressive as we have been in the past few years, we cannot boast of having revealed the last trace of civilization. When we look back to the history of rhinology, we find that as a specialty it is not of modern invention, as many suppose it to be. Egypt was the earliest home of medical skill, and every mummy of the more expensive and elaborate sort involved a process of anatomy, particularly as to its pathological condition, and these interesting pathological specimens were more numerous by reason of the profession being divided into specialties. Herodotus says:¹ Egypt claims the invention of healing art. The medical practice among the Egyptians is divided, and each physician is for one kind of sickness and no more, and all places are crowded with physicians, for there are physicians for the eye, physicians for the head, physicians for the nose, physicians for the teeth, physicians for the stomach, and for internal diseases.

It is claimed that the best anatomists among those specialists were those who practiced on diseases of the nose and stomach; they were the embalmers.² Embalming was first done by the rhinologist, removing a part of the brain through the nostrils by means of a crooked iron, and destroying the rest by injecting caustic drugs; and by the practitioners of the stomach, who made an incision along the flank with a sharp Ethiopian stone, and the whole of the intestines removed. The cavity was rinsed out by palm wine, and afterwards scoured with powdered perfumes. It was then filled with pure myrrh, pounded cassia and other aromatics, except frankincense. This done, the body was sewn up, and steeped in natron for seventy

days. When the seventy days were accomplished, the embalmers washed the corpse and swathed it in bandages of linen cut in strips and smeared with gum. They then gave it up to the relatives of the deceased, who provided for it a wooden case, made in the shape of a man, in which the dead was placed.

Besides embalming, the rhinologists were also assigned as executioners in punishment of adultery, which was inflicted upon adulterers by amputation of the nose. Strabo says:³ Rhinocolura is so called from the colonists whose noses had been mutilated. Some Ethiopians invaded Egypt, and instead of putting the malefactors to death, having cut off their noses they settled them at Rhinocolura, supposing that they would not return to their own country, on account of the disgraceful state of their faces. This gave those specialists opportunities for inspecting a vast amount of material, varying in every possible pathological condition. Such opportunities were sure to be turned into account by the more diligent among the faculty. Their reputation was so widely established that Cyrus and Darius, kings of Persia, sent to Egypt for physicians. The former was afflicted with nasal polypi, the latter with ophthalmia.

From all historical accounts it is demonstrated that rhinology was one of the most cultivated specialties in the art of medicine. I have no doubt that rhinoscopic examinations were made by the Egyptians as well as they are made to-day. The use of mirrors among them was so common that they not only used them in their residences, but even as ornaments on their garments, and arranged them in their hair. And in the Egyptian temples, it was the custom for women to worship in linen garments, holding a mirror in the left hand and a sistrum in the right. Sir G. Wilkinson says⁴ that the mirrors were susceptible of a lustre which has only been partly revived at the present day.

The treatment in rhinology we may imagine was absurd; yet Hippocrates described the same treatment of inhalation, fumigation and inspiration of essential oils, just as it is used at the present day.

In the treatment of syphilis, fumigations were extensively applied in clearing away the incrustations which generally exist in syphilis of the nose. Injection of lotions have been used from time immemorial. As to the success, whatever it might have been, we are unable to find any records thereof. Various compilations are in existence of the relative sum of the

⁵ Ancient Egypt, iii, 384.

disease of the various organs, but none pertaining to rhinocal. If there is such in existence, we can only expect an approximation to accuracy. Rhinology, like many other specialties of this century, began by men incompetent for the task. Any data, therefore, from this source, are too uncertain for philosophical deduction.

Medicine is no doubt one among the many lost ancient sciences. From the period of the cultivated Egyptians to about the fifteenth century, very little was known of the science of medicine. From Hippocrates to the days of Galen, a period of about six hundred years, and from the time of Galen to Fracastora, a period of about thirteen centuries, the science of medicine was like a barren desert. At the beginning of the sixteenth century she began to break the clouds which overspread the skies of blue, and the cultivation of medicine made its progress from day to day; though in the rear of other sciences, yet she is amid civilization.

It was not until the beginning of the present century, when the scopic method was thought of, that physicians became able to make a correct diagnosis of diseases. Great has been the usefulness of the urethroscope, rectoscope, stethoscope, ophthalmoscope, otoscope, microscope, laryngoscope, and only within the last few years the rhinoscope. Considering the numerous difficulties, and the multitude of conflicting theories which had from time to time been promulgated, on account of the parts and by reason of their being hidden from view, the pathological theories of nasal diseases were absurd and unphilosophical. Yet, with all its antagonism, it has in a great measure unveiled itself before the light of modern investigation, and become reduced to a more scientific basis, though we cannot boast, however, we opened a new road to medical science.

Our first acquaintance with some sort of an illuminator of the upper respiratory tract is mentioned by Levret, of Paris,⁶ in 1743. In 1803, Bozzini⁷ invented a kind of hand mirror for the purpose of examining all sorts of obscured cavities in the human body. In 1827,⁸ Senn, of Geneva, proposed to examine the larynx by a small mirror, by introduction into the mouth. In 1829, Dr. Babbington,⁹ of London, invented an instrument which he termed glottiscope, and also some sort of a tongue depressor of polished steel combined with a mirror. In 1832,¹⁰ Kaslinsky, of Warsaw, invented a combined mouth speculum and gag. In 1835,¹¹ Plate, of Amsterdam, describes a double mirror for the examination of the larynx and pharynx. In 1837,¹² Selligie, a very intelligent machinist of Paris, who himself was subject to laryngeal phthisis, invented a laryngeal speculum consisting of two tubes, through which light was thrown into the glottis, and by a counter glass, which he placed in his guttural extremities, he was able

thereby to view his own disease. In 1838,¹³ Baumès, of Lyons, demonstrated a laryngeal speculum which cannot be found anywhere described. In 1840,¹⁴ Liston, of London, applied in the examination of the larynx a dental mirror with a long handle, similar to that of Babbington. In 1844,¹⁵ Dr. Warden, of Edinburgh, introduced a contrivance made of an argand burner lamp, for the examination of the glottis. In the same year Avery, of London, is said to have invented a successful instrument, for the purpose of examining the dark parts of the upper respiratory organs. In 1855,¹⁶ Garcia, a Spanish vocalist and teacher in the City of London, wrote a paper entitled "Physiological Observations on the Human Voice," which he read before the Royal Society, wherein he explains in what manner a large reflecting mirror, with a small dental mirror in the mouth, can be made to exhibit the anatomy and the physiological actions of the laryngeal and pharyngeal organs.

At this time a period of half a century has elapsed, with discoveries from year to year to open a path to rhinology, yet not until 1847¹⁷ the illustrious Dr. Türck, of Vienna, perfected a laryngoscope upon the same order as that invented by Garcia, of which he claimed to know nothing; it was much superior but of great resemblance to Garcia's. In 1859,¹⁸ Dr. Czermak, of Pesth, and Dr. Gruber, of Krakau, with the assistance of Dr. Türck, experimented with the latter's instrument, until they had opened a broad road to the obscure places which we are here to discuss.

The system of rhinology has made a rich harvest of natural discovery which benefited mankind more than any progression in medical science made in this century, save anæsthetics. No organs within the human system can be so disclosed and show their pathological conditions, as those affected by the laryngoscope and rhinoscope. I speak of the laryngoscope, because rhinology and laryngology work hand in hand, and the former developed itself through the latter; and through Türck's invention of the laryngoscope we are indebted to Czermak for the invention of the rhinoscope. Since he has demonstrated the pathological conditions of the upper respiratory tract by illumination, many have tried to improve upon the process of illuminating the nasal pharyngeal cavities, with many good and important results.

The improved methods of Schroeder, Schnitzler, Senefelder, Cramer, Voltolini, Stoerk, Lewin, Traube, Fraenkel, Hirschberg, Ruete, Merkel, Waldenburg, Krishaber, Middeldorpf, Gerhard, Ziemssen and Tobald, of Germany; Raufuss, Poznisky, Ritter and Volltzior, of Russia; Mandl, Maura Bourouillon, Batrille, Cusco, Trauvel and Beverbire, of France; Mackenzie, Gib, Johnson and Boxt, of England, and so many others of this side of the Atlantic, that it would require an entire volume to name them all.

Through their constant effort to improve the illuminary apparatus they have made many valuable ob-

servations within the nasal cavities, necessitating the invention of many other instruments, such as rhinoscopic mirrors, nasal speculums, tongue depressors, palate hooks, uvula holders, nasal douches, nasal syringes, nasal spouts, nasal sprays, nasal catheters, nasal inhalers, nasal sponge holders, nasal forceps, nasal probes, nasal respirators, nasal powder blowers, nasal tampons, nasal snares, nasal écraseurs, nasal retractors, nasal cannals, nasal scissors, nasal brushes, nasal caustic holders, nasal evaporators, nasal dilators, nasal comesoils, nasal plugs, nasal gauges, nasal drills, nasal blowers, nasal burs, nasal saws, nasal trocars, nasal spoons, nasal knives, nasal curettes, nasal clamps, nasal applicators, nasal fumigators, nasal cauterizers, nasal cauterys, nasal electrodes, etc.

The rhinoscope evidently brought to light the necessity of inventing the appliances mentioned, and their inventors, in order to complete them, were forced to experiment with them, and by their experiments many observations were made, to such an extent, that it had made many deaf ears hear, and many blind eyes see, because many of those afflictions are caused by rhinocal disease, to say nothing of the numerous other kindred diseases, to which the upper respiratory tract is the sole cause. It has lately been discovered that many of the lower respiratory organs cannot be healed until the disease of the nasal cavities is cured. The dreadful disease, asthma, which has always been considered a nervous disease, has recently been successfully treated by the removal of a large hypertrophy of the posterior nares.¹⁹ Others, as I, have cured cases of nervous prostration by healing the nasal pharyngeal cavities, and many other organs connected therewith. Such affections may frequently be observed in the bladder, liver, kidney, stomach and brain.

In 1881 I succeeded in curing a case of epilepsy of two years standing by the removal of two large polypi of the posterior nares. The patient was a girl 11 years old. In the same year I successfully treated a case of insomnia by the same operation as in the former case. Last year I cured a case of supposed insanity by extirpating a large turbinated process. Indeed, there is scarcely an organ or structure of the body in which they are not occasionally affected by nasal disease; it stands to reason; the nose is the gate to disease; in nine cases out of ten the causes of human ailments pass through the pathway of the nasal cavities. If an inhalation of obnoxious gases can enter the lower intestines and produce a typhoid fever, why cannot it enter to the other organs or structures of the upper and lower extremities? When a piece of heavy artillery passes along the highway it can be traced from the very spot the wheel commences to revolve; it leaves its impression from the starting point to its destination. All diseases caused by exposure, or inhalation, must evidently make their first impression within the gate, the nose. It would therefore be better in all cases that rhinoscopic examinations should be made whatever the disease may be, the gate should be first examined.

The nose is the foundry of a large machine-shop,

wherein disease appears in its rough casting. Other organs are finishing rooms, wherein they appear entirely developed. In fact, the whole human body is comparatively a machine, and such a machine should be handled by different machinists; as all the cogs are connected, therefore they ought to be understood by each mechanic the connection of the entire machine; as a single cog, in a single wheel, is no doubt but a small part of its mechanism, and can contribute but a small portion to the effect of the entire work; yet the want of its coöperative influence may, if not entirely stop, yet greatly impede its motion. It is ever so with the physician, though he ought to understand every physiological action, and its anatomical connection with every part within the human body, yet, I hold that he ought to practice only a specialty. If a mechanic, for example, a fabric, wood, or a metal worker, who requires simply physical training, can produce better special work, why not a physician make better cures if he confines himself to a specialty? If a cabinet maker can make a better bureau than a bedstead, or a pants-maker can make a pair of pants better than a coat-maker, or a metal-worker can produce better filing than an anvil-worker, or *vice versa*, why not a cultivated physician with an active brain and mind, who devotes himself to one special subject, make a better physician? A man who devotes his mind and trains his eye to microscopy, makes a competent microscopist; why not he who devotes his time and trains his mind to the ophthalmoscope, make a good ophthalmologist? or a laryngoscopist a laryngologist? and a rhinoscopist a rhinologist? Above all, I believe that rhinoscopy is one of the hardest studies of all. It takes more perseverance, patience and assiduity to make a correct rhinoscopic diagnosis than in all other "scopics." Only such persons who are constantly devoting their time to rhinocal pathology are qualified.

Specialism is a discovery of lost thought in medical art. Sooner or later we will all be specialists, but not until the common prejudice has vanished and the narrow-minded will cease to influence those who are eager to learn the truth. Dr. Crosby, of Manchester, President of the New Hampshire Medical Society, in his Annual Address says:²⁰ "Shall the practice of medicine sink to the level of a trade, where every competitor supplements his skill as an artisan by all the tricks of cunning and diplomacy of which he is able? Shall the body of the profession be broken up into fragmentary joints, each little segment calling itself a specialist, until the organs of the body are parcelled out as booty is divided among thieves? Shall the grand old column be broken up into detachments that shall ultimately destroy one another, because men honestly differ as to means employed to subdue disease?"

Just think of such irreverent assertions by men who ought to seek the truth which is before them, and forsake the errors of the past. But, gentlemen, fear it not; such is like the wretched ghosts of the idle and the inglorious in the Inferno of Dante, who did neither good nor harm while on earth, and who

¹⁹ JOUR. AM. MED. ASS'N, vol. vi, 1886, p. 696.

²⁰ Boston Med. and Surg. Jour., vol. cxv, 1886, p. 15.

are in consequence debarred all admission into heaven and hell as having no direct character for either place:

Cacciarlii Ciel per non essermen bello ;
Nè lo profondo Inferno gli riceve.

The remarks of Dr. Crosby are heretical to the sentiments daily advanced by great men of medicine. Our beloved lamented late Dr. Austin Flint gives the following to the world with the last stroke of his pen:¹ "The unavoidable subdivision of medical literature and medical instruction into special departments makes necessary, to a certain extent, specialism in the practice of medicine. It is certain that this will not lessen, but increase in the near future, and it is important to think of possible emergencies which are even now foreshadowed. Specialism conduces to the advancement of knowledge. It behooves us, however, to consider, where the practice of medicine is to be given up to specialists, what would become of the medical profession? With due appreciation of services devoted to special branches of medical knowledge, there are tendencies pertaining to the practice of a specialty that should not be overlooked."

Dr. Angell, of Rochester, President of the Medical Society of Central New York, in his Annual Address, says:² "It is an undeniable or selfevident fact, that at the present day medical science has expanded to such an extent that its intelligent cultivation as a whole, by one person, has become impossible."

The body of the medical profession should and must "be broken up" into "specialisms." It should not remain as "a Jack of all trades and master of none." "The grand old column" which has been standing for so many years, must be repaired and decorated with fine jewels to meet the present demand in medical science, that she may glitter in the midst of other sciences. Nor "shall certain methods be considered Catholic, and all else irregular and to be damned by bell, book and candle."

If rhinology had to depend on the treatment recommended by writers of general medicine, she could not reach the bright future before her. We must take cognizance of the fact that her future is filled with admiration of the striking phenomena, having an inexhaustible mine of pathological developments lying dormant within the reach of those who wish to adjure them. For there is no condition, no period of life that can claim immunity from disease within the nasal cavity.

It is said that about nine-tenths of the human family are more or less afflicted with rhinocal disease, and which were not observed on account of insufficiency in rhinocal appliances.

Here a wide and wonderful chasm occurs, which cannot be, as formerly, overlooked. The illumination by the rhinoscope, the examination by the microscope, the extirpation by electro-cautery, the inspiration by the spray, and by the true, honest and

conscientious method of our friend Dr. Rumbold, will make rhinology fruitful and progressive. If we will not remain idle, many important facts will be unveiled and rhinology will be the greatest in the whole domain of medicine. The microscope will reveal new pathological organic disease of the olfactory sense. The variety of nasal catarrh will be divided by each individual characteristic discharge, having its own nomenclature, according to their morbid condition.

The various muco-purulent discharges which originate in the different sinuses, will, as well, be recognized by microscopic examination. All the hypertrophies within the nasal chambers will bear their own pathological name. The eruptions and ulcers in the nose will be regarded like the variety of eczema. The abscesses, polypi, and all other foreign bodies within the nasal cavities will be assigned to their own nomenclature. By a combination of the rhinoscope and the microscope diagnosis will be made easy and certain.

The treatment in nasal diseases might change in the use of drugs and remedies, but in the manner in which it is applied the spray and Rumbold's method will remain certain and without end. The day is not far when all diagnosis of the respiratory and their kindred organs will first be looked after in the upper respiratory tract. Hospitals and asylums will be well fitted out with rhinoscopic appliances for the purposes of examining all those who may become inmates of these institutions. The public will become acquainted with this specialty as well as they are with the dental profession, so that the rhinologist will not have to depend mainly on practice which is sent or recommended by the general practitioner.

Gentlemen, from all the foregoing you will doubtless place me as a specialist. I am sorry to state that I am not; nor will I be until the profession has adopted "the best policy," and that is, "honesty." I mean honesty with their professional brethren. I know of a physician in good standing befriended by all the practitioners (about one hundred in number) within his city, who three years back commenced to practice, as a specialty, diseases of the nose and throat; though he was encouraged daily while in conversation, however, during said period but a single patient was recommended to him. I hold this dishonesty; for the simple emolument of a few shekels they were but too willing to undertake to treat disease for which they are neither competent nor prepared.

There are theories which some men despise because they will not consider them, and which they will not consider, because they despise them. They naturally despise specialties, because they think them insufficient, and hate specialists, because they think them inferior; with such men, be cautious in your intercourse, as they always consider themselves greater; such men seldom confer obligations on their supposed inferiors but from interested motives. Friendly they appear, as long as it serves their own turn; but they will render no assistance in time of actual need.

In conclusion to the foregoing I will say, all those

obstacles are indeed great, but to determined and persevering exertion they are not insuperable; though we cannot conceal them from ourselves, we should not allow them to daunt our spirit; let us comfort ourselves by devoting our time and talents for the good, not only for the world of medicine, but the world of man.

ORIGINAL ARTICLES.

PNEUMONIC FEVER IN PREGNANT FEMALES.¹

BY EDWARD F. WELLS, M.D.,

PROFESSOR OF MATERIA MEDICA, PHARMACOLOGY AND CLINICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, OF CHICAGO.

Recently I have had to treat an important case of pneumonic fever in a pregnant female, in the course of which several momentous questions of practice arose in such a manner as to again, forcibly and practically, bring before my mind a subject which had already attracted much of my attention.

Case 1.—Mrs. H. K., aged 31. On December 10, 1882, being two months advanced in her fourth pregnancy, she attended church, walked home, a distance of a mile, and was at once seized with a lacerating pain under the right nipple, followed by a severe rigor, fever, cough, expectoration, and all the ordinary symptoms of a moderately severe attack of pneumonic fever, with hepatization of the lower lobe of the right lung. The malady pursued an uneventful course, during which a profuse epistaxis, an abundant labial and nasal herpetic eruption and a low range of temperature were the only remarkable features. Crisis occurred on the seventh day, and she carried her child to full term. Thirteen months later she suffered a second attack, with implication of the left base, which ran a mild course and terminated by crisis on the fifth day. At this time she was pregnant about a month, but was unaware of the fact, and again abortion did not occur.

On March 13, 1886, being near full term with her sixth pregnancy, this lady was taken with her third attack of pneumonic fever. There was a severe rigor of three hours' duration, followed by ardent fever, agonizing pain in the left side of the chest in the axillary line, distressing dyspnoea, cough, expectoration of characteristic sputa, and the other ordinary symptoms of the disease. I first saw her on the evening of the second day, and found her with, besides the above-mentioned symptoms, a flushed and anxious countenance, a rapid pulse, vomiting, etc. Throughout the entire left lung there were abundant crepitant râles, with beginning dulness and tubularity at the base posteriorly. Her abdomen was greatly enlarged and the foetal movements were vigorous and frequent. The malady gradually assumed a most alarming aspect, so that by the fourth night she was delirious and had a parched tongue and abundant sordes upon the teeth. At this juncture I advised the production of premature labor, but the measure was peremptorily declined by the

patient. On the sixth day there was low, muttering delirium, with total unconsciousness of all surroundings, a pulse of 130, temperature of 104.2°, and a respiration rate of from 48 to 60 per minute. There was retention of urine, involuntary discharge of fæces, absence of expectoration and tracheal râles. At 5 o'clock P.M. I determined to deliver, having in view the saving of the child's life and the forlorn hope of improving, however slightly, the chances of my patient. I introduced deeply into the uterus a gum elastic catheter, which brought on contraction in about four hours, and the child, a boy, was safely delivered in three hours more. The placenta was found detached and was removed in a few minutes. There was about the usual amount of hæmorrhage.

For a few hours the condition of my patient was somewhat improved. Her pulse became less frequent, falling to 92, the temperature declined gradually to 99°, and the respiration to 40 per minute. Expectoration returned, the tracheal râles disappeared, and she became, at times, more rational. On the seventh day, however, distinct symptoms of puerperal mania manifested themselves, and, these increasing in severity, she died exhausted on the ninth day. For several hours before her death there was, clearly perceptible to all who approached near the patient, present a peculiar odor—the *odor mortis*. In this connection it is but fair to say that the pulmonary symptoms, as evidenced by the diminished frequency of the respirations and cough, the easy expectoration, the moisture of the râles, etc., continued to improve to the last, and that the fatal termination was clearly due to the complications. With a full and complete knowledge of all the circumstances attending the case, I feel satisfied that had not the puerperal mania—which has already repeatedly affected her mother and two sisters—attacked her, she would have recovered. An autopsy was not allowed.

Inasmuch as a certain and almost constant proportion of women within the limits of the child-bearing age are at all times pregnant, and as pneumonic fever is no great respecter of persons, as we shall presently see, it must follow that a definite percentage of pneumonic patients are pregnant females. The mutual influence which these conditions exercise upon each other must, in the light of the experience detailed, ever remain a subject of the deepest interest and one involving questions of the greatest practical importance. Some of these interrogations may be formulated as follows:

1st. What proportion do the pregnant females bear to the total population?

2d. What proportion of the females of child-bearing age are pregnant?

3d. Does pneumonic fever attack females more or less frequently than other classes of the population?

4th. In what manner is the course and terminations of the disease modified by the condition of pregnancy?

5th. In what proportion of these cases does abortion or premature delivery occur?

6th. What modifications of treatment are desirable or necessary?

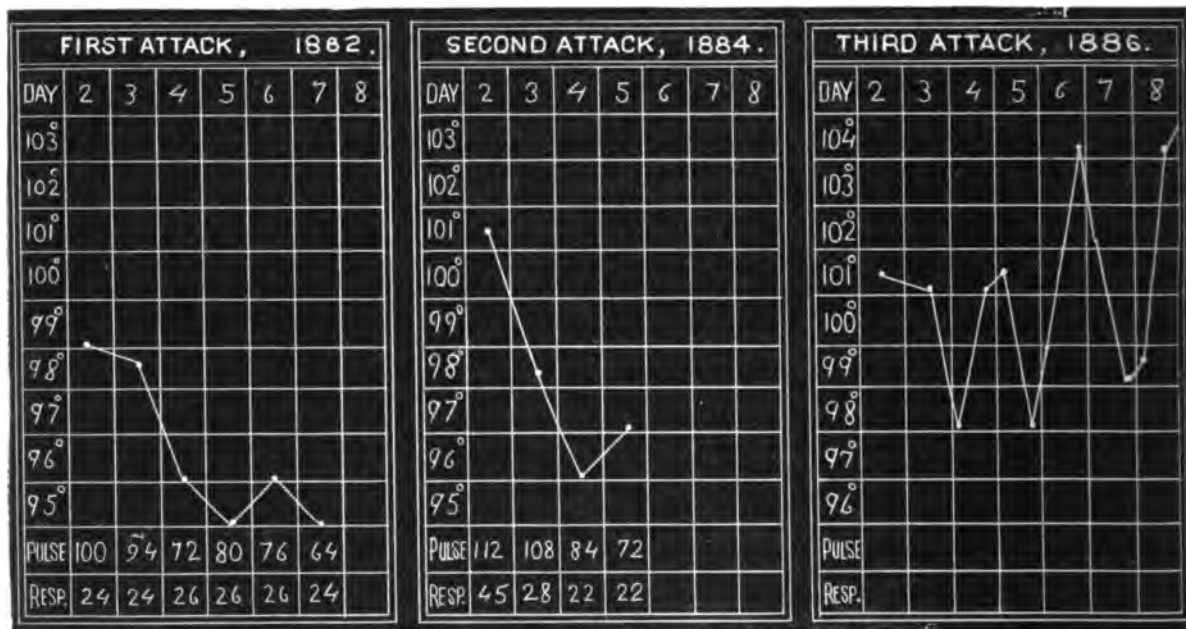

I pass by the first and second questions as being

¹ Read by title in the Section on Medicine at the Thirty-seventh Annual Meeting of the American Medical Association.

of minor importance, and come at once to the third. Jürgensen¹ considers pregnant females as being less liable to attacks of pneumonic fever than other classes of the population. Of the 2475 female pneumonic patients treated in the Vienna General Hospital only forty-three were pregnant. From the total number of patients must be subtracted 611 who were over 50 years of age, and twenty-four who were under 15 years. There remains 1824 of child-bearing age, of whom forty-three, or 2.3 per cent., were pregnant. Of these forty-three, twenty-five aborted,² and of these twenty-five, seven died, a mortality of 28 per cent.³ Of my 456 cases ninety-four were married females of child-bearing age, and of these eleven chanced to be pregnant. In these cases pregnancy had existed from one to three months, in four cases, and from six to nine months in seven cases. Of these eleven cases none of the first class aborted, and of the second class one at six months and two at eight months were prematurely delivered, and in the case related labor was brought on at near full term. The remaining seven cases carried to full

It has generally been considered that pneumonic fever pursues a more acute, rapid and severe course in the pregnant female, and that the danger is greatly augmented. This has not been the rule in my individual experience, although I do not deny that it might appertain in the practice of others. Thus Tyler Smith⁴ says that "it is well known that blood drawn from healthy women during pregnancy generally shows the buffy coat, and it is found that all inflammatory diseases have a tendency to a more acute form than usual and require a more prompt and active treatment than under any other circumstances. This is particularly the case in inflammatory diseases of the chest." Peter⁵ considers organic disease of the heart a common cause of acute pulmonary diseases in the pregnant female, and advises that women affected with heart disease should be cautioned against becoming pregnant, and should they unfortunately become so, prophylactic measures against pulmonary affections should be had recourse to.

Grisolle⁶ long ago made the statement that more

CHARTS, SHOWING TEMPERATURE, PULSE AND RESPIRATION RATE IN THE THREE ATTACKS.

term. All the patients, save one, recovered. The children were all born alive, but all except the one delivered at near term died very soon after delivery. Judging from the data afforded by Jürgensen's and my own statistics, I am clearly of the opinion that pneumonic fever is met with in pregnant females in fully as great a proportion as amongst the non-pregnant of the same age and condition. I must therefore dissent from the opinion of Jürgensen as above expressed.

than one-half of the pregnant women attacked by pneumonic fever abort or are prematurely delivered, and subsequent experience only confirmed him in this belief.⁷ Jürgensen's statistics⁸ show a somewhat larger, and my own a somewhat smaller, proportion, but the number of cases is too small to serve as a basis for correct conclusions on numerical grounds. Judging from my individual observations and from the unpublished experience of others with whom I have conversed, I am of the opinion that it would

⁷ Arch. Gen. de Méd., Jan., 1850. ⁸ Op. cit.

be more correct to say that before quickening abortion will rarely occur, but after this time premature labor will take place in the majority of cases. Gussierow⁹ and Ringe¹⁰ have made some extensive studies concerning the conditions under which abortion or premature delivery occurs in the acute infective diseases, and have come to the conclusion that the increase in the body heat is the one exciting cause. They found that a temperature of 108° certainly caused the death of the child *in utero*, with consequent delivery; and that any temperature above 104° was pretty sure to be followed by the same result. Although a high temperature may be one of the causes of miscarriage in these cases, yet I am convinced that until additional proof is offered us that it is the only cause, we ought to render a verdict of "not proven" to the proposition of Gussierow and Ringe. In my cases there were two premature deliveries in subjects with a temperature of not above 102°, and there were two others in which pregnancy proceeded to full term in which the temperature exceeded 104°. In the case detailed at the beginning of this paper there were no symptoms of approaching labor, although the temperature exceeded 104° and the child was not destroyed. It is probable, therefore, that there are other factors, equally potent, besides the exalted temperature, which determine delivery in pneumonic fever. With the multitude of possible causes at play, each of which might be instrumental in causing delivery, it must be difficult or impossible to determine exactly the influence which each exerts.

It has been thought by some that the interference of the respiratory function by pregnancy and pneumonic fever might be a cause of premature delivery.¹¹ I have never been impressed with the idea that this is the case, although I hold that such embarrassment is an indication for the production of premature labor if the child is viable.

My cases, in abstract, are as follows:

Case 2.—Mrs. M. G., aged 27, six months advanced in her third pregnancy, was taken, April 21, 1880, with the ordinary symptoms of pneumonic fever, the base of the right lung being the part locally affected. At 7 P.M. the pulse was 118, respiration 24 and temperature 101.6°. During the night she slept from 12 to 4 o'clock, being awakened by commencing labor pains. At 6 A.M. the pulse was 109, respiration 24 and temperature 101°. The os uteri was dilated to the size of a silver dollar, the membranes had just ruptured and the cord and right shoulder presented. The faulty position was rectified and a dead fœtus was at once expelled, followed in a few minutes by the placenta. The pulmonary inflammation, beginning at the base of the right lung, gradually crept upward until the entire lung was affected. The case was further complicated by a metro-peritonitis. On the seventh day there were well-marked tracheal râles, delirium and a tendency to a comatose condition. By the thirteenth day,

however, she was convalescent, and soon regained her ordinary health. A year later phthisis developed, and she died from this malady about eighteen months later.

Case 3.—Mrs. A. C., aged 26, seven months advanced in pregnancy, was attacked, March 20, 1880, with pneumonic fever, affecting locally the base of the left lung. The case ran a very severe course, with typhoid symptoms, but convalescence began on the eighth day and she carried to full term.

Case 4.—Mrs. H. F., aged 25, two months advanced in her second pregnancy, suffered an ordinary attack of pneumonic fever, locally affecting the base of the right lung, and recovered in ten days without abortion.

Case 5.—Mrs. J. B., aged 40, two months advanced in her sixth pregnancy, passed through a mild attack of this disease, affecting the right lung, in seven days without aborting.

Case 6.—Mrs. J. S., aged 35, eight months advanced in her sixth pregnancy, was seen, in consultation, just as she was entering upon convalescence from an attack of pneumonic fever, locally affecting the base of the right lung. She carried to full term.

Case 7.—Mrs. S. S., aged 20, seven months advanced in her first pregnancy, was taken, January 11, 1879, with the ordinary symptoms of pneumonic fever, affecting the base of the right lung. On the seventh and ninth days the pulse had fallen to 50, and the temperature to 96° and 95°. On the tenth day she was suddenly delivered of a living child, which died in two days. Two days later a very severe attack of diphtheria began, but she eventually recovered.

Case 8.—Mrs. F. R., aged 35, eight months advanced in her eighth pregnancy, was taken, December 2, 1878, with the ordinary symptoms of pneumonic fever, locally affecting the upper lobe of the left lung. The malady pursued an ordinary course, with a temperature curve not exceeding 102°, until the sixth day, when she was delivered of a living child, which died after a few hours. There were no premonitions of labor. She had been sleeping for hours when she was awakened by labor pains, and was at once delivered. Resolution began on the ninth day and the patient was soon well.

Case 9.—Mrs. H. W., aged 22, eight months advanced in her second pregnancy, was attacked, December 23, 1878, with pneumonic fever, locally affecting the lower and middle lobes of the right lung. The disease ran a mild course and the patient was convalescent on the eighth day, on which day there were threatenings of premature labor which were speedily relieved by appropriate treatment, and she carried to full term.

In those cases of pneumonic fever in which pregnancy does not cause any impediment to free breathing, I do not think the condition exerts any influence indicating a modification of my ordinary treatment of the disease. Miscarriage under these circumstances is a decided evil, and if it were threatened, measures should be instituted for its prevention—if this is possible. But if pregnancy be so far advanced as to cause a considerable encroachment upon the

⁹ Berliner klin. Wochenschr., 1880, No. 17.

¹⁰ Volkmann's klin. Vorträge, No. 174.

¹¹ Duncan (Lancet, 1884, vol. 1, p. 471) claims that, because the transverse diameter of the thorax is increased, the respiratory capacity of a female at full term is not always diminished.

respiratory capacity, from the amount of lung consolidation and upward pressure from the uterus, with dyspnoea and great rapidity of breathing, as in my first case, I am prepared to strongly advocate the production of premature labor. The advantages of this measure are that, if undertaken sufficiently early, the child's life is almost certainly saved, with very great relief to the patient, and, judging from my limited experience, a favorable impression upon the disease and a lessening of the danger and mortality attending it. I should advise, therefore, that premature labor should be brought on as soon as the respirations become very frequent or the dyspnoea pronounced.

It might be supposed that labor would very greatly increase the danger, but I feel assured that this is not the case, but rather the contrary. In quite a number of cases in which premature labor has occurred in the course of febrile diseases I have seen the temperature and pulse decline and the other symptoms ameliorated, even during the progress of labor, and this has also been the case in the few of my cases of pneumonic fever which were so complicated. I should be glad to see this question fully discussed, believing that valuable light can be shed upon an important class of cases.

PROPHYLAXIS MORE IMPORTANT THAN REMEDIAL TREATMENT.¹

BY T. R. BUCKHAM, A.M., M.D., F.S.Sc. (LOND.).

OF FLINT, MICHIGAN.

Although I have not given the subject which this Section has in special charge as much consideration as I have bestowed upon some other departments of our professional field, yet, I beg to outline, rather than to particularize, the importance of prophylaxis, especially in early infant life; and, while according the fullest measure of importance to the scientific treatment of diseases of infants and children, I wish to emphasize, in the strongest manner, the opinion, that if ever the fearful mortality among infants shall be so reduced as to rescue it from being classed as an *opprobrium medicorum*, it must be done by united, persistent, scientific preventive, rather than by remedial measures.

While embryocide and foeticide, technically considered, are not a part of our subject directly, yet it is a most melancholy fact, that were the debasing crimes extirpated there would be an immense number added to those who are properly within our domain; hence, although not directly, it is indirectly, a proper and most important matter for our consideration. There are no data on which to even approximately determine the extent to which this vice is practised, for the obvious reason that it is declared to be a crime and punished as a felony; therefore there are most cogent reasons for the perpetrators keeping it strictly secret. Notwithstanding the fact, however, that we are unable to furnish definite proof

of the extent, it is an open secret that the number of lives destroyed is very large. It is a surprising fact that there are many intelligent wives and husbands who yet believe, or affect to believe, that there is no life until after the third month of pregnancy; *ergo*, there is no crime in destroying the embryo. While we may not be able to convince such persons of the scientific fact, which they do not wish to understand, that there is life from the moment of conception, we may, at least, wash our hands of guilt, by taking the necessary time and trouble to demonstrate the truth to them, so that if they persist in perpetrating the most revolting of crimes—destroying the fruit of their own bodies—they shall do so fully warned of their moral turpitude, and also of the physical danger to the mother. Could we but close that one flood-gate through which pours such a stream of embryonic and foetal life, we could save more lives than by our united armamentaria of infantile remedial agents.

Before considering the diseases that directly belong to our Section, please bear with me while I call your attention to some statistics which will aid us in the investigation of the subject. The figures have been kindly furnished by the able Secretary of the State Board of Health of Michigan, or taken from Ziemssen's "Cyclopædia of Medicine." Of all the deaths in Michigan about 40 per cent. are of children under 5 years old, 2.55 per cent. die between 3 and 4 years of age, 3.67 per cent. between 2 and 3, 6.82 per cent. between 1 and 2, and about 26 per cent. under 1 year; of those who die under 1 year old, more than half die under 2 months, and, one-third under 1 month old. Observe the astonishing rapidity with which the death-rate increases as we descend from 5 years of age toward birth. From 3 to 4, the percentage is 2.50, from 2 to 3, 3.33, from 1 to 2, 6.34, and under one 26; 14 per cent. die under 2 months and more than 9 per cent. under 1 month old. To what extent can we reasonably expect our remedial agencies to control, in early infancy, the rapid course of disease which relentlessly hurries its tender victims to the grave, ere, as infants, they have fairly begun to live?

Have we always done our whole duty in actively, earnestly, warning the people, and in pointing out the road by which the danger, to some extent, at least might have been avoided? From about 9,000 deaths reported, occurring in the first year we find about 15 per cent. were nursed at the maternal font, while of those otherwise fed the percentage is 85; a difference of 70 per cent. in favor of natural feeding. Have we always earnestly and faithfully warned the devotees of fashion, who considered it little less than a calamity that they were mothers, of the onerous and sacred claim maternity laid upon them in the care of their offspring, and of the imperative duty of providing a healthy wet-nurse, if they could not, or would not themselves furnish their infants with natural sustenance? While urging in the strongest manner that mothers should nurse their children, of course exception must be made where, from debility, the life of the mother would be endangered by the tax upon her vitality by nursing, or where, from maternal disease, the milk would be injurious to the

¹ Read in the Section on Diseases of Women and Children, at the Thirty-Seventh Annual Meeting of the American Medical Association.

child. When, for sufficient reasons infants must be fed artificially, the most careful and minute details should be given to nurses and mothers as to the care and feeding of their delicate charges. I shall not occupy your time in stating what directions should be given, but I will say that I know of no more trustworthy directions than those given by Dr. Jacobi on the subject of infant feeding; and I would call especial attention to the value of barley-water as a diluent of the milk according to his recommendation. With the utmost deference, however, I remark that my experience, limited as it is in comparison with his, would lead me to dilute the milk to double the extent that he advises. Possibly the difference of opinion lies in the original richness of the milk used. In country towns we have plenty of fresh rich milk from Jersey cows; while in large cities I have often been served with milk so thin and blue that I judged its bulk had at least been doubled by too close proximity to the town pump.

While our chief attention should at first be directed to alimentation, I need not remind you that in the second year the source of danger largely changes from the alimentary to the respiratory system. "In the first year of life, stomach and intestines, in the second bronchi and lungs are the sources of increase of the death-rate. The respiratory organs are better protected habitually, in the first year and the digestive organs more improperly treated. Those infants who survive the first, are exposed to the same parental ignorance and carelessness concerning the requirements of the organs of respiration in the second." There is another factor in the diseases of infants and children which ought to be always born in mind: *i. e.*, the great relative disproportion between the weight of brain to body in infants as compared with adults. The weight of the male infant brain being in proportion to its body as about 1 to 5.85, while that of the male adult is about 1 to 46, and this proportion slightly diminished, is also true of the medulla spinalis, which wields such absolute sovereignty over infantile movements.¹ It naturally follows, that with nerve centres almost eight times as large in proportion in infants as they are in adults, that the nervous susceptibility and irritability must be very much more acute, so that it is not a surprise to us when we find that which would be a severe chill in a grown person, is generally a convulsion in an infant; hence, we cannot too carefully guard from irritation their brains and spinal cords on account of the augmented danger both direct and reflex. From the fact that there is so much more to be dreaded from the respiratory organs during the second year, we should consequently urge the absolute necessity for their being always warmly clad, breathing pure air, and being carefully guarded from sudden changes of temperature, and in many localities we may find it to be our imperative duty, unpleasant as the task

would be, to even urge personal cleanliness upon the nurse or mother.

The advantages that would arise from well-directed efforts on the part of physicians, boards of health, and civic officers to enforce strict hygienic regulations among the poor and vicious cannot well be over-estimated; as, apart from the direct mortality involved, it is in such quarters that most of our epidemics have their origin, and thus they indirectly imperil the lives of thousands upon thousands. Much has already been done in this direction by boards of health, but very much remains yet to be done. Let us give such boards of health, and all agencies having a like object in view, our active aid, as individuals; and, as a profession, our earnest outspoken support; especially should this be the case in overcoming the repugnance of the ignorant, and sometimes of those who ought to know better, to having the subject of infectious or contagious diseases put under proper quarantine, or when quarantine is impracticable then to the enforcement of the most complete isolation possible.

I trust my motives will not be misconstrued, in referring here briefly to my plan of prophylaxis of diphtheria. The details were published some twelve years ago in the Detroit medical journals, and about two years ago were referred to by THE JOURNAL. The theory is a very simple and, I think, rational one, being an assumption that the remedies which cure the disease, will prevent its development in those who have been exposed to the contagion, and therefore to all who have been exposed, or are of the household, treatment similar to that for the diphtheritic patient is administered for from six to eight days; and, permit me to add that where the medicine was faithfully administered, I have yet to see the first case in which the disease was not confined to the original patient; and further, to show the severity of the tests to which the prophylaxis was subjected, several of those first taken died, in spite of all that I and the best counsel I could obtain, could do to save their lives. I may also mention that I have received a large number of letters from Maine to California and intermediate points, in which the writers, with very few exceptions, narrate experiences in that direction similar to my own. Notwithstanding these favorable results, I no not assert that the prevention will always be as complete as in the cases to which reference has been made, because those reported to me, or which have come under my own observation are too insignificant in number, compared with those of which I know nothing, to warrant a universal conclusion; but I think enough observation has been made, and with results sufficiently favorable, to warrant my asking for the plan a fair trial, as, if it shall prove trustworthy as a prophylactic, independent of the benefit to those who have been exposed, there are few households which cannot take exclusive care of *one* sick member, and hence, the risk from the spreading of the devastating disease will be reduced to the minimum.

Of the advantages of vaccination as a prophylactic, I do not now think it necessary to say anything. Years ago, when we were compelled to use

¹ Tiedeman gives the same proportionate weight of infant brain, but gives that of the adult at 1 to 36 instead of 46. From a somewhat extensive investigation of the subject while preparing my work on "Insanity," I am satisfied that his comparative relation is erroneous, as the average male brain is from 49 to 50 ounces; hence, at his proportion, the average weight of a man would be less than 112 pounds, and his height less than 5 feet.

humanized virus, and some times had to admit that syphilis and other diseases had been inoculated with the vaccine, I confess I had often grave doubts of the benefit, as a whole, of that method of preventing variola, but now that pure bovine virus can readily be obtained all doubts respecting the great boon conferred by Jenner have disappeared.

SYSTEMATIC INSTRUCTION IN COOKERY AS A BRANCH OF COMMON SCHOOL EDUCATION.¹

BY GEORGE H. ROHÉ, M.D.,

PROFESSOR OF HYGIENE AND CLINICAL DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE, MD.

"The number of inhabitants who may be supported in any country, upon its internal produce, depends almost as much upon the state of the art of cookery as upon that of agriculture." (Count Rumford, *Complete Works*, vol. iv, p. 407.)

It is needless to call the attention of the members of this Section to the great importance of a sufficient supply of digestible and assimilable food for the maintenance of health. Physiologists have determined, both by experiment and empirically, that the different classes of food-stuffs—proteids, fats, and carbohydrates, with salts and water, must be consumed in definite proportions, if the individual's health shall be preserved. It is equally unnecessary to argue in favor of having all the various articles of food used by man of good quality and free from deleterious properties, because the sanitary conscience of every individual, no less than the physical reactions of the system, demand that healthy meat, fresh vegetables and pure water are food constituents absolutely requisite for perfect nutrition.

While, however, these propositions are accepted without dispute, it seems to be considered of minor importance how food is prepared before being taken into the stomach. Most persons, including, I am sorry to say, the large majority of physicians, are wofully ignorant of the chemistry of cookery. The changes that take place in food during its preparation for the table are not only imperfectly understood, but many physicians and nurses seem to consider it beneath their dignity to give the subject any serious thought. To say nothing of the almost universal ignorance of the culinary art, I merely call attention to the grave errors that prevail among the profession in regard to the nutritive value of meat essences, soups or teas, or of boiled meats. One hears much from quasi-professional and lay sources of the wholesome character of what is called "simple cookery." But, in the majority of instances, simple cookery means simply bad cooking. Frying, as the operation is usually done in this country, constitutes the basis of American simplicity in the culinary art, and all physicians are agreed that probably no other single factor is so prominent in the production of our national disease, dyspepsia, as this. I do not desire to be understood as condemning frying or any of the

modifications of this process of cooking, when properly done. On the contrary, I think it is an excellent method of preparing meats, fish, and many vegetables for the table. But how rarely is the American frying-pan anything else than a utensil for slowly stewing an article in grease! Saturated and permeated with fat, the fried article of food becomes an indigestible mass, incapable of acting as an aliment.

The healthy common sense of many Americans, who have given thought to this matter, has led to the establishment of cooking schools in various cities, and in connection with some scholastic institutions, in this country. In a special report on "Industrial Education in the United States," issued by the Bureau of Education in 1883, reference is made to a number of schools of instruction in the culinary art. In Lasell Seminary, at Auburndale, Mass., cooking has been taught since 1877. In the same year, this branch of domestic economy received recognition in the Iowa Agricultural College, and the instruction seems to be very thorough, both on the theoretical and practical sides of the subject. A School of Domestic Science was also organized in the Illinois Industrial University in 1874, but the instruction in the chemistry of food and cooking seems to be largely didactic. At all events, the account of this institution in the report above referred to does not indicate that any practical instruction is given in cookery. Of cooking schools proper, I believe that of Miss Juliet Corson, known as the New York School of Cookery, was the first in this country. It was established in 1876, and has been the forerunner of a number of similar institutions in various cities. The Boston Cooking School was started about 1877, and conducted by Miss Parloa. In Baltimore, a wealthy gentleman, Mr. Chas. J. Baker, has given a handsome building especially constructed for a model cooking school. The institution was opened in 1884, but has unfortunately languished, apparently on account of lack of experience on the part of the board of management.

In Raleigh, N. C., Staunton, Va., and Washington, D. C., cooking schools have been put in successful operation. In this movement in the South, Miss Helen Campbell, a well-known writer upon social and domestic subjects, has been a prominent and successful worker. A private cooking school was in operation in Memphis in 1879. Cooking classes have also been formed under the auspices of the New Century Woman's Club, of Philadelphia. Practical and systematic instruction in cookery and other useful arts is given to young women of limited means.

The limitations of institutions dependent upon private support are, however, too contracted to permit the full development of this necessary reform. The absence of a sufficient number of paying pupils for a single term, may seriously cripple, if not entirely break up a private cooking school. This has happened in one instance known to the writer. In order to avert such insecurity, cooking should be made a part of the curriculum in the public schools. Time for the introduction of a new subject of such vital importance could be obtained by dropping some of the highly ornamental "studies" with which the cur-

¹ Read by Title in the Section on State Medicine, at the Thirty-Seventh Annual Meeting of the American Medical Association.

ricula of most of our girls' schools are crowded. "Mental philosophy," trigonometry and technical grammar could with very great advantage be replaced by practical instruction in household economy, and doubtless some time could also be gained for a little needed instruction in private and domestic hygiene.

This idea is not Utopian. In London, practical lessons in cooking are given in the girls' common schools. In this country the same thing has been carried into practical effect in the city of Boston. For several years volunteer efforts have been made by Mrs. Augustus Hemenway, of that city, to give instruction in cooking to a number of girls selected from the upper classes of the grammar schools. The results attained had a good effect upon the members of the school board, and for the present year cookery has been made a regular part of the curriculum in the girls' schools. This pioneer effort should be quickly followed in every municipality in the United States, and I would urge upon the members of the Section on State Medicine and Hygiene to endeavor to secure similar action in the States they represent.

139 N. Calvert Street, Baltimore.

TREATMENT OF PUERPERAL MASTITIS

By the External Use of Spirits of Turpentine.¹

BY P. J. MURPHY, M.D.,

SURGEON IN CHARGE OF THE COLUMBIA HOSPITAL FOR WOMEN AND LYING-IN ASYLUM, WASHINGTON, D. C.

In the *Medical Record*, of July 31, 1885, page 123, appears the following article by Dr. Llewellyn Eliot, of this city: "About fifteen years ago I witnessed the beneficial effects of the free application of spirits of turpentine to abscesses and whitlows in their early stages. The result in each case in which such applications were employed was a drying up and disappearance of all traces of inflammatory or suppurative processes. From the earliest years of my professional life this has been a routine treatment with me, and arguing from analogy, it has been adopted in cases of mammary abscess when seen in its incipency. The only disadvantage attending this treatment is the odor of the turpentine, which is of no importance when contrasted with the intense pain, sleepless nights, and suffering accompanying suppuration of the gland.

"If, upon the discovery of a drawing pain upon suckling, or a tender, hard spot in any part of the gland, the part be bathed with the spirits of turpentine, and then covered with a cloth, rag, or piece of flannel saturated with the same, we may, as a rule, look for the disappearance of the hardness, the tenderness, and all other uneasiness attending this troublesome affection, in the course of two, or at the most three days. During the course of such a treatment the child may be nursed from the affected breast, but not as frequently as from the well one. It is hardly necessary to say that all traces of turpentine should be washed away before such nursing. The amount of milk secreted has never appeared

lessened in the cases observed, nor have any of the ill results of the continued use of turpentine followed either in the mother or in the child. Whether this manner of dealing with this affection be in general use or not cannot be said, still, there is no mention of it in many of the recent text-books on obstetrics.

"It is not claimed to be infallible, but its application will be attended with no bad results, even if it be unsuccessful. Strapping, pressure, rest, applications of belladonna and soap liniment, and the continuous application of an ice-bag, are among the various modes of treatment employed; but my faith now centres around the application of turpentine as an abortive of mammary abscess."

I had not seen mention made, in any of the text-books accessible to me, of the abortive treatment of mammary abscess by the external use of turpentine, nor could I find any authority recommending it as applicable in reducing inflammation of the mammary gland. I determined, therefore, to give it a fair trial, and place before you the result in thirteen cases in which the treatment was carried out. In the limited clinical experience I have had in the employment of turpentine as a local and external means of treating internal inflammations, none of the severe smarting and vesication of the skin has occurred, and in the cases I am about to recite, a general sense of comfort and relief was experienced from its application.

There is, of course, to be observed the same precaution in the use of this agent as in any other remedy—*excessive use is often an abuse*.

Case 1.—A. B. Child lived but a few hours. Breasts bandaged and became hard, some milk being secreted. Spirits of turpentine applied as a lotion and bandages left off. Milk secretion ceased and induration disappeared after a few applications.

Case 2.—A. P. Abortion at about six months. Some milk secreted on second day, and considerable induration accompanied it. Breasts bandaged and spirits of turpentine applied. Secretion of milk rapidly ceased and the induration as rapidly disappeared.

Case 3.—M. C. Breasts indurated, probably from over-secretion of milk. Spirits of turpentine applied a few times and hardness in breasts disappeared, and the super-lactation ceased.

Case 4.—M. L. Some induration of breasts, accompanied by marked over-secretion of milk. Spirits of turpentine applied three times, and induration passed away. The secretion of milk after this was of a proper quantity for child.

Case 5.—Alice G. Admitted twelve hours after delivery. The child had died. Some milk was secreted before admission, and considerable induration was present in the breasts. Spirits of turpentine applied twice daily for ten days, and secretion stopped. The induration ceased five days before.

Case 6.—L. L. Quantity of milk small; child did not nurse; breasts became hard. Spirits of turpentine applied for two days and the induration disappeared; the secretion of milk ceased.

Case 7.—S. W. Still-birth at eight months; some induration as secretion of milk began. Applications of turpentine made and induration passed away; the secretion of milk ceased.

¹Read before the Medical Society of the District of Columbia, on November 3, 1886.

Case 8.—F. R. Still-birth. Breasts became indurated and spirits of turpentine was applied freely. Some milk was secreted after thirty-four hours. Turpentine continued and milk flow arrested in a few days.

Case 9.—F. J.—Child removed by friends after milk was secreted. Considerable induration and fever occurred. Two applications of turpentine per day for two days was made. Milk secretion, fever and induration stopped.

Case 10.—V. M. Child did not nurse. Breasts became indurated and considerable milk was secreted; four applications of spirits of turpentine were made in two days, and milk secretion ceased. Induration disappeared at the same time.

Case 11.—K. M. Breasts indurated directly after beginning of lactation. Three applications of spirits of turpentine dispersed the induration. In this case, and at the same time, her temperature ran up to 103° F., and stayed above 100° until the breasts were in a normal condition.

Case 12.—M. R.—The secretion of milk from both breasts was unusually plentiful and hard lumps appeared in both glands in a short time. Spirits of turpentine was applied four times. The induration rapidly disappeared and the supply of milk was considerably lessened.

Case 13.—J. H. Was nursing child up to day of entering hospital. Breasts very large and full of milk. Did not begin treatment with spirits of turpentine until second day. Applications were made three times a day for one week, and secretion of milk ceased. There was *at no time* any hardening of the breasts.

In *none* of the above cases were alteratives, as iodide of potassium, iodine, etc., used; nor were revulsives employed.

One clinical feature wherein I differ from the experience of Dr. Eliot is, that the application of turpentine either in part checks the mammary secretion or entirely arrests it. This is amply proven in the cases above cited. I do not mean to be dogmatical in this assertion, and merely call attention to this fact in order that the experience of others may lead us to form a just conclusion as to when and where we are to make use of this remedy, if at all.

You are all familiar with the various agents adopted in the prevention of mammary abscess. Most of them have been pointed out in the brief article by Dr. Eliot; some are eminently successful in certain cases and again fail, much to our chagrin. All of them have had a fair trial in my experience, with alternate failure where I expected success and success when I had little faith in their beneficial influence.

Then, again, cases yield very slowly to turpentine applications, the hardness and induration passing away very rapidly in some and persisting for weeks in others.

If this agent prove as efficacious as my experience guarantees in the preventive treatment of puerperal mastitis, the *bête noire* of the lying-in hospital will have vanished, and hundreds of suffering women be relieved from pain and agony. But this remains to be proved, and I bring the matter to the notice of the Society for this purpose, and to give Dr. Eliot due credit for calling attention to such a valuable remedy.

MEDICAL PROGRESS.

HOT WATER AS A HÆMOSTATIC IN OBSTETRIC AND GYNÆCOLOGICAL PRACTICE.—The value of hot water injections in menorrhagia was proved many years ago by Trousseau, and for their general use in the diseases of women we are indebted especially to Emmet. Parvin, in 1876, called attention to the use of hot water in arresting hæmorrhage from ruptured adhesions in ovariectomy. Courty first applied this agent as a hæmostatic in plastic operations upon the external genitals and the vagina. The late Albert H. Smith was one of the first, if not the first, to advocate intrauterine injections of hot water in the treatment of post-partum hæmorrhage. Yet it is probable that the value of hot water is not fully recognized by the profession, nor do all seem to know at what temperature the application should be made.

Within a few years one of the most distinguished of German obstetricians has asserted that relaxation of the blood-vessels was the remote consequence of hot water injections, though contraction occurred at first. A very useful and timely contribution to the subject has recently been made by R. MILNE MURRAY, in the *Edinburgh Medical Journal*. He studied, experimentally, the effects of water at different temperatures, and found that, at 110° to 120° Fahr., it constricts blood-vessels and arrests hæmorrhage from small arteries; at a temperature of from 60° to 100°, it dilates small vessels and promotes hæmorrhage; and at a temperature of from 30° to 50 it checks hæmorrhage by constricting the blood-vessels, but this only temporarily.

In regard to its therapeutic application in inflammations, Murray claims that it is evident that in water at 120° Fahr. we have an agent of immense power in controlling the local circulation in an organ, provided we can bring the water to bear directly on the part. Accordingly, a stream of hot water injected into the vagina cannot fail to affect, in a very direct way, the circulation in the uterus. The smaller blood-vessels will respond in such a manner that their calibre becomes narrowed under the stimulating effect, the abnormal blood supply will to a large extent, be cut off, and the resulting phenomena of inflammation checked.

Undoubtedly hot water vaginal injections are useful in some cases of pelvic inflammation, but to claim for this treatment constant success and constant applicability is, we think, an error. Patients are met with in whom great discomfort follows its employment, when it should be discontinued. In considering the use of hot water in obstetric practice, Murray divides the cases into those in which the contents of the uterus have not been discharged, and those of actual or threatened post-partum hæmorrhage, the placenta having been expelled. He states, in referring to the first class, that in all cases in which the abortion is inevitable, hæmorrhage going on, and the os dilating, he adopts hot water injections as a routine practice. He regards the agent as being most valuable in those cases in which hæmorrhage is occurring or is imminent after the contents of the uterus

have been expelled, and that organ remains flabby and relaxed. Among the benefits claimed for hot water thus used are rapidity of action, duration of the tonus produced, and the absence of vascular reaction, and of exhaustion. This agent in the treatment of post-partum hæmorrhage certainly deserves all the commendation which it has received.—*Medical News*, December 4, 1886.

THE DANGER OF WOUNDING THE DIAPHRAGM IN OPERATIONS FOR EMPYEMA.—M. LAGRANGE says (*Archives Générales de Médecine*, Sept. 1886) that wounding of the diaphragm in operating for empyema is an accident the conditions of which it is necessary to know in order to avoid. He holds that it is a mistaken idea to suppose that the accident is rare, and cites cases in which it occurred when the seventh intercostal space was opened, and Kirrison on one occasion found the diaphragm as high as the sixth intercostal space. This anomalous position of the diaphragm may be caused by adherence of that structure to the lung, with retraction of the lung or retraction of the parietes of the thorax, with consequent exaggeration of curve of the diaphragm; and it is a mistake to suppose, as is stated in the textbooks, that pleural effusion is always accompanied by descent of the diaphragm. In many cases it is impossible to tell the exact position of the diaphragm, especially when it is intimately adherent to the thoracic walls. He advocates strongly that the operation of opening the pleura for the evacuation of pus should never be performed lower than the fifth intercostal space. Cases are recorded where the diaphragm has been wounded, and even the abdominal cavity opened and some of the contained viscera incised. At the Montreal General Hospital it has been the custom of late to open the pleural cavity low down, not uncommonly in the eighth and ninth spaces. I myself have frequently done this, and without any untoward result. The diaphragm can always be felt through the incision. It is a good plan, and one which I have always adopted, after cutting through the tissues down to the pleura, to use a dressing forceps, if nothing but pleura intervenes it is easily perforated, and pus immediately exudes; but if diaphragm be present, the forceps cannot be pushed through it without the exercise of considerable force, and the condition may be recognized before harm is done. The value of a low opening is very great, because we thus thoroughly empty the pleural cavity and run no risk of leaving the narrow posterior portion filled with pus. If the opening be made high up, this cavity cannot be thoroughly evacuated without washing out with some fluid, a proceeding which always complicates the operation, may introduce septic matter, and retards healing.—*Canada Med. and Surg. Journal*, December, 1886.

THE ACTION OF ANTIPYRINE.—There is an almost universal verdict that in antipyrine we have a most powerful antipyretic. That it is certain and quick in its action is generally conceded. There is no doubt that it is more certain and more rapid in its

action than all agents of this class used up to the present time, with the exception of cold water. Occasionally, however, we notice reports of disagreeable and even dangerous untoward effects, where it has been administered to reduce an elevated temperature. Dr. Graham, of Brussels, reported a case last winter where alarming symptoms of collapse followed its administration to a typhoid patient. In the *British Medical Journal* for October 2d, 1886, Dr. Fairland reports a similar alarming state where it was given to a typhoid patient. The German medical periodicals of the current year contain a considerable number of reports pointing to a like action. The question naturally arises, Is it possible to obtain all the benefits of antipyrine and at the same time to avoid its untoward effects on the circulation? We believe this can be answered in the affirmative. Antipyrine can be given in such a way as to almost preclude the possibility of its acting as a cardiac depressant. It is simply a matter of dosage. The dose should *never* exceed 20 grains; doses of 30 grains and upwards are dangerous. When given in quantities of 10 grains and repeated every hour or two until the temperature reaches 101° F., the danger of collapse is practically *nil*. To give larger doses, or to reduce the temperature to below the normal even with less quantities, is not safe.

Many able physicians question the utility of any agent that simply acts as an antipyretic in febrile diseases. They contend that nothing is gained by simply reducing the temperature for a few hours. When the course of the disease is not in any way modified, how is the patient benefited? they ask. Are not the evils arising from the disturbance of the patient's nervous and digestive systems greater than the supposed gain we obtain by lowering the temperature? When we consider the direct pernicious influence that a continuous high temperature has on the nerve centres and muscular tissues, we believe we have quite sufficient justification for the use of those agents whose only effect is to reduce the temperature. The acute granular and fatty cardiac degeneration which is so frequently an active factor in the causation of deaths from typhoid fever and pneumonia, must surely be in some measure prevented or delayed by the judicious use of such an agent as antipyrine.—*Canada Med. and Surg. Jour.*, December, 1886.

ANALGESIC PROPERTIES OF SOLANINE.—Solanine belongs to the class of poisons which includes eserine, philocarpine, atropine; etc., the first physiological effect being to paralyze the nerve terminals of the non striated muscular fibres. There are, however, certain differences in the particular action of solanine which Dr. GENEUIL proposes to utilize in medicine. The alkaloid may be prepared from the fresh seed of potato by means of boiling water slightly acidulated with sulphuric acid; ammonia is added to the hot decoction, precipitating solanine and phosphate of lime. The alkaloid is then dissolved out with alcohol and evaporated to crystallization. These crystals are insoluble in water, but slightly soluble in ether, readily so in hot alcohol. It is colored orange by

strong sulphuric acid, turning to deep violet and brown. With acids salts are formed. The hydrochlorate of solanine is obtained by dissolving solanine in alcohol, to which hydrochloric acid has been added, and precipitating the salt with ether. It forms a gelatinous body readily soluble in water. In doses of from 1 to 3 grains its action is confined to the medulla and cord, but in larger doses the cerebral cortex is also affected, the symptoms being vertigo, heaviness and noises in the ears. In poisonous doses there is violent headache, followed by delirium, cyanosis, and somnolence. Respiration is rendered deeper and slower, the pulse is not affected by the drug in medicinal doses. Its administration by the mouth in large doses is apt to give rise to nausea and vomiting with a desire to defæcate. In the stomach solanine is transformed into solanidine and glucose. Generally speaking the pupil is not dilated. Dr. Geneuil has found solanine of the greatest service in the treatment of sciatica and rheumatic neuralgia in doses of from 3 to 4 grains daily by the mouth or hypodermically. He has also used it in prurigo, cystitis, and in certain nervous affections where restlessness and insomnia were prominent symptoms. He has found it useful in acute dyspepsia and gastritis, lessening the pain and spasm, and good results have followed its administration in the obstinate vomiting of pregnancy. He recommends it strongly, in the treatment of bronchitis, bronchial asthma, cardiac asthma, and emphysema. Solanine, he says may be prescribed without danger in large doses, and its use is not attended by the same inconveniences as morphine and atropine. It is particularly in lieu of the former that he finds it of service, especially in children.—*London Medical Record*, November 15, 1886.

RESECTION OF THE TARSAL BONES IN CLUB-FOOT.—In a paper read at the Fifteenth Congress of the German Society of Surgery, Dr. KRAUSS, of Darmstadt, brought forward objections to those methods of treating club-foot, which consist in removal of portions of the skeleton of the foot, and in attempts to straighten the extremity by forcible manipulations. The author thus briefly states his views: 1. The different methods of resection of the tarsal bones impair more or less the form of the foot, the stability of its osseous arch, and the dependent mobility and usefulness of the extremity. On the other hand, a club-foot that has been successfully submitted to orthopædic treatment and tenotomy present a much-improved form, which, especially in young subjects, deviates very little, if at all, from that of the natural foot, and the usefulness of which will correspond with the innervation of its muscles. 2. Resection of the tarsus is not free from risk, whilst orthopædic treatment with tenotomy is quite safe. 3. Extirpation of the astragalus is a more suitable operation for restoring the form of the foot, than removing a wedge-shaped piece of the bones in the direction of the medio-tarsal joint, but it leaves an immovable or insufficiently movable ankle, a weak union between the os calcis and the second row of tarsal bones, and serious shortening of the foot. 4. Resection of a portion of the tarsus spoils the skeleton of the foot

to such an extent, that its performance removes almost all chance of a future restoration of the natural form of the extremity, and of its natural functions, by means of suitable orthopædic treatment. 5. There is no conceivable form of club-foot in which tarsal resection is justifiable, except it be in a case of one that is persistently painful in an old subject, and in which there is no prospect of good result from orthopædic treatment. In such a case resection might fairly be tried instead of amputation.—*London Medical Record*, October 15, 1886.

COFFINS IN THE CHURCH PORCH.—A correspondent calls attention to the practice, sanctioned by the clergy, of allowing the coffin to be brought into the church during the early part of the funeral service which takes place inside the church. In some parts of the year, this is not only offensive but even dangerous to those who sit by the decaying human tabernacle, and no possible good can result from it. The idea of bringing the corpse inside the church is, our correspondent points out, a superstition which came in about the fourth century, when the apostasy from the early faith began. The coffin, as is pointed out, might as easily be left in the porch. This is a matter to which attention may well be directed, and members of the profession would do well to endeavor to influence the clergy in favor of some change in respect to this ancient but unsanitary custom.—*British Medical Journal*, November 13, 1886.

TREATMENT OF SYPHILITIC CONDYLOMATA.—Dr. A. G. PARSONS, of Durham, N. C., writes that he has tried the following ointment in many cases of syphilitic growths on the scrotum, and around the anus, and has never met with a failure:

B. Morph. sulph.	gr. ij.
Pulv. camphor.	gr. xx.
Bismuthi subnitrat.,	
Hydrarg. chlor. mitis.	aa ʒ jss.
Cosmolin	ʒi

Sig. Wash with soap and water, and then rub the ointment in twice a day. In a few days Dr. Parsons says, the warts will be found to have entirely disappeared.—*Medical Record*, November 13, 1886.

TREATMENT OF ORCHITIS AND EPIDIDYMITIS.—Mr. LOWNDES describes the treatment adopted at the Liverpool Lock Hospital for cases of orchitis and epididymitis. The affected testicle is painted with a solution of nitrate of silver (two drachms to the ounce), at the same time strict rest in bed is enforced, and the inflamed organ is supported upon a small pillow. When the patient is compelled to go about his ordinary work, the painting of nitrate of silver tends to cure the case more rapidly, but it does not get well so quickly as those that take complete rest in bed. [In 1868 Mr. Jordan cured cases in twenty-four hours.]—*London Medical Record*, October 15, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

DRUMINE—THE NEW LOCAL ANÆSTHETIC.

The characteristics and properties of the Euphorbiaceæ are so multiple and so different, that it is scarcely a matter of surprise to learn that one of the order has now been shown to yield an anæsthetic. DR. JOHN REID, of Port Germain, South Australia, has recently obtained a local anæsthetic from *Euphorbia Drummondii*, and this drug, for want of a more convenient term, he calls *Druminc*, until chemists give a better name. In his experiments he used the hydrochlorate, *Drumini chloridum*, very soluble in water, and obtained in the following manner: A tincture is made with rectified spirit (though he believes proof spirit would answer, especially if acidulated with hydrochloric acid). After standing a few days it is evaporated to get rid of the spirit, ammonia is added in excess, and the solution filtered. The residue, after the ammonia smell is gone, is dissolved in dilute hydrochloric acid, and the filtrate is filtered through animal charcoal to destroy the abundant coloring matter, which is inactive medicinally, but causes a bluish tinge of the skin. The filtrate is evaporated slowly, and leaves the alkaloid. It gives a colorless solution with little taste, almost insoluble in ether, freely soluble in chloroform and water, and depositing from solutions microscopic colorless acicular and stellate crystals, the latter being more numerous in the deposit from aqueous solutions. Roughly speaking the length of the crystals is about one to twenty diameters of a white blood corpuscle (or from 4 to 260 mmm.). Those deposited from hydrochloric acid solution, are filtered through animal charcoal, are circular or boat-shaped at the circumfer-

ence, and stellate, or perhaps more correctly, discs, as if formed of concentric circles, and with radiating or other fissures. Under high power the acicular crystals are sometimes of a rhomboid shape, and seem less soluble in chloroform; from which it may be suspected that there are two alkaloids, though Dr. Reid was unable to investigate this point.

Dr. Schomburg, of the Adelaide Botanical Gardens, who determined the species of the plant for Dr. Reid, states that many sheep and cattle are annually killed by eating it, and that it is more poisonous according to the quantity of milky juice which it contains. It is said that animals die within twenty-four hours to seven days after eating it, all being paralyzed in the extremities, and some hanging the head as though intoxicated, though the appetite does not seem to be impaired. It is also said that yellow eyes, and even jaundice, occur in some cases. Its most remarkable and valuable effect, however, is that of causing local anæsthesia. When a few drops of a watery solution, estimated at 4 per cent., was dropped into the eye of a cat, the eye was found in a few minutes to be tolerant of contact with the finger, and the orbicularis muscle did not contract firmly as did the other. The pupil was not appreciably dilated. Three grains injected subcutaneously into the back had no other apparent effect than local anæsthesia. When Dr. Reid applied it to his tongue, nostrils and hand very marked anæsthesia was produced; even the sense of taste for quinine was abolished on the side of the tongue to which it was applied. Small doses taken internally seemed to produce no constitutional effects. In a case of sciatica in an old man, in which he had tried iodide of potassium and ammonia, the first hypodermatic injection of 4 minims of a 4 per cent. solution, enabled him to stand and walk in a short time with comparative ease, the pain having disappeared. A second injection, on the following day, acted as well, and at the time of writing the report the pain had not returned. Dr. Reid used it for cases of sprain, and the "speedy effect is probably sufficient to allow us to bid farewell to evaporating and lead lotions. I have seen it work like magic in a boy, (boil?) the dose being the same, and injected over the adductors of the thigh. For tic I have dropped it into the eye and applied locally with success."

In regard to the physiological action of drumine: "Where death arose from an overdose of the drug, paralysis of the extremities occurred. . . and we may suppose that the posterior cornua of the cord (sensation) are primarily affected, the poison passing to contiguous parts. I am very much inclined to be-

lieve that reported cases of paralysis are neither more nor less than cases in which movements remain, but the sense relations with the external world exist to a very limited extent, while motion is still possible. . . It will be seen that strychnia, as an antidote, affects only the motor parts, while there is *possibly an antagonism* to a slight extent between chloroform and the drug. . . There seems to be no special action on the pupil, although the cornea is insensitive by local application. In no case have convulsions followed its use. To sum up: cocaine seems to have a mixed action, sensory and motor, to cause preliminary excitement—Drumine is almost a pure sensory (no action on the pupil) paralyzer, without preliminary excitement; can be given with comparatively slight, if any, risk. A fungus is generated in the drug solution after some days. Its uses may be summed up as follows: Nerve troubles of a painful character, not due to a constantly exciting cause which remains potent, operations, irritation, œdema, sprains and such like; but I believe there is a brilliant future for this drug in the domain of cerebral physiology on account of its almost purely topical action. For hydrophobia, and croup with spasms, it would be used fearlessly and applied either to the nostril, by spray, or with a very fine hypodermic needle into the larynx. Those daring spirits who inject antiseptics, *e. g.*, corrosive sublimate to the phthisical lung, will probably, in this drug, find a valuable adjunct. Let us hope, from its causing no preliminary excitement, it may be useful in peritoneal and bowel ailments of a painful nature, whether by hypodermic needle or by the mouth. Writer's cramp and its congeners appear to indicate its use." In cases of poisoning by it Dr. Reid would recommend Epsom or Glauber's salts alone, or combined with tartar emetic in small doses, with plenty of fresh food, in order to eliminate it and act antidotally.

Of course the correct interpretation of facts, on untrodden ground, with a limited supply of a drug, and without such apparatus for manufacture and experimentation as would be desired, is very difficult; and certainly no one would be inclined to quarrel with Dr. Reid for not telling us more about *Drumine*—on the other hand, the world is his debtor, especially that portion of the medical world which is in the habit of making annual addresses, and which has been ringing the changes on cocaine for two years. Let us hope that, so long as they have no new facts to present, they will at least give part of their attention to *Drumine*. Dr. Reid's interesting paper may be found in the *Australasian Medical Gazette*, of October 15, 1886.

THE GENERAL MEDICAL COUNCIL OF GREAT BRITAIN.

This body, as is generally known, has the supervision of medical education and registration of those legally qualified to practice in the United Kingdom, and until the present time it has been composed of representatives appointed by the Crown, the Universities, and the Corporations or Royal Colleges of Physicians and Surgeons. By an amendment to the medical laws, adopted by Parliament in the early part of the present year, provision was made for the addition of five members to the General Council, to be chosen or elected by the profession at large. The object was to give the whole body of registered members of the profession, and especially the general practitioners, a voice in the General Medical Council. As might have been expected, many candidates were announced either by themselves or their friends, and a very general interest developed in the election. Three of the new members were to be elected in England, one in Scotland, and one in Ireland. The results of the election show that fourteen candidates were voted for in England, three in Scotland, and two in Ireland. Of the fourteen candidates voted for in England Dr. Claudius Galen Wheelhouse, of Leeds, received 8,548 votes; Sir B. Walter Foster, of Birmingham, 7,718 votes; and Dr. James Gray Glover, of London, 6,619 votes. The next two highest on the list were Dr. B. W. Richardson, of London, 4,705, and Dr. Thomas M. Dolan, of Halifax, 3,063; while the votes for the remaining nine candidates ranged from 1,223 down to 214. Of the three voted for in Scotland Dr. William Bruce, of Dingwall, received 661 votes, being a plurality of 51 over the next highest candidate. In Ireland Dr. George Kidd, of Dublin, received 1,212 votes, it being 287 majority over his only competitor. A large majority of the candidates were general practitioners, and those elected are to be regarded as pledged to represent the real interests of this important part of the profession.

AN ANATOMY ACT NEEDED IN MARYLAND.

Recent dispatches from Baltimore state that a most horrible murder was committed on December 10 for the purpose of securing the body of an old woman for the dissecting room of the University of Maryland. The fact that there had been foul play was discovered by Dr. Herbert Harlan, the Demonstrator of Anatomy, and it is thought that the negro janitor is implicated. The details of the affair have no medical interest, and need not be described. The fact that in this day the dissecting room of a medical

college, situated in a large city, or anywhere, should be dependent upon grave-robbers is, however, worthy of comment; to say nothing of the possibility for crime afforded by such dependency. It is not difficult to make a Legislature see that human bodies are necessary for medical colleges, or to get them to pass laws which will bring dissecting material to the colleges without the possibilities of grave-robbing or crime. At present enlightened, and even uneducated, people can be easily made to see that dissection is a necessary part of a medical education. But the practice of receiving bodies torn from the grave is one that brings the profession into a certain amount of disrespect, or disrepute, even among people whose sensibilities are not extraordinarily fine. It is about time that the medical profession of Maryland, and other States which have no anatomy acts, should exert themselves to the utmost in order to have proper provision made for supplying their medical colleges with dissecting material.

DIED.—At Pasadena, Cal., December 4, 1886, Edith Cole Scott, wife of Dr. X. C. Scott, of Cleveland, Ohio, in the 30th year of her age.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA.

Stated Meeting, November 3, 1886.

THE PRESIDENT, C. H. A. KLEINSCHMIDT, M.D.,
IN THE CHAIR.

(Concluded from page 669.)

DR. P. J. MURPHY read a paper on

THE TREATMENT OF PUERPERAL MASTITIS BY THE EXTERNAL APPLICATION OF SPIRITS OF TURPENTINE.

(See page 683.)

DR. L. ELLIOT said: The report which Dr. Murphy has just read, I have heard with much pleasure and satisfaction, as this method of treatment has been the one I have followed for some years, and, so far as I know, had not been reported previous to the appearance of my paper. We all know the pain and suffering attending these abscesses, and the fear with which women allow their incision. In the treatment of threatened mammary abscess, I have tried the application of ice, belladonna, tight strapping and iodine, as well as the internal administration of calcium sulphide; and have at times prevented suppuration.

About sixteen years ago I saw spirits of turpentine applied to an abscess on the neck, on account of the excessive pain experienced, and, strange

to say, after the burning had passed away, the surface became hardened and no further trouble followed. In 1879 and 1880, it was my fortune to meet with several cases of mammary abscess, all of which went to suppuration, one reaching such a state that it more resembled a cancer; free incisions with and without, drainage with horse-hair, ice-bags, supports of all kinds, strapping so tight that the pressure was painful, belladonna and camphorated soap liniment were tried, but with no good result. After this experience, the idea of the spirits of turpentine recurred to me, and in the next case it was tried with the result of seeing all inflammatory symptoms pass away in three days. The manner of its application, which I published in the *Medical Record* for July 31, 1886, is simple, and does not interfere with the employment of other measures.

The breast is bathed well with turpentine, then dried, a piece of soft cotton or flannel wrung out of turpentine is applied and allowed to remain on for a short time, possibly half an hour. This is to be repeated three or four times a day. After each application the breast is to be washed well before nursing the child. It has never been necessary to stop nursing the infant from the affected breast.

I believe if women would pay more attention to the premonitory symptoms of this trouble, seeking advice as soon as they feel a drawing pain upon suckling, and find a hard, tender spot in the breast, abscesses of this structure would be much rarer than they now are. Following this plan of treatment I have had to open but three breasts in forty cases of threatened abscess. No strangury or other unpleasant symptoms have occurred from absorption of turpentine, either in the mother or the child.

DR. S. C. BUSEY said he thought the title of Dr. Murphy's paper slightly misleading, as he does not believe that after pus has formed turpentine would effect a cure so rapidly. After reading Dr. Elliot's paper (in the *Record*, July 3, 1885,) he had determined to use turpentine when occasion offered. On October 24, last he had been called to see a lady who was nursing a ten-months old infant. The lady had had, the night before, a chill, followed by fever and sweating. She was just recovering from a second one when he saw her. Her temperature was 102.5°. She had also had pain in the right breast for several days, and that gland he found swollen, red and very painful. She had attributed this to her corsets. He could not get fluctuation, but his diagnosis was threatened mammary abscess. He ordered quinia and turpentine to the breast. If turpentine irritated it was to be diluted with oil until bearable. The next day the patient had no fever or pain in the breast, and in forty-eight hours she was well. This was a case of mastitis following injury, and was consequently more significant than some of Dr. Murphy's cases. He was, however, certain that no pus was there and that the chills were a coincident affection.

In all his long experience he had never found any method so satisfactory as this, and so far as one case goes he testifies to the efficacy of turpentine as abortifacient of threatening suppurative inflammation.

A year later the lady had a similar attack. Turpentine was used but was not successful in dissipating inflammation. There was, however, no supuration.

Mammary abscess, however, is a comparatively rare affection. It occurs most frequently in primipara, and usually follows a fissured nipple. He thought that physicians should treat promptly all fissures or abrasions upon the breast, and in this way prevent a possible abscess.

DR. C. E. HAGNER said he had had no experience in mastitis, but he agreed with Dr. Busey in the importance of prophylactic measures against abscess. He thought it important to keep the breast from becoming engorged. It ought to be properly supported as soon as milk appears, and after that kept nearly empty. He did not think it rational or according to our knowledge of pathology to suppose that any drug should be so accommodating as to pass through the skin, reach the lacteal ducts, and abort an inflammation, without getting into the milk in the ducts, as was affirmed. Warmth and moisture to relax engorged vessels were necessary in inflammation. For these, and in addition counter-irritation, turpentine might do. Cold or some hæmostatic, as ergot, might do in first stage of inflammation, but beyond that stage he did not believe abortion possible.

DR. S. C. BUSEY said that he thought Dr. Hagner a little "out" in his ideas of the pathology of mammary abscess. There were three forms. The most common was the superficial, in the subcutaneous tissue; then there was the parenchymatous and the submammary. Turpentine put on the skin does not get beyond the subcutaneous tissue, which is absorptive tissue; hence the parenchyma of the gland is not affected. Dr. Hagner says that an hæmostatic may be of use. Turpentine is an hæmostatic, though he cannot say how it acts. Dr. Hagner also says that he has never used turpentine, but when he has used it as many as thirteen times perhaps he will think better of it. If we exclude drugs whose method of action we are not familiar with, we will have to shorten our list considerably. Thus the method of action of most of the drugs we use externally is unknown.

DR. HAGNER replied that he was not referring in his previous remarks to the submammary and rare forms of abscess, but to the two commoner forms. In the thirteen cases reported by Dr. Murphy it was by no means certain that pus was going to form. Surely no pus was present in any of them so far as he could see. In fact, some were reported cured of mammary abscess before the usual time for abscess to appear under the circumstances. As for the frequency of this affection, in seventeen years of practice he had had but one case of mammary abscess.

DR. T. C. SMITH asked how the irritation and vesication usual with turpentine on a delicate skin was prevented?

DR. P. J. MURPHY replied that at the first symptom of too severe an irritation the drug was removed or the parts smeared with ointment or oil.

GYNÆCOLOGICAL SOCIETY OF BOSTON.

Stated Meeting, October 14, 1886.

THE PRESIDENT, H. O. MARCY, M.D., IN THE CHAIR.

H. J. HARRIMAN, M.D., SECRETARY.

DR. E. W. CUSHING presented a mass of HYPERTROPHIC RECURRENT GLANDULAR TISSUE REMOVED FROM THE FUNDUS UTERI.

This mass of atheromatous tissue filled a four-ounce measure and was recurrent the fourth time. Dr. Cushing called attention to the practical malignity of such growths.

He also exhibited an

OVARIAN CYST

which was interesting from the fact that it had been diagnosed as a pregnancy by a practitioner of eminence. The tumor was multilocular, and it was with difficulty extracted through a small opening. Dr. Cushing asserted that, in spite of Mr. Lawson Tait's success in operating with an incision of two inches, it was bad surgery to remove a tumor through an opening too small for comfort, and that a large incision, if aseptic, would heal as readily as a small one.

DR. W. SYMINGTON BROWN read a paper entitled

THE RÔLE OF THE OVARY.

The writer criticised the study of pathology to the exclusion of normal physiological processes. Pathological minutiae were compared to the scaffolding about a house during its erection. It serves a practical purpose, but becomes useless after the completion of the building and must be removed, else it will mar the beauty of the structure. More is to be learned by careful observation of natural processes and guarded deductions therefrom, than from the twisted facts which disease presents. For similar reasons the writer attached but little importance to vivisection as a means of discovery. Experiments on living animals may corroborate or test a great disclosure, but seldom or never find one out. The changes which the ovary undergoes each month may be called the cycles of involution and evolution. When the latter attains its maximum the ovary becomes nearly twice as large as at the close of involution. The ovary is a gland which secretes free cells. It maintains an intimate connection with many other glands—a relationship more marked during pregnancy, but also noticeable during menstruation. Various glandular diseases, such as jaundice, albumenuria, salivation and mastodynia, may all be dependent on or connected with changes in the ovary. The more rapid recovery of robust women than delicate ladies from puerperal diseases is attributed to the greater activity of the glandular system in the former class of patients.

The theories of Dr. Noeggerath, of New York, in regard to the widespread and pernicious influence of latent gonorrhoea upon the tubes and ovaries, producing sterility, were referred to with approval. The fact that prostitutes so seldom conceive is without doubt due to salpingitis and periuterine inflammation arising from gonorrhoea. This sterility is also often

found in virtuous women whose husbands are the subjects of a latent gleet and have communicated it to their wives. The fibrous ovarian sheath becomes thickened; the Fallopian tubes are filled with mucus, or closed, and it is highly probable that the ova themselves never become developed. If both sides are thus affected, sterility is a foregone conclusion.

The removal of the ovaries for metrorrhagia, salpingitis, long-continued agonizing pain or intractable pelvic disease, was discussed. Dr. Brown maintained that the common objection to these operations, that they unsex the patient, was baseless. Sex is not lodged in either ovary or testicle; if it be in one part more than another it is in the brain. A long series of observations had convinced the writer that insanity in women often depends on sexual disorders, and that such cases can only be cured by local treatment. In severe cases of hystero-epilepsy, Battey's operation is conceded by the most conservative to be justifiable.

Reference was made to a class of cases where sterility follows a sudden arrest of menstruation. Whether this unfortunate event is due to the closure of the fimbriated extremity of the Fallopian tubes by a low-grade inflammation, or to arrest of development of ova due to nervous shock, is uncertain.

In considering the question of cases in which menstruation persists after removal of the uterine appendages, attention was called to the possible existence of a third ovary or of single ovisacs in the human parovarium. Where menstruation persists for some months after such operations, it is probably due to the persistence of the original menstrual impetus. Ovariectomy has proven that the sex of the foetus does not depend upon the particular ovary which furnishes the germ. The determination of sex probably does not depend upon anything done by either party, but occurs long prior to conception in either the ovary or testicle.

DR. E. W. CUSHING wished to thank Dr. Brown for his excellent paper. He agreed with him in regard to the importance of gonorrhoea as an agent in producing disease of the uterine appendages. These results may follow from an old gleet when for years there has been no discharge at the meatus. In many cases the latent gleet can only be diagnosticated by a microscopical examination of the secretions of the urinary tract. In all cases the *gonococcus* can be found. Dr. Cushing expressed the opinion that nine-tenths of the inflammatory troubles peculiar to women arise from the clap.

DR. L. F. WARNER did not believe that a slight gleet often caused ovaritis, metritis, or many of the other diseases so often attributed to gonorrhoea. He did not believe that Noeggerath's views upon that point had ever been generally accepted by the profession.

STATE MEDICINE.

SANITARY CONVENTION AT BIG RAPIDS, MICHIGAN.

A Sanitary Convention, under the auspices of the

Michigan State Board of Health, was held November 18 and 19, 1886. It was opened by an address of welcome by the Mayor of the city, E. W. Hudnutt, Esq. Dr. John Avery, of Greenville, Mich., President of the State Board of Health, spoke in response to the address of welcome, and said that the object of the Convention was not to benefit physicians, but the public. The members of the State Board of Health also wished to gain information, that they may better serve the people.

DR. JOHN P. STODDARD, of Muskegon, read a paper on

INJURIES OF EVERY-DAY DRUG-TAKING.

He said the habit of taking drugs and nostrums was beyond comprehension. It partly came from mothers dosing babies with soothing syrup, hive syrup, paregoric, worm lozenges, etc. Druggists and proprietary medicine companies distributed flaming bills, chromos and free samples of nostrums from house to house. The prevention was to educate the people in the injurious effects of drugs. There should be less medicine taken, and only on the advice of a physician after a careful diagnosis. A doctor was not capable of prescribing for himself when ill, much less the laity, who knew nothing of the action of drugs.

DR. DAVID INGLIS, of Detroit, read a paper entitled

ALCOHOL: WHAT EFFECT HAS IT AS FOOD, MEDICINE OR POISON?

In closing his remarks on alcohol as a medicine, he said: I should like to produce the continually accumulating evidence of the positive harm caused by such indiscriminate use of all kinds of alcoholic drinks, bitters and tonics. I should like, even more carefully, to define the conditions in which alcohol ought to be used than I have here done. I have only time to urge that we ought, in all cases, to let alcoholic liquors be the last, and not the first, remedy; that we ought to give alcohol in definite and known doses, and only during such time as the drug is required, and to make it our business to see that its use is then suspended, just as we do in case of opium.

DR. J. L. BURKHART of Big Rapids, read a paper on the *Water-Supply of Big Rapids*, which embodied the report of the committee appointed by the common council to investigate the matter of procuring a better article of water for that city, and contained much of special interest to the citizens of Big Rapids.

PROF. W. N. FERRIS, of the Big Rapids Industrial School, read a paper on

HYGIENE OF SCHOOLS.

He said that he could not recall ever having visited a room regularly occupied by forty or fifty pupils, that could be said to be properly ventilated. Dullness, nervousness, headache, colds, catarrh and consumption are among the frequent effects of staying in such rooms. Under the influence of bad air, study is irksome, good behavior difficult, and the play-ground a heaven. He dwelt upon the lack of ventilation in the Big Rapids schools; and said that the foul-air openings could be made several times

larger with slight expense. Strange as it may seem, school patrons think very little about ventilation, and care less. Their sleeping and sitting rooms are without any intentional means of ventilation. Viti-ated air is the most expensive commodity which man takes into his body; for in thousands of families the expenditure of money for a single year which sickness and loss of time occasion by inhaling poison would defray the necessary expenses for properly ventilating a decently constructed house. In several of the school rooms of Big Rapids, the air space for each pupil does not exceed 200 cubic feet. We should construct rooms for lower grades very large, and use single desks. The speaker denounced the style of desks in use in one school-room in Big Rapids as "torture appliances."

JUDGE M. BROWN, of Big Rapids, read a paper on

PUBLIC HEALTH LAWS.

After referring to the health regulations of the ancients, he said: As civilization has advanced, and the average of mankind has reached a higher condition upon the plane of intelligence, health laws have become more general and better enforced. It may be stated as a fact that the race of man has advanced mentally and physically in proportion as heed has been given to the laws for the promotion of health. A kind of intuition seems to pervade the human race, aside from and above all law, that it is necessary to care for the public health in order to be comfortable and happy, and to enjoy this life. This intuition has probably led to the enactment of health laws by persons and bodies having legislative authority. Some offenses against the public health are punishable by the common law—by fine and imprisonment—such as the selling of unwholesome provisions. When articles of food are sold for domestic purposes, the law implies a warranty that they are fit for such purposes. The supreme court of this State says that this rule is not only reasonable, but essential to public safety. He then discussed English sanitary work. He thought the laws of Michigan in regard to public health were good enough, but the way they are usually enforced is very bad. Perhaps one of the greatest sources of sickness in our midst is the want of proper ventilation in buildings occupied as dwellings, public halls and other public places where large assemblages of people convene. In this county, until a very recent date, at every term of the circuit court more or less people in attendance became sick. Court was held in a room entirely unfit for occupancy on account of not being properly ventilated. . . . I desire to call attention to the subject of prisons and jails in this part of the State. I don't know a jail within the ninth congressional district that is properly ventilated, and hardly one that is proper for a human being to remain in over night. This subject has been agitated and investigated by the State Board of Health and the State Board of Correction and Charities, and a great deal of valuable work has been done; but there is still very much to do.

SURFACE FILTH AS A MEDIUM OF DISEASE

was the subject of a paper by REV. HENRY A.

WALES, of Big Rapids. He said: In 1876, Dr. Henry Bowditch, of Boston, made an estimate of the annual cost to the people of the United States because of unnecessary sickness, and placed the figures at \$100,000,000. Later, one of our own physicians—who is with us to-day—revised the estimate, going more into detail, and he increased the amount to \$300,000,000; a loss each year of over \$10,000,000 to the people of Michigan. And this estimate leaves out of view the physical suffering, the mental pain and anguish, and the death of loved ones around our social circles. In regard to filth he said: By surface filth we mean anything of this disgusting nature that is thrown upon or is suffered to lie upon the surface of the ground around our habitations or places of business—garbage, or the refuse of vegetable and animal matter; dirty water of every description, from that in which food is cleansed, to the dish-water and slops of a household; dirt swept from the floors of the home or shop; the contents of the wood-box and spittoons; the refuse of wood-yard, hen-house or pig-pen; and the excrement from chambers and privies. Besides these, there are sources of filth in musty rooms, woolen blankets, feather-beds, and the cellars under the house. Rubbish of any kind always becomes filthy if allowed to stand; and dampness increases filth by causing fermentation and vegetable growth. A close inspection of all the premises of a habitation is continuously needed, that nothing which may cause filth shall be allowed to accumulate. Mr. Wales thought that the "grand march of the giant contagion begins in the surface filth and the vaults of the civilized privy;" and he thought that if the dry earth system was universally introduced, it would exterminate such diseases as cholera, dysentery, and typhoid fever, as they are propagated solely by germs in the voided excrement.

DR. JNO. AVERY, of Greenville, President of the State Board of Health, read a paper on *Pasteur and Protective Medicine*.

FOREIGN CORRESPONDENCE

LETTER FROM LONDON.

(FROM OUR OWN CORRESPONDENT.)

Economy of Cremation—Bequest to Cambridge University—Paraplegia in Pott's Disease—Solution of Tannin for Ingrowing Toe-nail.

Mr. W. Eassie, who is Honorary Secretary of the Cremation Society of England, in a paper on *The Economy of Cremation*, shows that our present system of interment is very costly. At a low estimate the cost of the metropolitan cemeteries was taken at £272,000. Assuming cremation to be practised and to become the mode of disposing of the dead by even 50 per cent. of the population of London, a piece of ground of about 500 acres in extent would be sufficient. It shows, too, that £75,000 would amply cover the expense of the cremating area, and in addition, Mr. Eassie remarked that on

the same basis of calculation some 605 acres of ground would be saved from pollution by the dead. Furthermore, the 500 acres set apart for cremation purposes would serve a population of two and a half millions for 1000 years. The cost of funerals in England and Wales alone in 1874 amounted to £4,871,000. On a fair estimate the cost of cremating 3,100 bodies in 310 working days would only amount to some 10s. 6d. each. The facts and figures introduce in a very plain fashion a question of vast public interest. They involve considerations connected in a more than intimate fashion with the public health, and they afforded food for thought to all who are disposed to discuss a matter, which in its bearings on our physical welfare assumes a high rank. The subject of cremation is, of course, one which it is neither desirable nor possible to force into public prominence. But it is eminently one which demands the quiet and earnest consideration of all thinking people. There are in the question of the proper disposal of the dead many points of sentimental nature, which possess their due influence in modifying opinions, and in raising objections to so-called innovations. The practice of ordinary burial has been so long the way of the tomb, that any departure from this method of disposing of the dead must needs, for a time at least, be regarded with feelings approaching to impatience if not to absolute repugnance.

The most important of all the objections to the present system is the danger to health. Burial grounds, especially around London, tend to become crowded, and the condition of some cemeteries is a crying disgrace to civilization. Coffins piled one on top of the other, and separated by only a few inches of earth, present a spectacle which, while it affords a powerful argument for cremation, must also rudely shock the supporters of the method of ordinary burial. It is a known fact of science that the germs of many infectious diseases are not destroyed by prolonged burial in the earth. Pasteur's experiments on the vitality of the bacilli of splenic fever in cattle have proved this much. Hence, in times of plague and epidemic we only perpetuate by ordinary burial the danger of fresh infection of the living. Add to this the danger of pollution of water supply and of the air itself, and one can readily allow that the advocates of cremation are by no means supporting a foolish project for selfish ends when they advise the incineration of the body in preference to its long and slow decay in the ground.

At the Sanitary Congress at York, the supporters of which are known as "reformed funeral" took part in a discussion on cremation. The leading idea of this reformed method is the quick mingling of human dust with the earth. But it is obvious that one fatal objection remains to all such methods of disposal of the dead. That a body may be resolved sooner or later into its elements in the ground, and that the earth may act as a natural disinfectant, it is absolutely necessary to have a soil of a particular kind. The ground of many cemeteries, so far from disposing readily and quickly of bodies buried therein, actually leads to preserve them. The horrors of clay cem-

eteries, for example, which are essentially water-logged plats of ground can scarcely be overdrawn, and unless therefore one could invariably pick and choose our burial-grounds, it would appear that the "earth to earth" earth system is put out of court. In many localities it would be impossible to find the necessary kind of soil, therefore cremation alone is left as an unobjectionable means of decently disposing of the dead, with a due regard to the health of the living. Crematoria now exist at Woking which silently and quickly reduce a human body to a condition of dust, such as would take many years to produce under burial even in the most favorable soil. It must also be noted that the real end of burial and of cremation is practically and chemically the same. It is the disintegration of the body into its elements. Burial accomplishes this slowly and often very imperfectly, cremation produces this quickly and without danger to the living. The public is apt to associate the process of cremation with flames and funeral pyres, and the real facts of the case require to be made widely known. Did the public but know that there is no exposure of the dead, no infringement of decency or respect, and no spectacle calculated to hurt the feelings of the mourners, cremation would be more common than at present.

By the will of the late Mr. John Lucas Walker the University of Cambridge receives the munificent bequest of £10,000 "for the promotion without regard to sect or party, of scientific and literary research or of either of these objects, in Cambridge, or in the metropolis or in either of these places." After careful consultation the Vice-Chancellor, Professor Huxley, Sir James Paget and several others, have determined to establish the "John Lucas Walker Studentship," and its administration to be entrusted to the Professor of Pathology in Cambridge University, and a board of management consisting of the Cambridge Regius Professor of Medicine and Professor of Physiology, and the President of the Royal College of Physicians. The income to be applied: 1. To endow a studentship, to be called the "John Lucas Walker Studentship" of the annual value of £200, or such larger sum as the managers may determine, not exceeding £300, tenable for three years, the holder of which shall devote himself to original research in pathology. 2. To further original research in pathology, by additional studentships or exhibitions, prizes or grants at Cambridge or in London. It is stipulated that the studentships, exhibitions, or prizes may be held by and awarded to persons of either sex. It is also expressly set forth that the studentship shall not be awarded as the result of a competitive examination, but the students are to be elected on the nomination of the Professor of Pathology.

At the Harveian Society of London, Dr. Huhlings Jackson remarked on the great length of time during which a patient might remain paraplegic in cases of Pott's disease of the spine and yet recover, sometimes as long as twelve months. He trusted to rest in bed, and put no faith in drugs or applications to the spine, as he had fully made up his mind that they had no beneficial effect upon the spinal cord disease.

At the meeting Dr. Huhllings Jackson showed a boy of 12, recovering from a second attack of paraplegia associated with Pott's disease of the spine. The only treatment had been rest, and he considered the prognosis in such cases was invariably good when complete rest was enforced.

The application of a concentrated solution of tannin to an ingrowing toe-nail is highly spoken of, as it is said if applied with a camel's-hair brush to the soft parts twice a day, to quickly lessen the pain, and after a few dressings it is stated the patient is able to move about with comfort. The strength used is 6 drachms of water and an ounce of tannic acid.

LETTER FROM NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Phthisical Lung Injected with Iodine—Intubation for Laryngeal Diphtheria.

At the first December meeting of the New York Academy of Medicine, Dr. J. Blake White presented a very interesting specimen of a *Phthisical Lung Injected with Carbolized Iodine*. In his remarks upon it he said that the results which he had met with during the past year the local treatment of diseased lungs had very greatly excited his enthusiasm. Theoretically, intra-pulmonary medication seemed to be a very rational therapeutical method, and practically he had found it to be of much efficacy. He mentioned particularly a case of his in which it was followed by recovery; the progress of the patient being watched with interest by three medical friends. The preparation which he prefers for injections is a mixture of carbolic acid and tincture of iodine, to which a small quantity of morphia and atropia is added. In the cases in which he has employed it all the symptoms have been relieved; the cough being controlled, expectoration diminished, sleep improved, and night sweats checked.

The specimen presented was the left lung of a patient in whose case, although hopeless as regards cure at the time the first injection was made, the effect of the treatment was very marked and gratifying. He was a milkman, 46 years of age, and Dr. White gave a somewhat detailed history of the case. When first seen by him last summer at Charity Hospital, he was in the third stage of phthisis, with a large cavity in the upper part of the left lung, which was in a state of active suppuration. There was profuse expectoration, exhausting night sweats, and all the ordinary symptoms of advanced pulmonary tuberculosis. On the 19th of July the first injection of ten minims of carbolized iodine was made in the first intercostal space. It was followed by no reaction, and there was immediate and marked improvement in the patient's condition. The following week a second injection, of the same character and quantity, was given, and this also, without any reaction whatever, was followed by a great improvement in all the symptoms.

On August 30 a third injection was made; this time twenty-five minims of the carbolized iodine being administered. It was attended by a brief paroxysm of coughing, but no bad results followed, and marked improvement was subsequently noted in the symptoms, as before. Dr. White's term of service at the hospital now expired, and no more injections were made. The patient died October 19, and at the autopsy both the left lung and the pericardium were found involved in the most extensive pleuritic adhesions. In the vicinity of the cavity at the apex of the lung a considerable space was seen to be tinged by the injections. The upper portions, where the injections had been made, presented a marked contrast to the lower portions, where the tissues were in a state of advanced disintegration. During life also the auscultatory signs had indicated a dry condition of the upper parts very different from that met with in the lower. But very little pus was found in the cavity.

The principal paper of the evening, by Dr. Wm. P. Northrup, was on *Laryngeal Diphtheria and its Treatment by Intubation*. Had Bouchut, he said, only been a little more prudent and temperate in controversy with Trousseau in 1858, it would have been France, and not America, which would have had the honor of successfully introducing this now widely accepted method of treatment. As it was, however, the Paris Academy of Medicine announced its deliberate opinion that intubation of the larynx was impracticable, and no more was heard of it for nearly thirty years, when it was revived by a Fellow of the New York Academy of Medicine, Dr. Joseph O'Dwyer, in a manner which soon attracted the attention of the entire profession. All of Bouchut's severe cases, it was true, terminated fatally; but the fact remained that the stenosis had been relieved, and it was also incontestably shown that the larynx would tolerate a tube. These were the data upon which O'Dwyer's successful achievement was based.

Dr. Northrup then proceeded to give the statistics of all the cases of death from laryngeal diphtheria which had occurred among the children of the New York Foundling Asylum during the past five years. He did not make any distinction between croup and diphtheria of the larynx; all the fatal cases of the former being apparently included in the deaths from laryngeal diphtheria. The number of children connected with the institution is about 1800 per annum; of which 1100 are cared for by paid nurses in their own homes, and the remainder accommodated in the asylum buildings. There were 87 deaths in all from this cause; of which 50 were in females and 37 in males; and the greatest mortality was found to be between the ages of three and four years. In 56 the membranes began to form in the larynx before or simultaneously with the exudations in the pharynx. In two cases croup was the first symptom, and death occurred within twenty hours. In 54 cases there was pneumonia, and broncho-pneumonia was very frequently met with. Twenty-seven children died from extension of the membranes into the bronchi, and in 29 the pneumonia was sufficiently severe to cause death alone. In 19 the highest temperature

noted was 104°, in 15, 105°, in three, 106°, in two 103°, and in one, 107°. In all but three of the 87 cases the extent of the membranes was very marked. Interstitial emphysema occurred in eight cases. There were 51 cases of primary diphtheria, and 31 in which the disease was nearly or remotely related to scarlatina or measles.

Dr. Northrup exhibited a set of O'Dwyer's instruments for intubation, and explained the method of introducing and extracting the tube. It was better, he said, to make several short attempts to introduce it than one prolonged effort, on account of the interference with respiration thus caused. The extraction of the tube is more difficult than its introduction, and at the suggestion of Dr. O'Dwyer he recommended that physicians should practice both introduction and extraction upon the cadaver. Those beginning to practice intubation, he continued, were apt to use too small a tube, with the result that it was coughed up. Care should be taken, therefore, always to select the size of tube suitable for the age of the child, as indicated by the scale accompanying each set of instruments. There was, however, no danger of the tube slipping down into the trachea, as some seemed to fear, since the head of the smallest tube could not pass the cricoid cartilage, where the narrowest point of the passage is situated. Neither was there any danger of ulceration of the vocal cords being caused by the tube.

If the condition of the child continued encouraging for forty-eight hours after the insertion of the tube, Dr. Northrup thought that a favorable prognosis might be given; but that it was entirely unsafe to make such a prognosis at any period before the expiration of the forty-eight hours. Not infrequently the greatest possible relief was temporarily secured by intubation in cases which afterwards terminated fatally by the extension of the membranes downwards or by the occurrence of pneumonia. He also spoke a word of caution in regard to withdrawing the tube too soon. Whether it would be advisable to reintroduce the latter in any case would depend on the condition indicated by an examination of the chest. If, on auscultation, the vesicular murmur was normal, there was no cause for uneasiness; but if it was found that the air could not get well into the lungs, especially the posterior portions, it was time to reintroduce the tube. The condition of the pulse also served as a valuable guide to the experienced.

Having mentioned that O'Dwyer's tubes were of good service in stenosis of the larynx in adults, and especially when the condition was due to syphilis, he announced some general conclusions, among which were the following: Intubation relieves dyspnoea due to laryngeal stenosis, and is open to few objections. It is comparatively simple and is also free from danger. No anæsthetic is required, nor is there need of a trained assistant. There is no fresh wound to serve as a new focus for infection. If intubation proves inefficacious, tracheotomy can still be performed. Intubation, however, he said, had one conspicuous fault, viz.: that it embarrasses and sometimes interferes with deglutition. There is also one danger connected with it: the tube might possibly push some

of the tenacious membrane down before it, and thus cause a blocking up of the trachea below.

Did it meet the requirements? he asked. The statistics undoubtedly showed that it did. Waxham had had 96 cases, and O'Dwyer 48; and in the 165 cases which had thus far been reported, no less than 28½ per cent. had been saved. It was to be remembered, too, that the method was still new. Valuable experience had been gained, and it could scarcely be doubted that in the future the results would be even more favorable. The statistics of tracheotomy showed no such satisfactory result as this, and Dr. Northrup believed that if all the fatal cases of the operation were reported, the percentage of mortality would be considerably larger than it now appeared.

In the discussion which followed the reading of the paper, Dr. Francis Huber stated that he had practised intubation in eleven cases. The special conditions which led him to resort to it were aphonia, stridulous expiration, and extreme recession of the chest walls, above and below the sternum. He gave a brief sketch of each of his cases, and then said that out of the eleven there had been four recoveries, while one child was still wearing the tube. Five had died, and one other, in which he had just practised intubation, would probably also prove fatal. These results were much better than he had obtained with tracheotomy, which he had performed twelve times, but had succeeded in saving only two out of the twelve children. He stated, also, that in all his cases of intubation the method was resorted to very late. In conclusion, he exhibited a modification of the O'Dwyer gag devised by his friend, Dr. Denhard, who had also had eleven cases of intubation. Five of them were successful, and all of the eleven, like his own, were late cases.

Dr. A. S. Hunter related two cases, both seen in consultation, in which he had practised intubation. The first was that of a child 6 years of age who had been suffering from membranous croup for two days. The stenosis was extreme, and pulmonary cedema was coming on. He introduced the tube with little difficulty, and the relief was immediate and very marked. After forty-eight hours, however, he saw the patient again, and found the respiration very rapid. It had great difficulty in walking, and he found that by trying it with a considerable quantity of nourishment at a time it did better than if the attempt was made to feed it by the teaspoonful. The pulmonary trouble was now so great that it was evident that the child could live but a few hours longer. He therefore removed the tube, and found that it breathed well without it. Death occurred about seven hours afterward. The second case was in a child 2½ years old with diphtheria, who had a temperature of 103.5°. There was marked stenosis of the larynx, and it was almost completely asphyxiated. The relief afforded by intubation, as in the other case, was prompt and satisfactory. The next day, however, the child coughed up the tube, and it was reintroduced by the attending physician; but death ensued in five or six hours later. Dr. Hunter stated that he had practised intubation five or six times on the cadaver before he attempted it on the living subject.

Dr. Partridge said that Dr. Northrup had mentioned that the only danger from intubation was the possible detachment of portions of membrane which might act as a diaphragm in the trachea below the tube. The same objection held true, however, in regard to tracheotomy; and he referred to a case of this operation in which fatal obstruction occurred in the manner described.

On the evening of December 3, the first meeting of the Section on Public Health, Hygiene and Legal Medicine was held; when Dr. Blaine, of the Willard Asylum at Ovid, N. Y., read a paper on "Bovine Tuberculosis; Its Communication by Inhalation, Ingestion and Hereditary Transmission, and its Dangers to Public Health."

P. B. P.

PENETRATING WOUNDS OF THE ABDOMEN. TO THE EDITOR OF THE JOURNAL:

Dear Sir:—I notice by the report of the discussion which followed the reading of Dr. H. H. Smith's paper on "Penetrating Wounds of the Abdomen," read in the Section on Surgery, at the thirty-seventh annual meeting of the Association, as given in your issue of November 27, I am credited with remarks which do not clearly represent my position or views upon the important subject which was presented. Most likely, at the time of the discussion, I was not distinctly heard by the Secretary; or else the necessity to condense prevented him reporting me as fully as I should have desired.

What I did say in substance was this: That although I *had been credited* with the honor of having been the first to open the abdomen to search for perforated gunshot wounds of the intestine, *where there had been no protrusion*, and to apply sutures to the intestinal wounds, yet I was by no means disposed to urge this practice as the best under all circumstances. On this account I would mention my two published cases. The first of these was the one in which the operation was done for artificial anus following a bullet wound received some weeks previously. There had been no intestinal protrusion. I opened the abdomen, freed the wounded intestine from its many adhesions, resected the same, thus restoring the continuity of the gut, by suturing together the freshened surfaces (See *Amer. Jour. of the Med. Sciences*, July, 1867; also 2d vol. "Surgical History of the War").

In the other case, the abdomen was opened for a recent pistol wound of abdomen without protrusion (See *Transactions of South Carolina Medical Association*, 1882; also *Medical News*, May 13, 1882). Here I exposed and sutured five perforations of the small intestines, and two of the mesentery, but failed to discover, as shown by the post-mortem, one additional intestinal wound. I mention this case because of the turn this discussion has taken. It is a fixed idea with many that where there are perforations of the intestines there must be fecal extravasation. No such extravasation was found at the autopsy, although, as said, I had failed to suture one of the perforations of the gut. And yet there had occurred diffusive

peritonitis and death. So, then, the argument that there must be fecal extravasation, which will lead on to a fatal termination if there be no immediate operation, cannot always be sustained. I am, from my report of these early cases, upon record as an advocate for immediate operation by abdominal section in wounds of the character described; and I still hold to this view, while admitting that those who advocate a different practice have some reason to sustain them.

Dr. Gregory, who has been most earnest in condemnation of the immediate operation, has spoken very wisely and judiciously in some regard. But I cannot accept one of the propositions as announced by him, viz.: that traumatic inflammation is always a limited process. This is not true, and such a doctrine cannot be used as an argument to induce us to remain passive where the intestines have probably been perforated. Traumatic inflammation, as I know to my cost, often extends rapidly. Practically it matters not whether such extension be caused by *sepsis* or not. I remember many years ago, forcing down by the finger in the rectum, a small sessile fibroma of the uterus, and causing it to encroach upon the posterior vaginal wall. Then I cut open the small tumor and twisted it off in a second. My patient died in a few days of diffusive peritonitis. Was not this an extension of a traumatic inflammation? The same result can as readily, or more readily, follow a perforated bullet wound of the intestine. Are we, then, not warranted in trying to prevent such a calamity by an early abdominal section? Respectfully,

R. A. KINLOCH, M.D.

285 Meeting St., Charleston, Dec. 8, 1886.

ABUSE OF MEDICAL CHARITIES.

TO THE EDITOR OF THE JOURNAL:

Dear Sir:—The editorial in *THE JOURNAL* for November 27 suggests one point in connection with Dispensary service for neglect of which the profession is blamable. The principles inculcated in the Code of Ethics, Sec. 3, Art. 1 ("duties of the profession to the public"), are most praiseworthy, but it would be well to define them by adding "in the absence of provision for that purpose, or in cases of sudden emergency." In every centre of population exists a large body of the impecunious. This comprises first, those whose means are small, or whose employment is irregular and income uncertain; and second, the habitual pauper and the habitual "dead-beat." Honest, legitimate poverty deserves the sympathy and assistance of every right minded man, and in most cases can command it. In this country such a condition is, as a rule, temporary or due to passing causes, and with these unfortunates any regular ethical practitioner can accommodate circumstances to cases without violating the spirit of his fee bill. It is in dealing with the habitual pauper and the habitual dead-beat, that the profession does itself grave injustice, and tends to still further demoralize this class. Practically they only exist in towns containing some thousands of inhabitants, and when resident for any

length of time become well known. Their demands upon the practitioner are arbitrary, arrogant, and unceasing; while the general testimony is that they are more troublesome and unreasonable than good paying patients. It is from their ranks that the unwarrantable but none the less harrassing actions for malpractice arise; and they furnish the majority of the litigants in damage cases against corporations and private individuals of means.

The point I wish to urge is that the profession should in practice be more discriminating; where means of relief have been provided by the local authority, they should unhesitatingly refuse applications for services from these classes, and where attendance has been accidental or involuntary it should be immediately discontinued.

It tends still further to demoralize, where medical men allow bills to be contracted by persons having no means and very rarely any intention of liquidating them.

Indirectly the druggists as a body suffer from similar causes, as their bills for prescriptions compounded are impossible to collect. That a young practitioner will occasionally meet a case which possesses sufficient interest or rarity to repay him, is not to be gainsaid, but the instances are few and far between. On the other hand, the dignity of the profession is lowered, its motives misinterpreted, and good intentions brought into disrepute by this element, which sneers at the eagerness of physicians for business, boasts that it can obtain the services of "any doctor in town," and is ever importunate, ungrateful and vindictive.

Yours truly,

JAMES H. PARKINSON, L.R.C.S.,
City Physician, Sacramento, Cal.

NECROLOGY.

JAMES T. MEEK, M.D.

Dr. James T. Meek was born in York Co., S. C., in 1842, and died in Ennis, Texas, November 11, 1886, aged 44 years. He was educated at the Kings Mountain Military Institute, graduating in 1859. He at once began the study of medicine under the direction of Drs. Lindsley and Jackson, of Yorkville, S. C., and attended his first course of lectures in 1859-60 at the South Carolina Medical College. On the breaking out of hostilities between the States, he laid aside his studies and shouldered a musket as a private soldier in the 5th S. C. Regiment (Confederate). The authorities soon found that he could be much more serviceable in the medical department than in the ranks, and he was accordingly transferred to the former. Notwithstanding the fact that he was already relieved from the position of a private soldier, he persisted in retaining his former post during the first battle of Manassas, in which his nerve and undoubted courage won him the approbation of his comrades, both officers and men.

Dr. Meek graduated in medicine at the Virginia Medical College, Richmond, Va., during the session

of 1862-3. Soon after his graduation in medicine he passed a most successful examination before the Board of Army and Naval Medical Examiners (C.S.A.), and was at once given the rank of assistant surgeon in the army, and assigned to duty in the Winder Hospital, Richmond, Va., where he soon, by his studious habits, gentlemanly bearing and the successful practice of his profession, won distinction and honor. He continued in the medical service of the Confederacy till the final collapse, filling various positions of trust both in the field and hospital, and laying up precious stores of clinical experience, both in medicine and surgery, upon which he was able to draw in after years with honor to himself, and of untold advantage to his patients and medical friends.

The war being over he located in Johnsville, Bradley Co., Ark., in the summer of 1865, where he at once entered on a large and lucrative practice. His work in this field was immense, and far too trying for his physical strength. After six years of arduous labor at Johnsville (during which he contracted the malady, which finally proved fatal), he moved to Ennis, Texas, where he resided till the time of his death. In this new field, as elsewhere, he soon made many warm friends among the profession as well as the laity, and to the very last was honored with the business and confidence of a numerous and respectable clientèle. He was a man of most noble traits of character, and of sterling worth, firm and decided in his opinions, yet kind and courteous in his intercourse with others, and especially so towards his professional brethren. As a man he loved truth, loved honor, and could be trusted and confided in under all circumstances. As a physician he was conscientious, conservative, able, and his practice both in medicine and surgery was eminently successful. He took a deep interest in medical societies, and was a member at the time of his death of the American Medical Association, the Texas State Medical Association, and the Ellis County Medical Society.

BOOK REVIEWS.

A MANUAL OF MIDWIFERY. By ALFRED LEWIS GALABIN, M.A., M.D., F.R.C.S. (Lond.), Obstetric Physician and Lecturer on Midwifery and the Diseases of Women to Guy's Hospital, etc. Illustrated with 227 wood engravings. 8vo., pp. xxxii-753. Philadelphia: P. Blakiston, Son & Co. 1886. Chicago: W. T. Keener.

The first thing to be noticed in opening this book is that the author has, and wisely some may think, omitted a general description of the anatomy of the female sexual organs, or of the development of the embryo, for the very good reason that students are supposed to be familiar with this subject before beginning the study of midwifery. He has only given so much of the anatomy of the pelvis as has a direct bearing upon the subject of the book. With the exception of some points the teaching of the book agrees with that given by most obstetrical authorities. Among the exceptions may be mentioned the choice

of leg to seize in version for shoulder presentation, the application of a noose to the prolapsed arm, the use of the vectis in protracted labor with an unreduced occipito-posterior position of the vertex, and the use of an oscillatory movement in forceps extraction. In regard to the choice of the leg to be seized in transverse presentations, Dr. Galabin's teaching is practically the same as that given by Lusk, and opposed to that of Simpson, who held that the facility of version depended upon seizing the leg of the *opposite* side of the body to the presenting shoulder. The author's teaching with regard to the application of a noose to the prolapsed arm has also been followed in this country, and in the *American Journal of Obstetrics*, vol. ix, p. 203, may be found the account of an ingenious method which Dr. F. P. Foster employed for making use of the prolapsed arm as an aid to version.

Dr. Galabin uses the vectis in the following manner in occipito-posterior positions: "When labor is arrested or protracted and the occiput fails to rotate forward, rotation may be effected either by a force actually directing the occiput forward, or by one which causes flexion, since it is through defect in flexion that the inclined plane of soft parts fails to turn the occiput forward as usual. Both these indications are fulfilled by the use of the vectis. If the vectis is applied over the occiput and traction made toward the vaginal outlet, as much forward as possible, first, flexion is promoted by the descent of the occiput, and, secondly, the occiput is directly drawn forward, since the vaginal outlet is directed forward in reference to the direction of the pelvic axis at the point where the centre of the head is lying. . . . Even when called in to perform craniotomy, after vigorous efforts to extract with forceps had failed, I have found that the occiput could be turned forward by the vectis with surprising ease, and that then extraction with the forceps presented no difficulty whatever." Without Dr. Galabin's direct statement it would scarcely seem probable that delivery could not be effected with the forceps alone with the complication mentioned; but in other than skilful hands it seems that the vectis is less capable of causing injury to the maternal soft parts, as it is used as a lever, the left hand, pushed up as high as possible, being the point of lever-resistance, and not the pelvic wall.

The gain which can be obtained by oscillatory movements of the forceps, says Dr. Galabin, is due solely to the amount of friction which can be reversed; and this movement is only admissible in those cases in which friction is an important obstacle to advance. And even in these cases he thinks that it is best avoided if direct traction can effect the object sought. "When, however, the head is engaged in the pelvic canal, and impacted in it by friction so that it cannot be readily pushed back in the interval of a pain, and when moderate traction fails to cause any advance of the head, oscillatory movement of the handles may be cautiously tried before recourse is had to craniotomy. The oscillation should be limited in degree, and with each oscillation should be combined firm compression of the handles, so as to make the head one solid mass with the

blades, and the maximum of traction which it is thought safe to exert. The oscillation, to be of service, should be in that diameter in which the head is most tightly gripped by the pelvis. Thus, in a flattened pelvis it should be backward and forward, and in a uniformly contracted pelvis it may be in both directions, or the two may be combined in a limited circular movement. . . . The oscillatory movement should not be persevered with long unless the head is found to advance with it, for, if the leverage is successfully called into play, there must be an advance at each oscillation."

There are other points of special interest in this book on which we would gladly touch did space allow. We can only say that one cannot be otherwise than pleased with the work. It is well written; and both author and publishers have reason to congratulate themselves upon its value and appearance.

OUTLINES OF THE PATHOLOGY AND TREATMENT OF SYPHILIS AND ALLIED VENEREAL DISEASES. By HERMANN VON ZEISSL, M.D., Late Professor at the Imperial-Royal University of Vienna. Second Edition, revised by MAXIMILIAN VON ZEISSL, M.D., Privat-docent for Diseases of the Skin and Syphilis, at the Imperial-Royal University of Vienna. Authorized edition. Translated, with Notes, by H. RAPHAEL, M.D., etc., New York, 8vo., pp. xii, 402. New York: D. Appleton & Co. 1886. Chicago: A. C. McClurg & Co.

The most needle-eyed critic, except he be a unicist, can find nothing to carp at in this book, which is a summary of the life-work of one of the, if not the, most eminent syphilographer that ever lived. Added to this, the book has been translated by one who is sufficiently a master of both English and German as to have given us a good translation, singularly free from the round-about expressions too frequently seen in works translated from the German. Those who know anything of the methods of the late Professor von Zeissl need not be told that all his work and investigations were carried out with conscientious scientific exactness and thoroughness, and that while wedded to pathology he was never divorced from good therapeutics. It is rarely, indeed, that one can find a work in which pathology and therapeutics are so happily combined as that neither seems to have been given more consideration than the other. We would more especially recommend the work to some of our dermatological friends (a few of whom reside in England) who have a *penchant* for finding new syphilitic lesions, and for giving them incomprehensible and startling names.

HOW WE TREAT WOUNDS TO-DAY. A Treatise on the Subject of Antiseptic Surgery which can be understood by Beginners. By ROBERT T. MORRIS, M.D., Late House Surgeon to Bellevue Hospital; Consulting Surgeon to the Woman's Hospital of Brooklyn, etc. Second edition, pp. x, 164. New York: G. P. Putnam's Sons. 1886.

The first fault which a reviewer has to find with this book is that it is not indexed: this is a grave

fault in any book, however small it may be. But on careful search one must admit that this is the only fault that can be found in this very complete résumé of the antiseptic treatment of wounds. The author has a style which seems to be all his own, and for a larger and more pretentious work would be thought undignified; but it is a style which impresses facts upon the reader; and after all that is one great factor in making a book useful. No one who reads this book carefully and with understanding can afterwards feel that any of his time was wasted. Dr. Morris not only tells his readers how to dress wounds, and with what, but he tells them where the materials can be bought, how much they will cost, and how they should be prepared. The subject is presented to the readers as though it were something entirely new—and this is just what should have been done.

SURGICAL DISEASES OF THE KIDNEY. By HENRY MORRIS, M.A., M.B., F.R.C.S., Surgeon to and Lecturer on Surgery at the Middlesex Hospital, London. 12mo., 555 pages, with 6 chromo-lithographic plates and 40 engravings. Cloth, \$2.25. Philadelphia: Lea Brothers & Co., 1886. Chicago: A. C. McClurg & Co.

Ten or fifteen years ago, before surgeons handled the kidney so freely as at the present day, this book might have been considered a useless addition to surgical literature. But since we have learned so much about these organs, and have found out that there is much more to be learned, such a book, from a surgeon who commands as much respect as does Mr. Henry Morris, cannot be otherwise than favorably received. It is especially to be noted that the work is introduced by a few pages on the regional anatomy of the kidney. The directions for the various operations on the kidneys are given clearly and concisely.

ECONOMY OF COAL IN HOUSE FIRES; or how to convert an ordinary Fire Grate into a slow combustion Stove at a Small Cost. By T. PRIDGIN TEALE, M.A., F.R.C.S., Surgeon to the General Infirmary at Leeds. Illustrated. Pamphlet, cloth, pp. 47, 10 plates.

A DISCOURSE ON THE PRINCIPLES OF DOMESTIC FIREPLACE CONSTRUCTION. By T. PRIDGIN TEALE, delivered at the Royal Institution on February 5, 1886. Pp. 30, bound with above. Leeds: Goodall and Suddick. London: J. & A. Churchill. 1886.

The article on "Economy of Coal in House Fires" is an expansion of a lecture delivered in 1882, and is now "published in the hope that it may contribute to the diminution of the soot and smoke throughout the Kingdom, and so further one great aim of sanitary reformers, the improvement of the atmosphere of towns; that it may effect a large reduction in the amount of cinders and ashes, and so lessen municipal rates; that it may enhance the comfort of the sick room by rendering a fire more free from noise and dust and more lasting; and that it may induce many persons, including the delicate, the invalid, and the

hardworked family doctor, to look upon a fire in the bedroom, not as a superfluous extravagance, but as a much needed comfort, nay, as a profitable investment towards the maintenance of health." Surely such objects are worthy of all respect, and in no place should they be more appreciated, outside of England, than in Chicago.

It does not require a very great amount of knowledge or intelligence to follow the plain statements and directions of Mr. Teale in regard to fireplace construction and economy of fuel, and the illustrations are good enough to enable one to easily understand what is shown. In another department there will soon appear a more general discussion of Mr. Teale's work.

THE SURGICAL DISEASES OF CHILDREN. By EDMUND OWEN, M.B., F.R.C.S., Surgeon to the Hospital for Sick Children, Great Ormond Street, London. 12mo., 585 pages, with 4 chromo-lithographic plates and 85 engravings. Cloth, \$2. Philadelphia: Lea Brothers & Co. Chicago: A. C. McClurg & Co.

This volume may be called a "complete monograph" in a series of clinical manuals, rather than an attempt at an exhaustive treatise. It is not as its title implies, strictly limited to the surgical affections of children, but this does not render it the less valuable. The whole book is well written, is well indexed, and is a valuable addition to a valuable series of clinical manuals.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH.—The next meeting of the Fifth District Branch will be the third *annual meeting*, to be held in Brooklyn, on Tuesday, May 24, 1887. There will be a morning and an afternoon session. All Fellows are solicited to contribute to the meeting, either by reading papers, notes or communications, or by exhibiting specimens. All papers offered

are the property of the Branch, and in future will be published in a current Medical Journal. The Secretary desires to be notified of the title of any paper to be offered as early, as convenient.

E. H. SQUIBB, M.D., *Secretary*.

P. O. Box 94, Brooklyn.

TYPHOID FROM A SINGLE DOSE.—M. Dujardin-Beaumetz has forwarded to the Paris Academy of Sciences a communication on the Pierrefonds typhoid cases last summer. M. Fernet, who occupies a high post at the Ministry of Public Instruction, his wife and family, hired a house at Pierrefonds, a fashionable resort near Compiègne, contiguous to two others. After they had rented it for the season they were told to beware of the water in the well. On this account they drank exclusively mineral water until the last day, when the stock was out, and the servants were too busy preparing to return to Paris to go and fetch some bottles from the chemist. Madame Fernet said, "For once surely there can be no harm in drinking the well-water." They drank it. Six out of the nine persons have since died, including one of the servants. The cook, two of the four children, and Madame Fernet had had typhoid fever before, and though attacked again by it after their return from Pierrefonds, have got through the illness. The well has been examined and is reported to contain the bacilli which are believed to be associated with typhoid fever. This is a common danger to which visitors to so-called health resorts, both on the continent and at home, are frequently subjected. The facility with which well-water is infected is hidden from the population by the impunity with which filthy well-water may often be drunk by resident families who have become acclimatised, especially when that water is for the moment infected only by non-poisonous faecal matter, and this fancied immunity often leads to habits of carelessness, for which not themselves only, but their visitors have to suffer.—*British Medical Journal*, Nov. 27, 1886.

SANITARY INSPECTORS.—In a paper on this subject, read before the New Jersey State Sanitary Association on Nov. 19, DR. HENRY MITCHELL said: The inspector should so thoroughly know every part of every building in his district; its surroundings, its construction, its lighting, heating, ventilation, water supply and drainage, that he can almost certainly anticipate just how preventable disease may be produced on a given premises. He should be able to tell how it can happen, for instance, that typhoid fever could appear; whether the water supply, the cellar, the door-yard or the drainage is in fault, and whether an adjoining premises has probably caused the mischief; and whether the case was probably imported from another locality. He should know the vital statistics of every dwelling, and be thus aided in judging of the probability of the existence about a premises of some unknown source of danger to health. He should know the condition of every vacant lot, street, and public place in his district.

All of this valuable information should be carefully and regularly recorded and classified, so that it may

be available for daily study. Is it probable that these various facts can be carried in memory in a clear and useful form? And if death or removal from office deprives a locality of its inspector, shall the accumulated information which years, perhaps, may have been expended in gathering, be lost? Such a sanitary history should be on the files of every local board of health, and its story should be familiar to every member of such a board. Such a record is worthy of the greatest care in its preparation. Entries should be made with ink, and nothing vague or indefinite should mar its pages.—*Sanitary News*, Dec. 11, 1886.

WOMAN'S MEDICAL COLLEGE OF CINCINNATI.—The first Session will begin on February 16, 1887, with full Faculty and ample facilities. The Dean is Dr. D. D. Bramble, 165 Broadway, Cincinnati.

OHIO STATE SANITARY ASSOCIATION.—The fourth annual meeting of this Association will be held at Columbus, O., on the second Thursday and Friday of February, 1887.

DR. R. HARVEY REED, of Mansfield, O., recently gave "A Sanitary Talk for the Farmer" before a farmer's institute held in Mansfield. Such meetings afford excellent opportunity for the sanitarian to sow sanitary seed, and the *Sanitary News* suggests that State Boards of Health coöperate with agricultural boards so as to be heard at the regular meetings.

DR. OWEN T. HUNT, of La Crosse, Ark., died on September 22, from the effects of a gunshot wound. He was born in Tennessee in 1833, and was graduated from the University of Pennsylvania in 1854.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM DECEMBER 4, 1886, TO DECEMBER 10, 1886.

Major A. A. Woodhull, Surgeon, ordered for duty at post of Ft. Leavenworth, Kans. S. O. 138, Dept. Mo., Dec. 3, 1886.

Capt. F. C. Ainsworth, Asst. Surgeon, will repair to this city and report in person to the Secretary of War, and on completion of the duty which may be required of him will return to his station (New York City). S. O. 280, A. G. O., Dec. 3, 1886.

Capt. Fred. C. Ainsworth, Asst. Surgeon, relieved from duty as Recorder of the Army Medical Examining Board, New York City, and ordered to report in person to the Surgeon-General of the Army for duty in his office. S. O. 282, A. G. O., Dec. 6, 1886.

Capt. P. R. Brown, Asst. Surgeon, leave of absence for seven days, granted by Post Order, is extended twenty-three days. S. O. 124, Dept. Ariz., Nov. 24, 1886.

Capt. H. S. Turrill, Asst. Surgeon, ordered for duty as Post Surgeon, Ft. Spokane, W. T. S. O. 207, Dept. Columbia, Nov. 29, 1886.

Capt. Edward C. Carter, Asst. Surgeon, leave of absence extended six months. S. O. 281, A. G. O., Dec. 4, 1886.

First Lieut. Paul Clendenia, Asst. Surgeon, assigned to duty at Ft. Davis, Tex. S. O. 166, Dept. Texas, Nov. 29, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, DURING THE WEEK ENDING DECEMBER 11, 1886.

Percy, H. T., P. A. Surgeon, U. S. N., ordered to Naval Academy, Annapolis, Md.

Norfleet, Ernest, P. A. Surgeon, U. S. N., granted sick leave for three months.

ORIGINAL LECTURES.

VITILIGO.

A Clinical Lecture Delivered at the College of Physicians and Surgeons of Chicago.

BY HENRY J. REYNOLDS, M.D.,

PROFESSOR OF DERMATOLOGY IN THE COLLEGE; PROFESSOR OF SKIN AND GENITO-URINARY DISEASES, CHICAGO POLICLINIC; CHIEF DERMATOLOGIST TO THE WEST SIDE FREE DISPENSARY; SURGEON TO THE GENITO-URINARY DEPARTMENT WEST SIDE FREE DISPENSARY, ETC.

(Reported by WILLIAM WHITFORD.)

In the class of skin diseases known as "atrophies" we have a subdivision in which the atrophy or disease is entirely confined to the pigment or coloring matter of the skin. We meet with this condition at times as a congenital affection, when it is called *albinismus*. When it is acquired during the life of the individual it is called vitiligo. The congenital condition, or albinismus, is generally universal, of which the so-called albino is an example. The acquired form, or vitiligo, is always only partial.

While neither of these conditions is of great interest, therapeutically considered, as they are not, as a rule, very amenable to treatment, they are nevertheless, on account of their comparative rarity and the very striking deformity they produce, not only matters of great importance to those so afflicted, but of considerable interest to physicians. I therefore take great pleasure in introducing to your notice to-day a very well-marked case of the acquired form of the disease, or that known as vitiligo, or acquired leucoderma. This case is also interesting, inasmuch as it tends to show the hereditary tendency of the disease.

Let me first, however, briefly enumerate some of the more important characteristics of the disease. Though the case before us is a colored boy, the disease may occur in any race or age, and either sex. The disease first manifests itself as one or more small, white, non-pigmented spots, which may be of any shape, but are usually roundish at the onset. These patches are generally well-defined; in other words, the white color does not fade away gradually into the surrounding healthy skin, but terminates abruptly. The advance of the disease is by peripheral extension of the patches already formed, and by the development and spread of new non-pigmented spots. The surface of the diseased patch is always smooth and soft, there being nothing to indicate an involvement of any of the skin structures other than the pigment

or coloring matter; therefore the only form of lesion is the maculation. The secreting function of the sebaceous and sudoriparous glands is to all appearances unimpaired. It would be interesting, however, to know, in this connection, whether the natural, physiological odor of the part characteristic of the negro race was changed or not, as it would tend somewhat to show its source; but as the only scientific means at our disposal for making an estimate of this kind is the olfactory apparatus of the investigator, it is difficult, even in the more generalized form of the affection, or even in the universal form of albinismus, to state even approximately in this regard. The subjective sensation of the part is usually normal. The integument immediately surrounding the non-pigmented patches is frequently darker than normal, owing to a deposit there of an excessive amount of pigmentary matter. The hairs of the patch so affected are usually likewise destitute of pigment, and therefore white in color, though this is not universally the case. The disease, though sometimes very slow in its progress and extremely chronic, may eventually spread so as to cover very large areas. At certain times the disease seems to be more marked than at others, a fact which may be explained by the tanning, or bleaching of the surrounding integument incident to the change of the seasons or the occupation of the individual. The disease most commonly manifests itself on the backs of the hands, the neck, face, head, etc. There is no appreciable constitutional disturbance. It has by some been regarded as a form of leprosy, but it is not, as we shall see when we come to the question of diagnosis.

Case.—The history of the case is as follows: John Anderson, æt. 12, colored. Parents both colored, but mother has been afflicted since childhood with the same disease, and in a manner very similar to the case before you. He has eleven brothers and sisters, five of whom are marked like himself, one has only a white patch, involving both integument and hair, on the top of the head. The other five are all black and free from the disease. The disease commenced in all in early childhood. It soon reached its present state of development, and has not for years advanced any. You will first notice the white patch of hair extending from the forehead to the vertex. You will notice in this case that the disease is rather generally disposed, involving the arms, legs, body, face, hands, etc., in white patches of all sizes and shapes, from one to eight or ten inches in diameter. You will notice, also, that the skin to all appearances is

perfectly normal, apart from the lack of pigmentation, being smooth and free from other lesions of any kind; and that the subjective sensation of the parts is unaffected, as also the secreting function. In some places you will find an increased pigmentation of the surrounding integument, while in others it fades away more gradually. It is evident from its long existence and unchanging character that it is a very chronic, if not incurable disease. You see further that there is no evidence of any constitutional derangement, as he is a picture of physical vigor.

Etiology and Pathology.—The achromia is of course due to a lack of pigment in the rete mucosum of the affected part; and the darker color, sometimes observed surrounding the white patches, to an increased deposit of the same material; but what causes the deficiency or unequal distribution of the coloring matter, is at present practically unknown. Certain conditions, however, while they cannot be regarded as etiological factors, may be mentioned in this connection as having a certain etiological bearing. I refer to the age, race and sex. It usually makes its appearance in early and middle life, is more common in the negro, and is more frequently met with in males than females. Tilbury Fox thinks the sun's rays have a certain influence upon it. It is probable, however, that the disease results directly from a disturbance of the function of the nerves which preside over the nutrition of the part. This seems the more probable, inasmuch as the disease seems at times to follow the cutaneous distribution of certain nerves, and that the sensation of the affected part is, according to some observers, said also to be at times affected, but the causes which give rise to this perverted nerve function must with our present knowledge of the disease be, at best, only conjectural.

Diagnosis.—The diseases which most resemble vitiligo are partial congenital leucoderma, morphœa, tinea versicolor, chloasma and leprosy. In so pronounced a case as the one before us, however, it would be impossible, with even the slightest knowledge of the subject, to err in the diagnosis. In the diagnosis, for instance, in the white subject, and where the spots are not so numerous and the contrast not so great, more care may be required. The chief point of distinction between partial congenital leucoderma or partial albinism and vitiligo is that the former is acquired previous to birth, and remains permanently the same through life, while vitiligo is always acquired after birth, and is usually not stationary but progressive. Besides, we do not have the hyperpigmentation of the skin surrounding the patches in partial albinism which is frequently seen in vitiligo, but rather the reverse.

From morphœa the disease may readily be distinguished by the entire absence of any thickening or structural change of the derma, which is characteristic of morphœa. The margin is not so well defined in morphœa. In morphœa of any duration the secretory functions are impaired, owing to the structural changes. The tendency to spontaneous recovery is greater in morphœa.

In the white subject it might be necessary to differentiate between this disease and tinea versicolor.

It is only necessary, however, to determine which is the healthy and which is the diseased skin in order to settle this point, as the darkened skin is the diseased portion in tinea versicolor, whereas in vitiligo the darker skin is the normal skin. But this is not always so easy to determine in examining only a certain area. Tinea versicolor, however, is always found on the chest and trunk, and never extends up on the neck nor to the arms and hands, which are the favorite localities for vitiligo. We have the furfuraceous desquamation and the discovery of parasite with the microscope in tinea versicolor, which we do not have in vitiligo. This young lady, 16 years of age, represents a well-marked case of tinea versicolor, and as she passes around amongst you you will please notice the contrast.

In chloasma we have only the hyper-pigmentation or darkening of the skin without any absence of pigment in patches. It is usually due to constitutional derangement or cachexia, while there is not necessarily any systemic impairment in vitiligo.

Leprosy is a constitutional disease. We usually have structural changes in the derma, the sensation of the part is affected, it tends to fatal results, etc., all of which is the reverse of what is characteristic of vitiligo.

Treatment.—While vitiligo may usually be regarded as not amenable to treatment, we are nevertheless, at times, called upon to endeavor to relieve the deformity it produces. Various remedies have been recommended as constitutional measures. Among these may be mentioned nutritious diet, iron, mineral acids, nerve tonics, arsenic, phosphorus, nux vomica, the hypodermic injection of pilocarpine, etc. Locally, the use of cantharides, or mustard, applied to the patch, will sometimes produce at least temporary pigmentation. While, however, it is often difficult to produce pigmentation of the white patch, we are always able to diminish the pigmentation of the surrounding skin, and may thus greatly relieve the conspicuousness of the disease. For this purpose liq. potassæ, ammonia, acetic acid, bichloride of mercury, etc., may be applied in various strengths and combinations, as suggested in the treatment for chloasma.

ORIGINAL ARTICLES.

STRICTURE OF THE URETHRA; URETHRAL CALCULI; INTERNAL AND EXTERNAL URETHROTOMY; DEATH FROM PYELITIS.

BY S. T. ARMSTRONG, M.D., PH.D.,

PASSED ASSISTANT SURGEON U. S. MARINE HOSPITAL SERVICE.

Isaac Jackson, a negro, aged 30 (?), native of Mississippi, a laborer by occupation, was admitted to the City Hospital, Memphis, Tenn., on the evening of August 25, 1886, for inability to pass his urine. An attempt was made by the Internes, Dr. John Fricke, to introduce a catheter, but a stricture near the meatus prevented the passage of the instrument. As there was a constant dribbling of urine from the

urethra, thus partially relieving the over-distended bladder, no further operative interference was attempted that night.

As I was temporarily acting for the surgeon in charge of the hospital, the case came under my observation on August 26. The patient was a tall, muscular negro; his face wore an anxious expression; but slight febrile movement; the bladder was over-distended, reaching to within four centimetres of the umbilicus, and was distinctly noticeable as a large globular tumor beneath the abdominal parietes. The penis was of ordinary length; the prepuce, as is usually the case in negro men, was elongated; but the preputial meatus was so narrow that it was with great difficulty retracted, and when behind the corona it so effectually compressed the urethra that it was impossible to pass in an instrument.

The patient stated that the prepuce had been retracted with great difficulty all his life. He had gonorrhœa first when he was 21 years old, but since that age he had been rarely free from a gleety discharge. He has had within recent years some difficulty in passing his urine; and within the past six months this difficulty has markedly increased.

A No. 6 French *bougie à boule* was the largest instrument that could be introduced into the urethra; this detected three strictures within ten centimetres of the meatus, and the point of the bougie was stopped at that distance by a smaller contraction of the urethra. A Maisonneuve urethrotome was introduced, and the strictures incised, but the free passage of the instrument was prevented by some foreign body in the membranous urethra. These were supposed to be calculi, but no attempt was made to seize them, as no suitable forceps were at hand. The urethrotomy was made without an anæsthetic, some difficulty being experienced in manipulating the instrument on account of the prepuce. There was free hæmorrhage from the urethra, and the operation seemed to allow a free flow of urine. He was given sulphate of quinine and morphine, and further operative interference deferred until the following morning.

The patient passed a comfortable night, and on the morning of August 27 he was anæsthetized by chloroform, and first circumcised. Suitable forceps were introduced into the urethra, but the calculi could not be removed. The hair was shaved from the perineum and pubes, the entire region washed out with bichloride of mercury solution, and dissection of the perineum made to the urethra; the calculi were seized with dressing forceps, and two removed. A sound was passed from the meatus to the bladder, but no vesicle calculi were detected. Following the withdrawal of the sound, a quantity of purulent urine escaped through the perineal wound. The wound and the urethra were washed out with a warm bichloride solution, and iodoform dusted about the parts.

The patient reacted well after the operation, felt very comfortable, and was ordered five grains of quinine and ten drops of the tincture of the chloride of iron every three hours.

August 28 he felt better, the bladder comfortable;

the urethra was washed out with a warm solution of boracic acid. This treatment was continued daily, the Internes reporting no rise of temperature in the evening. But the patient was growing weaker, and died on the afternoon of September 1.

The necropsy was made seventeen hours post-mortem; rigor mortis. The brain was normal. The right lung was adherent by old pleuritic adhesions, otherwise normal; the left lung was adherent to the diaphragm, otherwise normal. The heart was normal. The liver was slightly enlarged. The spleen was light colored. Both kidneys were enlarged; suppurative inflammation of the pelvis and glandular substance; the ureters were dilated, being about five centimetres in diameter. The bladder contained urine and some blood coagulum. The prostate gland was normal, but just across the external boundary of the prostatic urethra was a thin band. The urethral and perineal wounds appeared healthy, and union had progressed well at the site of the circumcision. Death was caused by the pyelitis.

The calculi removed weighed 1.7 grains; they were phosphatic, and contained no nuclei.

This case is an admirable illustration of the advisability of removing a long tight prepuce, though by no means an argument for promiscuous circumcision. Had the prepuce been removed when the man was younger, he would have been less liable to the gonorrhœa, and if acquired, that disease would probably have followed its usually mild course in his race, thus escaping the stricture. Upon the latter, without doubt, depended the calculous formations, caused by deposit from the retained secretions. Their interference with the free evacuation of the bladder caused first cystic distension, then distension of the ureters and renal pelves, with the consequent inflammation.

MEDICAL PROGRESS.

THE TREATMENT OF PUERPERAL SEPSIS.—RUNGE, of Dorpat, states that his late experience in the treatment of puerperal sepsis has taught him a manner of dealing with the affection that yields far better results than other methods. A strict *local* therapeutics is carried out. Rigid antisepsis of hands and instruments in conducting the labor is the best prophylactic. The vulva is cleansed at the beginning of labor, but no vaginal irrigation is used before, during or after a normal labor, and in such uterine irrigation is held to be a *lapsus artis*. Lacerations are sutured if large, or dusted with iodoform if small. When fever sets in the cause is sought for, and if found in the genital apparatus he uses vaginal irrigations—temporary are preferred to permanent—and in cases of offensive lochia, uterine irrigation with a five per cent. carbolic acid solution. The latter is repeated once or twice, and during its use the vagina is protected by a stream of water. Further absorption of septic matter is in this way prevented. The object of general treatment is to raise and maintain the power of resistance of the system to enable it to

throw off the poison absorbed. To accomplish this purpose the most important vital functions of the organism must be maintained and regulated. These are sleep and digestion; and while these are preserved the system cannot yield to the disease.

All measures that impair the ability to take food must be considered objectionable in puerperal sepsis. Experience shows that the resisting powers of the organism are best maintained when *alcohol in large doses* is combined with *tepid baths*. The first results observable under their use are ability to take plenty of nourishment and the setting in of sound sleep, especially in restless patients. Alcohol is exhibited in the form of Stokes's mixture: *R. Cognac, aqua distil., aa 60.0; vitellus ovi unius, syr. simpl., 25.0*, of which one to two tablespoonfuls are given every hour, and between these doses, one to three tablespoonfuls of some strong wine. This is continued day and night until sound sleep ensues. To show the quantities taken he cites the instance of two patients, one of whom took during the first twelve days twelve bottles of port wine and 1200 grams of cognac, and the other, from the second to the ninth day, ten and one-half bottles of port or Madeira, and two liters of cognac. But alcohol alone does not bring on a desire for food. This is accomplished by the simultaneous use of tepid baths. Refusal of food, increased somnolency, a frequent and weak pulse, a high and equal temperature, restlessness and delirium, are indications for a bath. Collapse, also imminent collapse as indicated by unequal temperature and a flickering pulse, contraindicate a bath, while metastasis to the lungs and femoral thrombosis indicate great care in their use. The temperature of the bath should be 81° to 85° F., and in case of great somnolency one or two cold douches should be applied. It should not be extended beyond five to ten minutes, and at times a simple immersion is all that is admissible. He rarely begins with the baths before the third day, and gives one, two and three baths a day. Under this treatment patients readily take food, and milk, eggs, meat broths and meat, the latter finely cut or scraped, is freely given, and taken with relish. Castor oil is at first used to relieve constipation if present, and later on enemata are employed. Severe pain demands opium and ice to the hypogastrium, the ice being replaced by hydropathic compresses as the pain becomes less severe.

After defervescence is complete the patient is for a long time kept on large doses of ergot. The general should be begun conjointly with the local treatment. In the lymphatic form of puerperal sepsis, characterized by tympanitis, no great pain, frequent and feeble pulse, singultus, rare or absent vomiting, the puerperal peritonitis of authors, this line of treatment yields admirable results. It remains powerless in the form simulating perforative peritonitis or septic peritonitis after laparotomy, in which intense pain, enormous tympanitis, and incessant vomiting are pronounced symptoms.

Runge compares the present line of treatment with that of former years. The local treatment was what it is now, except that at one time voluminous irrigations were used for prophylactic purposes, but

again quickly abandoned when it became apparent that the mortality rate was increased. The general treatment consisted then, as now, of alcohol, but it was given in small, inefficient doses, and only when grave symptoms arose. Large doses of quinia were given under the sway of Liebermeister's views, for the purpose of reducing temperature. They did not at all influence the course of the disease. Thanks to the labor of Fränzel, Unverricht, and Naunyn, the views as to the injuriousness of fever have been set aside. But quinia, salicylic acid and the other antipyretics do not now exert as good influences on the course of the disease, but are positively injurious in puerperal sepsis by impairing and destroying the desire for food, and by covering up the real condition of the patient by their physiological symptoms when given in massive doses. The favorable influence on the heart's action and on the respiration, the action on the sensorium, the effect of maintaining and stimulating the desire for food, make the line of treatment now followed out stand out brightly before all others.—*Volkmann's Sammlung*, No. 287.

THE DIURETIC ACTION OF MERCURY.—In the *Practitioner*, September, 1886, an article is contributed by SPILLER LOCKE on the diuretic action of mercury. It has long been known that the action of digitalis and squills as diuretics is greatly assisted by the addition of a little mercury, and lately calomel alone has been lauded as a diuretic. The clue as to the diuretic action of mercury seems to be explained by the connection between bile-secretion and the formation of urea, lately demonstrated by Noël-Paton. This observer has noticed that uniformly a direct relation can be traced between the activity of a drug as a hepatic stimulant, and its activity in causing an increased formation and excretion of the most important nitrogenous waste-products. The administration of mercury to a dog in a state of nitrogenous equilibrium causes a marked increase in the amounts of urea, uric acid, and water excreted. Drugs which cause an increased formation of bile also cause an increased formation of urea; this fact gives new ground for the belief that the liver is the great seat for the formation of urea. Mercuric salts cause a greatly increased secretion of bile, as well as of urea, besides causing a destruction of red blood-corpuscles, according to Noël-Paton. It is well known that an increased quantity of urea in the blood acts as a powerful diuretic, and the good effects derived from the use of mercury in combination with digitalis and squills are readily explained by its action on some metabolic process—one outcome of which is the secretion of bile, and another the formation of urea. Rutherford has shown that calomel does not cause increased secretion of bile, and that mercuric salts only had a diuretic action; consequently in those cases in which calomel has produced diuresis, there must either have been some trace of the per-salt present, or the calomel has been transformed in the alimentary canal into the per-salt.—*London Medical Record*, Nov. 15, 1886.

THE
Journal of the American Medical Association.
PUBLISHED WEEKLY.

THE EDITOR OF THIS JOURNAL would be glad to receive any items of general interest in regard to local events, or matters that it is desirable to call to the attention of the profession. Letters written for publication or containing items of information should be accompanied by the writer's full name and address, although not necessarily to be published. All communications in regard to editorial work should be addressed to the Editor.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE.....\$5.00
SINGLE COPIES.....10 CENTS.

Subscriptions may begin at any time. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 65 RANDOLPH STREET,
CHICAGO, ILLINOIS.

SATURDAY, DECEMBER 25, 1886.

VITAL STATISTICS.

The value of correct records of the births and deaths in each town, county and State, for various purposes, is too generally known to require comment. Such vital statistics are as important to the medical profession in prosecuting inquiries concerning the causes, prevalence and results of disease, as they are to the sanitarian and the political and social economist in devising means for preventing disease, lessening poverty and increasing the duration of human life. And yet, their value for any of these purposes depends almost entirely upon their actual correctness. Many of the States have laws designed to ensure actually reliable returns of the births and deaths for their entire population, but in only a few have these laws been executed with such efficiency as to make the results of much value. This is illustrated by the annual reports of many of the State Boards of Health, and we have just been forcibly reminded of the same by a circular letter from the Secretary of the Illinois State Board of Health, containing the sections of the laws of the State relating to the returns of births and deaths and the penalties for neglecting the same, copies of which have been or will be sent to all the registered physicians and midwives in the State, accompanied by official notice that the law must be complied with from the first of January, 1887, or the penalties will be enforced.

A glance at the statistical tables in the recent annual report of the State Board shows that, although the law requiring all physicians and midwives to make returns to the designated officers of all births and deaths occurring under their care within thirty days, have been in existence since 1877, not an aver-

age of one-half of either have been returned in any part of the State except the city of Chicago. Here, the additional municipal law requiring the certificate showing the causes of death before permission can be obtained for burial, has resulted in a gratifying degree of correctness of the statistics of mortality. But even here not more than two-thirds of the births have been reported. We hope the physicians throughout the State will yield a cordial coöperation with the renewed efforts of the State Board of Health, to make the *vital statistics* of the State hereafter worthy of credit, and capable of subserving the important interests in advancing medical and sanitary science, as well as aiding in the solution of the important problems of social and political economy, for which they are designed.

CLOSE OF VOLUME VII.

The present number of THE JOURNAL closes the seventh volume, and contains a full index and title-page ready for binding. The beginning of the eighth volume the first week of January is a good time for new subscribers to commence taking THE JOURNAL. The fact that it contains all the papers read in the several Sections of the American Medical Association, many of the more important ones presented in the State Societies, and many valuable original contributions, enables it to give its readers pretty full information concerning all departments of the profession. This is rendered still more complete by regular reports of the most important Medical Societies of Boston, New York, Philadelphia, Washington and Chicago. The general circulation of THE JOURNAL in every part of the country makes it a desirable medium for medical writers and investigators to communicate with the profession, and we are having constantly a surplus of interesting matter on hand. If the friends of our State and National medical organizations would interest themselves sufficiently to give us a few hundred new subscribers we could enlarge THE JOURNAL by adding to its number of pages of reading matter, and increase the corps of assistants and correspondents to a very gratifying degree.

THE NATIONAL CODE OF MEDICAL ETHICS.—We republish in the present number of THE JOURNAL, the Constitution and By-Laws of the American Medical Association and the Code of Ethics, with the explanatory resolutions adopted at the annual meeting of the Association in 1885. The constant addition of new members to the Association makes it desirable that the Permanent Secretary should have a supply of these documents in convenient form for distribution. We shall therefore print an extra edition in cheap reprint form for general use.

PLAN OF ORGANIZATION FOR A NATIONAL MEDICAL ASSOCIATION.

Whereas, The Medical Convention, held in the city of New York, in May, 1846, have declared it expedient "for the medical profession of the United States to institute a National Medical Association;" and,

Inasmuch as an institution so conducted as to give frequent, united and emphatic expression to the views and aims of the medical profession in this country, must at all times have a beneficial influence, and supply more efficient means than have hitherto been available here for cultivating and advancing medical knowledge; for elevating the standard of medical education; for promoting the usefulness, honor and interests of the medical profession; for enlightening and directing public opinion in regard to the duties, responsibilities, and requirements of medical men; for exciting and encouraging emulation and concert of action in the profession, and for facilitating and fostering friendly intercourse between those who are engaged in it: therefore,

Be it resolved, In behalf of the medical profession of the United States, that the members of the Medical Convention held in Philadelphia in May, 1847, and all others who, in pursuit of the objects above mentioned, are to unite with or succeed them, constitute a National Medical Association; and that for the organization and management of the same, they adopt the following *Regulations* :—

I.—TITLE OF THE ASSOCIATION.

This institution shall be known and distinguished by the name and title of "The American Medical Association."

II.—MEMBERS.

The members of this institution shall collectively represent and have cognizance of the common interests of the medical profession in every part of the United States; and shall hold their appointment to membership either as delegates from local institutions, as members by invitation, as permanent members, or members by application.

The *Delegates* shall receive their appointment from permanently organized State Medical Societies, and such County and District Medical Societies as are recognized by representation in their respective State Societies, and from the Medical Department of the Army and Navy of the United States, and the Marine Hospital Service of the United States.

Each delegate shall hold his appointment for one year, and until another is appointed to succeed him, and shall participate in all the business and affairs of the Association.

Each State, County and District Medical Society, entitled to representation, shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number; *Provided*, however, that the number of delegates from

any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the Code of Ethics of this Association. The Medical Staffs of the Army and Navy shall be entitled to four delegates each. The Marine Hospital Service of the United States shall be entitled to one delegate.

No individual who shall be under sentence of expulsion or suspension from any State or local medical society of which he may have been a member, or whose name shall have been, for non-payment of dues, dropped from the rolls of the same, shall be received as a delegate to this Association, or be allowed any of the privileges of a member, until he shall have been relieved from the said sentence or disability by such State or local society, or shall have paid up all arrears of membership; nor shall any person not a member and supporter of a local medical society, where such a one exists, be eligible to membership in the American Medical Association.

No one expelled from this Association shall at any time thereafter be received as a delegate or member, unless by a three-fourths vote of the members present at the meeting to which he is sent, or at which he is proposed.

Members by Invitation shall consist of practitioners of reputable standing from sections of the United States not otherwise represented at the meeting. They shall receive their appointment by invitation of the meeting, after an introduction from, and being vouched for by, at least three of the members present, or three of the absent permanent members. They shall hold their connection with the Association until the close of the annual session at which they are received; and shall be entitled to participate in all its affairs, as in the case of delegates, except the right to vote.

The *Permanent Members* shall consist of all those who have served in the capacity of delegates, and of such other members as may receive the appointment by unanimous vote, and shall continue such so long as they remain in good standing in the body from which they were sent as delegates, and comply with the requirements of the By-laws of the Association. Permanent members shall at all times be entitled to attend the meetings, and participate in the affairs of the Association, so long as they shall continue to conform to its regulations, but without the right of voting; and, when not in attendance, they shall be authorised to grant letters of introduction to reputable practitioners of medicine residing in their vicinity, who may wish to participate in the business of the meeting, as provided for members by invitation.

Members by Application shall consist of such members of State or county societies, certified to be in good standing by the president and secretary of said societies, as shall make application for admission. They shall simply have the right to receive *THE JOURNAL* on the same terms as other members.

Every member elect, prior to the permanent organization of the annual meeting, or before voting on any question after the meeting has been organized, must exhibit his credentials to the proper committee,

and sign these regulations, inscribing his name and address in full, specifying in what capacity he attends, and, if a delegate, the title of the institution from which he has received his appointment.

III.—MEETINGS.

The regular meetings of the Association shall be held annually. The place of meeting shall be determined, with the time of meeting for each next successive year, by vote of the Association.

IV.—OFFICERS.

The officers of the Association shall be a President, four Vice-Presidents, one Permanent and one Assistant Secretary, a Treasurer, and Librarian. They shall be nominated by a special committee of one member from each State represented at the meeting, and shall be elected by vote on a general ticket.

Each officer, except the Permanent Secretary, shall hold his appointment for one year, and until another is elected to succeed him. The Permanent Secretary shall hold his appointment until removed by death, resignation, or a vote of two-thirds of the members present at a regular annual meeting.

The Presidents and Vice-Presidents shall assume the functions of their respective offices at the beginning of the annual meeting next succeeding their election; all other officers shall enter upon their duties immediately after their election.

The President shall preside at the meetings, preserve order and decorum in debate, give a casting vote when necessary, and perform all the other duties that custom and parliamentary usage may require.

The Vice-Presidents, when called upon, shall assist the President in the performance of his duties, and during the absence, or at the request of the President, one of them shall officiate in his place.

The Permanent Secretary shall record the minutes and authenticate the proceedings; give due notice of the time and place of each next ensuing annual meeting; notify all members of committees of their appointment, and of the duties assigned to them; hold correspondence with other permanently organized medical societies, both domestic and foreign; serve as a member of the Committee of Publication; and carefully preserve the archives and unpublished transactions of the Association.

The Assistant Secretary shall aid the Permanent Secretary in recording and authenticating the proceedings of the Association; serve as a member of the Committee of Arrangements, and perform all the duties of Permanent Secretary temporarily whenever that office shall be vacant, either by death, resignation, or removal.

The Treasurer shall have the immediate charge and management of the funds and property of the Association. He shall be a member of the Committee of Publication, to which committee he shall give bonds for the safe keeping and proper use and disposal of his trust. And through the same committee he shall present his accounts, duly authenticated, at every regular meeting.

The Librarian shall receive and preserve all the

property in books, pamphlets, journals, and manuscripts presented to or acquired by the Association, record their titles in a book prepared for the purpose, acknowledge the receipt of the same, and he shall be a member of the Committee of Publication.

V.—STANDING COMMITTEES.

The following standing committees, each composed of seven members, shall be organized at every annual meeting, for preparing, arranging and expediting business for each next ensuing year, and for carrying into effect the orders of the Association not otherwise assigned, namely, a Committee of Arrangements and a Committee of Publication.

The Committee of Arrangements shall, if no sufficient reasons prevent, be mainly composed of seven members, of whom the Assistant Secretary shall be one, residing in the place at which the Association is to hold its next annual meeting; and shall be required to provide suitable accommodations for the meeting, to verify and report upon the credentials of membership, to receive and announce all essays and memoirs voluntarily communicated, either by members of the Association, or by others through them, and to determine the order in which such papers are to be read and considered.

The Committee of Publication, of which the Secretaries, Treasurer, and Librarian must constitute a part, shall have charge of preparing for the press, and of publishing and distributing such of the proceedings, transactions, and memoirs of the Association as may be ordered to be published in such manner as the Association may direct. The six members of this Committee, who have not the immediate management of the funds, shall also, in their own names as agents for the Association, hold the bond of the Treasurer for the faithful execution of his office, and shall annually audit and authenticate his accounts, and present a statement of the same in the annual report of the Committee; which report shall specify the character and cost of the publications of the Association during the year, the number of copies still at the disposal of the meeting, the funds on hand for further operations, and the probable amount of the assessment to be laid on each member of the Association for covering its annual expenditures.

VI.—FUNDS AND APPROPRIATIONS.

Funds shall be raised by the Association for meeting its current expenses and awards from year to year, but never with the view of creating a permanent income from investments. Funds may be obtained by an equal assessment of not more than ten dollars annually, on each of the delegates and permanent members; by voluntary contributions for specific objects; and by the sale and disposal of publications, or of works prepared for publication.

The funds may be appropriated for defraying the expenses of the annual meetings, including the necessary expenses of the Permanent Secretary in maintaining the necessary correspondence of the Association; for publication; for enabling the Standing Committees to fulfill their respective duties, conduct their correspondence, and procure the materials nec-

essary for the completion of their stated annual reports; for the encouragement of scientific investigation by prizes and awards of merit; and for defraying the expenses incidental to specific investigations under the instruction of the Association, where such investigations have been accompanied with an order on the Treasurer to supply the funds necessary for carrying them into effect.

VII.—PROVISION FOR AMENDMENT.

No amendment or alteration shall be made in any of these articles, except at the annual meeting next subsequent to that at which such amendment or alteration may have been proposed; and then only by the voice of three fourths of all the delegates in attendance.

Provided, however, that when an amendment is properly under consideration, and an amendment is offered thereto, germane to the subject, it shall be in order, and if adopted, shall have the same standing and force as if proposed at the preceding meeting of the Association.

And, in acknowledgment of having adopted the foregoing propositions, and of our willingness to abide by them, and use our endeavors to carry into effect the objects of this Association as above set forth, we have hereunto affixed our names.

NAME OF MEMBERS.	RESIDENCE.	INSTITUTION REPRESENTED.

BY-LAWS.

I.—ORDER OF BUSINESS.

The order of business at the annual meetings of the American Medical Association shall at all times be subject to the vote of three-fourths of all the members in attendance; and, until permanently altered, except when for a time suspended, it shall be as follows, namely:

1st. The calling of the meeting to order by the President elected the preceding year, or, in his absence, by one of the Vice-Presidents.

2d. The report of the Committee of Arrangements on the credentials of members, after the latter have registered their names and addresses, and the titles of the institutions which they represent.

3d. The reception of members by invitation.

4th. The election of permanent members.

5th. The reading of notes from absentees.

6th. The hearing of the annual address of the President.

7th. The reception of the reports of all special committees and voluntary communications, and their reference to the appropriate sections.

8th. The appointment of the committee of one from each State represented, to nominate officers of the Association, and to fill the standing committees.

9th. The reading and consideration of the reports

of the Standing Committees, of Publication, on Prize Essays, and of Chairmen of Sections.

10th. Resolutions introducing new business, and instructions to the permanent committees.

11th. The selection of the next place of meeting.

12th. The report of the Nominating Committee, and the election of officers of the Association.

13th. Reports from the several Sections.

14th. Reading of the minutes by the Secretary.

15th. Unfinished and miscellaneous business.

16th. Adjournment.

II.—SECTIONS.

The general meetings of the Association shall be restricted to the morning sessions; and the afternoon sessions, commencing at three o'clock, shall be devoted to the hearing of reports and papers and their consideration, in the following Sections.

1. Practical Medicine, Materia Medica, and Physiology.

2. Obstetrics and Diseases of Women.

3. Surgery and Anatomy.

4. State Medicine.

5. Ophthalmology, Otology and Laryngology.

6. Diseases of Children.

7. Dental and Oral Surgery.

8. Medical Jurisprudence.

On the second day of each annual meeting each Section shall nominate its own officers to serve for the next ensuing year, their duties to commence with the close of the annual meeting at which they are nominated, and to continue until their successors are appointed.

The Section on State Medicine shall be composed of one member from each State, one from the army and one from the navy of the United States, representing, as far as practicable, the State Boards of Health. The officers of this Section to be also designated by the Committee on Nominations.

The chairmen of the several Sections shall prepare and read in the general sessions of the Association, papers on the advances and discoveries of the past year in the branches of sciences included in their respective Sections; the reading of such papers not to occupy longer than forty minutes for each.

It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper, or a *title* indicative of its contents, and its *length*, to the Chairman of the Committee of Arrangements at least one month before the annual meeting at which the paper or report is to be read. It shall also be the duty of the Chairman and Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge, for their respective Sections, the same length of time before the annual meeting. And the Committee of Arrangements shall determine the order of reading or presentation of all such papers, and announce the same in the form of a programme for the use of all members attending the annual meeting. Such programme shall also contain the rules specified in the By-laws and Ordi-

nances concerning the consideration and disposal of all papers in the Sections.

No paper shall be read before either of the Sections, the reading of which occupies more than twenty minutes. Such papers shall be referred by the Section to sub-committees especially appointed for their examination. The sub-committees shall be allowed thirty days for such examination; at the end of which time they shall forward the papers to the Committee of Publication, with such recommendation as they may deem proper. The author of such papers, however, may read abstracts before the Section within the allotted twenty minutes. No member shall address the Section more than once upon the same subject, nor speak longer than fifteen minutes without unanimous consent.

All papers presented directly to the Association, and other matters, may, at the discretion of the Association, be referred to the various Sections for their consideration and report.

Prize Essays.—There shall be four annual prizes of two hundred and fifty dollars each, which shall be awarded at the close of the second year after announcement, as hereinafter explained, for strictly original contributions to medical and surgical progress.

It shall be the duty of the chairman of each of the following four Sections: 1. Practical Medicine, Materia Medica, and Physiology; 2. Obstetrics and Diseases of Women; 3. Surgery and Anatomy; 4. State Medicine, to appoint annually before the adjournment of the meeting of the Association three members of ability and good judgment, who shall constitute a Committee of Selection, and who shall, within thirty days thereafter, select and publicly announce for competitive investigation and report, a subject belonging to one or other of the branches of medicine included in the title of the Section.

It shall also be the duty of the chairman of each of the Sections mentioned to appoint annually a Committee of Award, consisting of three experts, who shall carefully examine the essays offered for competition, and, if any one shall be found worthy of the prize as a substantial contribution to medical knowledge, to recommend the same to the Association.

All essays placed by their authors for competition shall be in the hands of the chairman of the respective Committees of Award on or before the first day of January preceding the meeting of the Association at which the reports of the committees are required to be made.

All Prize Essays shall be considered as the property of the Association.

The names of the authors of the competing essays shall be kept secret from the committees by such means as the latter may provide.

Membership in either of the two committees shall not debar from membership in the other; nor shall membership in the Committee of Selection exclude a member from the privilege of offering a competing essay.

III.—STANDING COMMITTEES.

The following are the Standing Committees of the

Association, to be filled by the Committee on Nominations, and to report at the next annual meeting subsequent to their appointment, namely, Committee of Arrangements, Committee of Publication, and Committee on American Medical Necrology.

The *Committee of Publication* shall append to each volume of the *Transactions* hereafter published, a copy of the Constitution, By-laws and Code of Ethics of the Association. It shall print conspicuously, at the beginning of each volume of the *Transactions* the following disclaimer, namely: The American Medical Association, although formerly accepting and publishing the reports of the various standing committees, holds itself wholly irresponsible for the opinions, theories or criticisms therein contained, except when otherwise decided by special resolution.

The *Committee on American Medical Necrology* shall consist of one member for each State and Territory represented in the Association, whose duty it shall be to procure memorials of the eminent and worthy dead among the distinguished physicians of their respective States and Territories, and transmit them to the chairman of this committee on or before the 1st of April of each and every year.

IV.—THE PUBLICATION OF PAPERS AND REPORTS.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Committee of Publication on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of the author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Committee of Publication shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

V.—ASSESMENTS.

The sum of five dollars shall be assessed, annually, upon each delegate to the sessions of the Association, as well as upon each of its permanent members, whether attending or not, for the purpose of raising a fund to defray necessary expenses. The payment of this sum shall be required of the delegates and members in attendance upon the sessions of the Association previously to their taking their seats and participating in the business of the sessions. Permanent members, not in attendance, shall transmit their dues to the Treasurer.

Any permanent member who shall fail to pay his annual dues for three successive years, unless absent from the country, shall be dropped from the roll of

permanent members, after having been notified by the Secretary of the forfeiture of his membership.

VI.—DELEGATES FROM THE MEDICAL STAFFS OF THE ARMY AND NAVY.

Delegates representing the medical staffs of the United States Army and Navy, shall be appointed by the Chiefs of the Army and Navy Medical Bureaus. The number of delegates so appointed shall be four from the army medical officers, and an equal number from the navy medical officers.

VII.—DELEGATES TO FOREIGN MEDICAL SOCIETIES.

The President shall be authorized annually to appoint delegates to represent this Association at the meetings of the British Medical Association, the American Medical Society at Paris, and such other scientific bodies in Europe or other foreign countries as may be affiliated with us.

VIII.—DUTIES OF MEMBERS.

No one shall be permitted to address the Association, except he shall have first given his name and residence, which shall be distinctly announced from the chair, and the members may be required to go forward and speak from the stand, but not more than ten minutes at one time.

No one appointed on a special committee who fails to report at the meeting next succeeding the one at which he is appointed, shall be continued on such committee or appointed on any other, unless a satisfactory excuse is offered.

IX.—CONDITION EXCLUDING REPRESENTATION.

No State or Local Medical Society, or other organized institution, shall be entitled to representation in this Association that has not adopted its Code of Ethics; or that has intentionally violated or disregarded any article or clause of the same.

X.—OF THE PREVIOUS QUESTION.

When the previous question is demanded, it shall take at least twenty members to second it; and when the main question is put under force of the previous question and negatived, the question shall remain under consideration the same as if the previous question had not been enforced.

XI.—JUDICIAL COUNCIL.

A council, consisting of twenty-one members, shall be appointed by the Nominating Committee, whose duty it shall be to take cognizance of, and decide, all questions of an ethical or judicial character that may arise in connection with the Association. Of the twenty-one members of the council first appointed the seven first named on the list shall hold office one year, and the second seven named shall hold office two years.

With these exceptions the term of office of members of the council shall be three years, seven being appointed by the Nominating Committee annually.

The said council shall organize by choosing a President and Secretary, and shall keep a permanent record of its proceedings. The decisions of said council on all matters referred to it by the Association shall be final, and shall be reported to the Association at the earliest practical moment.

All questions of a personal character, including complaints and protests, and all questions on credentials, shall be referred at once, after the report of the Committee of Arrangements or other presentation, to the *Judicial Council*, and without discussion.

XII.—NEW BUSINESS.

No new business, resolutions by members, etc., shall be introduced at the general session of the Association except on the first and fourth days of meetings.

XIII.—OFFICERS AND COMMITTEES.

In the election of officers and appointment of committees by this Association and its President, they shall be confined to members and delegates present at the meeting, except in the Committee of Arrangements.

ORDINANCES.

Resolved, That the several Sections of this Association be requested, in the future to refer no papers or reports to the Committee of Publication, except such as can be fairly classed under one of the three following heads, namely: 1. Such as may contain and establish *positively* new facts, modes of practice, or principles of real value. 2. Such as may contain the results of well-devised original experimental researches. 3. Such as present so complete a review of the facts on any particular subject as to enable the writer to deduce therefrom legitimate conclusions of importance.

Resolved, That the several sections be requested, in the future, to refer all such papers as may be presented to them for examination by this Association, that contain matter of more or less value, and yet cannot be fairly ranked under either of the heads mentioned in the foregoing resolution, back to their authors with the recommendation that they be published in such regular medical periodicals as said authors may select, with the privilege of placing at the head of such papers, "Read to the Section of the American Medical Association on the day of 18." (Vide *Transactions*, vol. xvi, p. 40.)

Resolved, That, instead of yearly reprinting the list of members of the American Medical Association, the Committee of Publication be instructed to prepare and print in the *Transactions* an alphabetical catalogue triennially, containing a complete list of the Permanent Members, with their names in full, designating their residences, the year of their admission, the offices they may have held in the Association, and, in case of death or rejection, the date thereof. (Vide *Transactions*, vol. xvii, p. 33.)

Resolved, That no report or other paper shall be presented to this Association unless it be so prepared that it can be put at once into the hands of the permanent Secretary, to be transmitted to the Committee of Publication. (Vide *Transactions*, vol. xvii, p. 27.)

Resolved, That the Permanent Secretary hereafter and from this date be authorized to draw a warrant upon the Treasurer for the expenses incurred in his attendance upon each session of the Association, and that the Treasurer is hereby instructed to pay the same. (Vide *Transactions*, vol. xviii, p. 42.)

Resolved, That those gentlemen who desire to report on special subjects, and will pledge themselves to report at the next meeting, be requested to send their names, and the subjects on which they desire to report, to the Permanent Secretary. (Vide *Transactions*, vol. xix, p. 42.)

Resolved, That hereafter the necessary expenses for rent of hall for general meetings and rooms for sections to accommodate the annual meetings, and the necessary expenses for cards of membership, be paid out of the treasury of the Association. (Vide *Transactions*, vol. xix, p. 42.)

Resolved, That this Association recognizes specialties as proper and legitimate fields of labor.

Resolved, That specialists shall be governed by the same rules of etiquette as have been laid down for general practitioners.

Resolved, That it shall not be proper for specialists publicly to advertise themselves such, or to assume any title not specially granted by a regularly chartered college.

Resolved, That private handbills addressed to members of the medical profession, or by cards in medical journals, calling the attention of professional brethren to themselves as specialists, be declared in violation of the Code of Ethics of the American Medical Association. (Vide *Transactions*, vol. xx, p. 28.)

Resolved, That a Committee of one be appointed, residing at Washington, to render the Librarian of Congress such assistance as the interests of the Association may require. (Vide *Transactions*, vol. xx, p. 29.)

Resolved, That the Committee of Arrangements for the next ensuing meeting of this Association, and for all meetings thereafter, be directed to prepare a list of members present on a separate roll, for convenience and accuracy in calling the ayes and nays when the same shall be demanded. (Vide *Transactions*, vol. xxi, p. 60.)

Resolved, That each year, until otherwise ordered, the President-elect and the Permanent Secretary be directed to appeal in the name of the Association, to the authorities of each State where no State Board of Health exists, urging them to establish such boards. (Vide *Transactions*, vol. xxvi, p. 50.)

Resolved, That the Permanent Secretary is hereby directed annually to report the names of States where boards of health exist, and also of those which decline to establish them; said report to form a part of the annual proceedings of the Association. (Vide *Transactions*, vol. xxvi, p. 50.)

Resolved, That members of the medical profession who in any way aid or abet the graduation of medical students in irregular or exclusive systems of medicine, are deemed thereby to violate the spirit of the ethics of the American Medical Association. (Vide *Transactions*, vol. xxvii, p. 48.)

Resolved, 1. That the American Medical Association adopts the International Metric System, and will use it in its Transactions. (Vide *Transactions*, vol. xxx, p. 44.)

2. Requests that those who present papers at its future meetings employ this system in their commu-

nications, or reprints thereof. (Vide *Transactions*, vol. xxx, p. 44.)

3. Requests the medical boards of the hospitals and dispensaries to adopt the Metric System in prescribing and recording cases; and that the Faculties of the medical and pharmaceutic schools adopt it in their didactic, clinical, or dispensing departments. (Vide *Transactions*, vol. xxx, p. 44.)

Resolved, That the President and Secretary of this Association are directed to annually petition Congress to enact a law which shall permit every person engaged in a scientific pursuit to import for his own use, free of duty, any one book or instrument appertaining to his special pursuit. (Vide *Transactions*, vol. xxx, p. 45.)

Resolved, That the above-named officers are further directed to urge the State Medical Societies and their auxiliary branches to aid this Association in accomplishing this purpose, by petitions to Congress, and by otherwise influencing Congressmen. (Vide *Transactions*, vol. xxx, p. 45.)

Decision by Judicial Council: A gentleman who is not in affiliation with a County, District, or State Medical Society, where such organizations exist, is not entitled to be registered as a permanent member upon the claim of having been a delegate from a body not now entitled to representation in this body. (Vide *Transactions*, vol. xxx, p. 57.)

Resolved, First. That a committee of five be appointed by the President of the Association, to be called the Standing Committee on "Atmospheric Conditions, and their Relations to the Prevalence of Diseases."

Second. That that committee be authorized to select such places as will best indicate atmospheric conditions in the more important climatic and sanitary districts of the United States—not less than six, nor more than twelve—and establish therefor a means for continuous observation and record of all appreciable conditions of atmosphere, according to the most approved methods, and of the origin and prevalence of all acute diseases.

Third. That the Committee, through their chairman, be authorized to draw upon the Treasurer of this Association for such sums as may be found necessary for the proper execution of the work assigned to it, the aggregate amount not to exceed \$500, during the ensuing year, and that a detailed report of all sums drawn, and expenditures made must be presented at the next annual meeting of the Association. (Vide *Transactions*, vol. xxxii, p. 35.)

CODE OF MEDICAL ETHICS.

OF THE DUTIES OF PHYSICIANS TO THEIR PATIENTS, AND OF THE OBLIGATIONS OF PATIENTS TO THEIR PHYSICIANS.

ART. I.—*Duties of physicians to their patients.*

§ 1. A physician should not only be ever ready to obey the calls of the sick, but his mind ought also to

be imbued with the greatness of his mission, and the responsibility he habitually incurs in its discharge. These obligations are the more deep and enduring, because there is no tribunal other than his own conscience to adjudge penalties for carelessness or neglect. Physicians should, therefore, minister to the sick with due impressions of the importance of their office; reflecting that the ease, the health, and the lives of those committed to their charge, depend on their skill, attention, and fidelity. They should study, also, in their deportment, so to unite *tenderness* with *firmness*, and *condescension* with *authority*, as to inspire the minds of their patients with gratitude, respect, and confidence.

§ 2. Every case committed to the charge of a physician should be treated with attention, steadiness, and humanity. Reasonable indulgence should be granted to the mental imbecility and caprices of the sick. Secrecy and delicacy, when required by peculiar circumstances, should be strictly observed; and the familiar and confidential intercourse to which physicians are admitted in their professional visits, should be used with discretion, and with the most scrupulous regard to fidelity and honor. The obligation of secrecy extends beyond the period of professional services; none of the privacies of personal and domestic life, no infirmity of disposition or flaw of character observed during professional attendance should ever be divulged by the physician except when he is imperatively required to do so. The force and necessity of this obligation are indeed so great, that professional men have, under certain circumstances, been protected in their observance of secrecy by courts of justice.

§ 3. Frequent visits to the sick are in general requisite, since they enable the physician to arrive at a more perfect knowledge of the disease—to meet promptly every change which may occur, and also tend to preserve the confidence of the patient. But unnecessary visits are to be avoided, as they give useless anxiety to the patient, tend to diminish the authority of the physician, and render him liable to be suspected of interested motives.

§ 4. A physician should not be forward to make gloomy prognostications, because they savor of empiricism, by magnifying the importance of his services in the treatment or cure of the disease. But he should not fail, on proper occasions, to give to the friends of the patient timely notice of danger when it really occurs; and even to the patient himself, if absolutely necessary. This office, however, is so peculiarly alarming when executed by him, that it ought to be declined whenever it can be assigned to any other person of sufficient judgment and delicacy. For the physician should be the minister of hope and comfort to the sick; that, by such cordials to the drooping spirit, he may smooth the bed of death, revive expiring life, and counteract the depressing influence of those maladies which often disturb the tranquility of the most resigned in their last moments. The life of a sick person can be shortened not only by the acts, but also by the words or the manner of a physician. It is, therefore, a sacred duty to guard himself carefully in this respect, and to

avoid all things which have a tendency to discourage the patient and to depress his spirits.

§ 5. A physician ought not to abandon a patient because the case is deemed incurable; for his attendance may continue to be highly useful to the patient, and comforting to the relatives around him, even in the last period of a fatal malady, by alleviating pain and other symptoms, and by soothing mental anguish. To decline attendance, under such circumstances, would be sacrificing to fanciful delicacy and mistaken liberality, that moral duty which is independent of, and far superior to, all pecuniary consideration.

§ 6. Consultations should be promoted in difficult or protracted cases, as they give rise to confidence, energy, and more enlarged views in practice.

§ 7. The opportunity which a physician not unfrequently enjoys of promoting and strengthening the good resolutions of his patients, suffering under the consequences of vicious conduct, ought never to be neglected. His counsels, or even remonstrances, will give satisfaction, not offense, if they be proffered with politeness, and evince a genuine love of virtue, accompanied by a sincere interest in the welfare of the person to whom they are addressed.

ART. II.—*Obligations of patients to their physicians.*

§ 1. The members of the medical profession, upon whom is enjoined the performance of so many important and arduous duties toward the community, and who are required to make so many sacrifices of comfort, ease, and health, for the welfare of those who avail themselves of their services, certainly have a right to expect and require, that their patients should entertain a just sense of the duties which they owe to their medical attendants.

§ 2. The first duty of a patient is to select as his medical adviser one who has received a regular professional education. In no trade or occupation do mankind rely on the skill of an untaught artist; and in medicine, confessedly the most difficult and intricate of the sciences, the world ought not to suppose that knowledge is intuitive.

§ 3. Patients should prefer a physician whose habits of life are regular, and who is not devoted to company, pleasure, or to any pursuit incompatible with his professional obligations. A patient should, also, confide the care of himself and family, as much as possible, to one physician; for a medical man who has become acquainted with the peculiarities of constitution, habits, and predispositions of those he attends, is more likely to be successful in his treatment than one who does not possess that knowledge.

A patient who has thus selected his physician should always apply for advice in what may appear to him trivial cases, for the most fatal results often supervene on the slightest accidents. It is of still more importance that he should apply for assistance in the forming stage of violent diseases; it is to a neglect of this precept that medicine owes much of the uncertainty and imperfection with which it has been reproached.

§ 3. Patients should faithfully and unreservedly communicate to their physician the supposed cause

of their disease. This is the more important, as many diseases of a mental origin simulate those depending on external causes, and yet are only to be cured by ministering to the mind diseased. A patient should never be afraid of thus making his physician his friend and adviser; he should always bear in mind that a medical man is under the strongest obligations of secrecy. Even the female sex should never allow feelings of shame or delicacy to prevent their disclosing the seat, symptoms, and causes of complaints peculiar to them. However commendable a modest reserve may be in the common occurrences of life, its strict observance in medicine is often attended with the most serious consequences, and a patient may sink under a painful and loathsome disease, which might have been readily prevented had timely intimation been given to the physician.

§ 5. A patient should never weary his physician with a tedious detail of events or matters not appertaining to his disease. Even as relates to his actual symptoms, he will convey much more real information by giving clear answers to interrogatories, than by the most minute account of his own framing. Neither should he obtrude upon his physician the details of his business nor the history of his family concerns.

§ 6. The obedience of a patient to the prescriptions of his physician should be prompt and implicit. He should never permit his own crude opinions as to their fitness to influence his attention to them. A failure in one particular may render an otherwise judicious treatment dangerous, and even fatal. This remark is equally applicable to diet, drink, and exercise. As patients become convalescent they are very apt to suppose that the rules prescribed for them may be disregarded, and the consequence, but too often, is a relapse. Patients should never allow themselves to be persuaded to take any medicine whatever, that may be recommended to them by the self-constituted doctors and doctresses who are so frequently met with, and who pretend to possess infallible remedies for the cure of every disease. However simple some of their prescriptions may appear to be, it often happens that they are productive of much mischief, and in all cases they are injurious, by contravening the plan of treatment adopted by the physician.

§ 7. A patient should, if possible, avoid even the *friendly visits of a physician* who is not attending him—and when he does receive them, he should never converse on the subject of his disease, as an observation may be made, without any intention of interference, which may destroy his confidence in the course he is pursuing, and induce him to neglect the directions prescribed to him. A patient should never send for a consulting physician without the express consent of his own medical attendant. It is of great importance that physicians should act in concert; for, although their modes of treatment may be attended with equal success when applied singly, yet conjointly they are very likely to be productive of disastrous results.

§ 8. When a patient wishes to dismiss his physician, justice and common courtesy require that he should declare his reasons for so doing.

§ 9. Patients should always, when practicable, send for their physician in the morning, before his usual hour of going out; for, by being early aware of the visits he has to pay during the day, the physician is able to apportion his time in such a manner as to prevent an interference of engagements. Patients should also avoid calling on their medical adviser unnecessarily during the hours devoted to meals or sleep. They should always be in readiness to receive the visits of their physician, as the detention of a few minutes is often of serious inconvenience to him.

§ 10. A patient should, after his recovery, entertain a just and endearing sense of the value of the services rendered him by his physician; for these are of such a character, that no mere pecuniary acknowledgement can repay or cancel them.

OF THE DUTIES OF PHYSICIANS TO EACH OTHER, AND TO THE PROFESSION AT LARGE.

ART. I.—*Duties for the support of professional character.*

§ 1. Every individual, on entering the profession, as he becomes thereby entitled to all its privileges and immunities, incurs an obligation to exert his best abilities to maintain its dignity and honor, to exalt its standing, and to extend the bounds of its usefulness. He should, therefore, observe strictly such laws as are instituted for the government of its members; should avoid all contumelious and sarcastic remarks relative to the faculty as a body; and while, by unwearied diligence, he resorts to every honorable means of enriching the science, he should entertain a due respect for his seniors, who have, by their labors, brought it to the elevated condition in which he finds it.

§ 2. It is not in accord with the interests of the public or the honor of the profession that any physician or medical teacher should examine or sign diplomas or certificates of proficiency for, or otherwise be specially concerned with, the graduation of persons whom they have good reason to believe intend to support and practice any exclusive and irregular system of medicine.

§ 3. There is no profession from the members of which greater purity of character and a higher standard of moral excellence are required, than the medical; and to attain such eminence is a duty every physician owes alike to his profession and to his patients. It is due to the latter, as without it he cannot command their respect and confidence, and to both, because no scientific attainments can compensate for the want of correct moral principles. It is also incumbent upon the faculty to be temperate in all things, for the practice of physic requires the unremitting exercise of a clear and vigorous understanding; and, on emergencies, for which no professional man should be unprepared, a steady hand, an acute eye, and an unclouded head may be essential to the well-being, and even to the life, of a fellow-creature.

§ 4. It is derogatory to the dignity of the profession to resort to public advertisements, or private cards, or handbills, inviting the attention of individ-

uals affected with particular diseases—publicly offering advice and medicine to the poor gratis, or promising radical cures; or to publish cases and operations in the daily prints, or suffer such publications to be made; to invite laymen to be present at operations, to boast of cures and remedies, to adduce certificates of skill and success, or to perform any other similar acts. These are the ordinary practices of empirics, and are highly reprehensible in a regular physician.

§ 5. Equally derogatory to professional character is it for a physician to hold a patent for any surgical instrument or medicine; or to dispense a secret *nos-trum*, whether it be the composition or exclusive property of himself or of others. For, if such *nos-trum* be of real efficacy, any concealment regarding it is inconsistent with beneficence and professional liberality; and if mystery alone give it value and importance, such craft implies either disgraceful ignorance or fraudulent avarice. It is also reprehensible for physicians to give certificates attesting the efficacy of patent or secret medicines, or in any way to promote the use of them.

ART. II.—*Professional services of physicians to each other.*

§ 1. All practitioners of medicine, their wives, and their children while under the paternal care, are entitled to the gratuitous services of any one or more of the faculty residing near them, whose assistance may be desired. A physician afflicted with disease is usually an incompetent judge of his own case; and the natural anxiety and solicitude which he experiences at the sickness of a wife, a child, or any one who, by the ties of consanguinity, is rendered peculiarly dear to him, tend to obscure his judgment, and produce timidity and irresolution in his practice. Under such circumstances, medical men are peculiarly dependent upon each other, and kind offices and professional aid should always be cheerfully and gratuitously afforded. Visits ought not, however, to be obtruded officiously; as such unasked civility may give rise to embarrassment, or interfere with that choice on which confidence depends. But, if a distant member of the faculty, whose circumstances are affluent, request attendance, and an honorarium be offered, it should not be declined; for no pecuniary obligation ought to be imposed, which the party receiving it would wish not to incur.

ART. III.—*Of the duties of physicians as respects vicarious offices.*

§ 1. The affairs of life, the pursuit of health, and the various accidents and contingencies to which a medical man is peculiarly exposed, sometimes require him temporarily to withdraw from his duties to his patients, and to request some of his professional brethren to officiate for him. Compliance with this request is an act of courtesy, which should always be performed with the utmost consideration for the interest and character of the family physician, and when exercised for a short period all the pecuniary obligations for such services should be awarded to him. But if a member of the profession neglect his business in quest of pleasure and amusement, he can-

not be considered as entitled to the advantages of the frequent and long-continued exercise of this fraternal courtesy without awarding to the physician who officiates the fees arising from the discharge of his professional duties.

In obstetrical and important surgical cases, which give rise to unusual fatigue, anxiety and responsibility, it is just that the fees accruing therefrom should be awarded to the physician who officiates.

ART. IV.—*Of the duties of physicians in regard to consultations.*

§ 1. A regular medical education furnishes the only presumptive evidence of professional abilities and acquirements, and ought to be the only acknowledged right of an individual to the exercise and honors of his profession. Nevertheless, as in consultations the good of the patient is the sole object in view, and this is often dependent on personal confidence, no intelligent regular practitioner, who has a licence to practice from some medical board of known and acknowledged respectability, recognized by the Association, and who is in good moral and professional standing in the place in which he resides, should be fastidiously excluded from fellowship, or his aid refused in consultation, when it is requested by the patient. But no one can be considered as a regular practitioner or a fit associate in consultation, whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology and organic chemistry.

§ 2. In consultations, no rivalry or jealousy should be indulged; candor, probity, and all due respect should be exercised toward the physician having charge of the case.

§ 3. In consultations, the attending physician should be the first to propose the necessary questions to the sick; after which the consulting physician should have the opportunity to make such further inquiries of the patient as may be necessary to satisfy him of the true character of the case. Both physicians should then retire to a private place for deliberation; and the one first in attendance should communicate the directions agreed upon to the patient or his friends, as well as any opinions which it may be thought proper to express. But no statement or discussion of it should take place before the patient or his friends, except in the presence of all the faculty attending, and by their common consent; and no *opinions* or *prognostications* should be delivered which are not the result of previous deliberation and concurrence.

§ 4. In consultations, the physician in attendance should deliver his opinion first; and when there are several consulting, they should deliver their opinions in the order in which they have been called. No decision, however, should restrain the attending physician from making such variations in the mode of treatment as any subsequent unexpected change in the character of the case may demand. But such variation, and the reasons for it, ought to be carefully detailed at the next meeting in consultation. The same privilege belongs also to the consulting physi-

cian if he is sent for in an emergency, when the regular attendant is out of the way, and similar explanations must be made by him at the next consultation.

§ 5. The utmost punctuality should be observed in the visits of physicians when they are to hold consultations together, and this is generally practicable, for society has been considerate enough to allow the plea of a professional engagement to take precedence of all others, and to be an ample reason for the relinquishment of any present occupation. But as professional engagements may sometimes interfere, and delay one of the parties, the physician who first arrives should wait for his associate a reasonable period, after which the consultation should be considered as postponed to a new appointment. If it be the attending physician who is present, he will, of course, see the patient and prescribe; but if it be the consulting one, he should retire, except in case of emergency, or when he has been called from a considerable distance, in which latter case he may examine the patient, and give his opinion in *writing* and *under seal*, to be delivered to his associate.

§ 6. In consultations, theoretical discussions should be avoided, as occasioning perplexity and loss of time. For there may be much diversity of opinion concerning speculative points, with perfect agreement in those modes of practice which are founded, not on hypothesis, but on experience and observation.

§ 7. All discussions in consultation should be held as secret and confidential. Neither by words nor manner should any of the parties to a consultation assert or insinuate that any part of the treatment pursued did not receive his assent. The responsibility must be equally divided between the medical attendants—they must equally share the credit of success as well as the blame of failure.

§ 8. Should an irreconcilable diversity of opinion occur when several physicians are called upon to consult together, the opinion of the majority should be considered as decisive; but if the numbers be equal on each side, then the decision should rest with the attending physician. It may, moreover, sometimes happen that two physicians cannot agree in their views of the nature of a case, and the treatment to be pursued. This is a circumstance much to be deplored, and should always be avoided, if possible, by mutual concessions, as far as they can be justified by a conscientious regard for the dictates of judgment. But in the event of its occurrence, a third physician should, if practicable, be called to act as umpire; and, if circumstances prevent the adoption of this course, it must be left to the patient to select the physician in which he is most willing to confide. But, as every physician relies upon the rectitude of his judgment, he should, when left in the minority, politely and consistently retire from any further deliberation in the consultation, or participation in the management of the case.

§ 9. As circumstances sometimes occur to render a *special consultation* desirable, when the continued attendance of two physicians might be objectionable to the patient, the member of the faculty whose assistance is required in such cases should sedulously guard against all future unsolicited attendance. As

such consultations require an extraordinary portion of both time and attention, at least a double honorarium may be reasonably expected.

§ 10. A physician who is called upon to consult, should observe the most honorable and scrupulous regard for the character and standing of the practitioner in attendance; the practice of the latter, if necessary, should be justified as far as it can be, consistently with a conscientious regard for truth, and no hint or insinuation should be thrown out which could impair the confidence reposed in him, or affect his reputation. The consulting physician should also carefully refrain from any of those extraordinary attentions or assiduities which are too often practiced by the dishonest for the base purpose of gaining applause, or ingratiating themselves into the favor of families and individuals.

ART. V.—*Duties of physicians in cases of interference.*

§ 1. Medicine is a liberal profession, and those admitted into its ranks should found their expectations of practice upon the extent of their qualifications, not on intrigue or artifice.

§ 2. A physician, in his intercourse with a patient under the care of another practitioner, should observe the strictest caution and reserve. No meddling inquiries should be made—no disingenuous hints given relative to the nature and treatment of his disorder; nor any course of conduct pursued that may directly or indirectly tend to diminish the trust reposed in the physician employed.

§ 3. The same circumspection and reserve should be observed when, from motives of business or friendship, a physician is prompted to visit an individual who is under the direction of another practitioner. Indeed, such visits should be avoided, except under peculiar circumstances; and when they are made, no particular inquiries should be instituted relative to the nature of the disease, or the remedies employed, but the topics of conversation should be as foreign to the case as circumstances will admit.

§ 4. A physician ought not take charge of or prescribe for a patient who has recently been under the care of another member of the faculty in the same illness, except in cases of sudden emergency, or in consultation with the physician previously in attendance, or when the latter has relinquished the case, or been regularly notified that his services are no longer desired. Under such circumstances, no unjust and illiberal insinuations should be thrown out in relation to the conduct or practice previously pursued, which should be justified as far as candor and regard for truth and probity will permit; for it often happens that patients become dissatisfied when they do not experience immediate relief, and, as many diseases are naturally protracted, the want of success, in the first stage of treatment, affords no evidence of a lack of professional knowledge and skill.

§ 5. When a physician is called to an urgent case, because the family attendant is not at hand, he ought, unless his assistance in consultation be desired, to resign the care of the patient to the latter immediately on his arrival.

§ 6. It often happens in case of sudden illness, or of recent accidents and injuries, owing to the alarm and anxiety of friends, that a number of physicians are simultaneously sent for. Under these circumstances, courtesy should assign the patient to the first who arrives, who should select from those present any additional assistance that he may deem necessary. In all such cases, however, the practitioner who officiates should request the family physician, if there be one, to be called, and, unless his further attendance be requested, should resign the case to the latter on his arrival.

§ 7. When a physician is called to the patient of another practitioner, in consequence of the sickness or absence of the latter, he ought, on the return or recovery of the regular attendant and with the consent of the patient, to surrender the case.

[The expression, "patient of another practitioner," is understood to mean a patient who may have been under the charge of another practitioner at the time of the attack of sickness, or departure from home of the latter, or who may have called for his attendance during his absence or sickness, or in any other manner given it to be understood that he regarded the said physician as his regular medical attendant.]

§ 8. A physician, when visiting a sick person in the country, may be desired to see a neighboring patient who is under the regular direction of another physician, in consequence of some sudden change or aggravation of symptoms. The conduct to be pursued on such an occasion is to give advice adapted to present circumstances; to interfere no further than is absolutely necessary with the general plan of treatment; to assume no future direction unless it be expressly desired; and, in this last case, to request an immediate consultation with the practitioner previously employed.

§ 9. A wealthy physician should not give advice *gratis* to the affluent; because his doing so is an injury to his professional brethren. The office of a physician can never be supported as an exclusively beneficent one; and it is defrauding, in some degree, the common funds for its support, when fees are dispensed with which might justly be claimed.

§ 10. When a physician who has been engaged to attend a case of midwifery is absent, another is sent for, if delivery is accomplished during the attendance of the latter, he is entitled to the fee, but should resign the patient to the practitioner first engaged.

ART. VI.—Of differences between physicians.

§ 1. Diversity of opinion and opposition of interest may, in the medical as in other professions, sometimes occasion controversy and even contention. Whenever such cases unfortunately occur, and cannot be immediately terminated, they should be referred to the arbitration of a sufficient number of physicians or a *court-medical*.

§ 2. As peculiar reserve must be maintained by physicians toward the public, in regard to professional matters, and as there exist numerous points in medical ethics and etiquette through which the feelings of medical men may be painfully assailed in

their intercourse with each other, and which cannot be understood or appreciated by general society, neither the subject-matter of such differences nor the adjudication of the arbitrators should be made public, as publicity in a case of this nature may be personally injurious to the individuals concerned, and can hardly fail to bring discredit on the faculty.

ART. VII.—Of pecuniary acknowledgments.

Some general rules should be adopted by the faculty, in every town or district, relative to *pecuniary acknowledgments* from their patients; and it should be deemed a point of honor to adhere to these rules with as much uniformity as varying circumstances will admit.

OF THE DUTIES OF THE PROFESSION TO THE PUBLIC, AND OF THE OBLIGATIONS OF THE PUBLIC TO THE PROFESSION.

ART. I.—Duties of the profession to the public.

§ 1. As good citizens, it is the duty of physicians to be ever vigilant for the welfare of the community, and to bear their part in sustaining its institutions and burdens; they should also be ever ready to give counsel to the public in relation to matters especially appertaining to their profession, as on subjects of medical police, public hygiene, and legal medicine. It is their province to enlighten the public in regard to quarantine regulations; the location, arrangement, and dietaries of hospitals, asylums, schools, prisons, and similar institutions; in relation to the medical police of towns, as drainage, ventilation, etc.; and in regard to measures for the prevention of epidemic and contagious diseases; and when pestilence prevails, it is their duty to face the danger, and to continue their labors for the alleviation of the suffering, even at the jeopardy of their own lives.

§ 2. Medical men should also be always ready, when called on by the legally constituted authorities, to enlighten coroners' inquests and courts of justice on subjects strictly medical—such as involve questions relating to sanity, legitimacy, murder by poisons or other violent means, and in regard to the various other subjects embraced in the science of Medical Jurisprudence. But in these cases, and especially where they are required to make a *post-mortem* examination, it is just, in consequence of the time, labor, and skill required, and the responsibility and risk they incur, that the public should award them a proper honorarium.

§ 3. There is no profession by the members of which eleemosynary services are more liberally dispensed than the medical, but justice requires that some limits should be placed to the performance of such good offices. Poverty, professional brotherhood, and certain of the public duties referred to in the first section of this article, should always be recognized as presenting valid claims for gratuitous services; but neither institutions endowed by the public or by rich individuals, societies for mutual benefit, for the insurance of lives or for analogous purposes, nor any profession or occupation, can be admitted to possess such privilege. Nor can it be justly expected of physicians to furnish certificates of inability to

serve on juries, to perform militia duty, or to testify to the state of health of persons wishing to insure their lives, obtain pensions, or the like, without a pecuniary acknowledgment. But to individuals in indigent circumstances, such professional services should always be cheerfully and freely accorded.

§ 4. It is the duty of physicians, who are frequent witnesses of the enormities committed by quackery, and the injury to health and even destruction of life caused by the use of quack medicines, to enlighten the public on these subjects, to expose the injuries sustained by the unwary from the devices and pretensions of artful empirics and impostors. Physicians ought to use all the influence which they may possess, as professors in Colleges of Pharmacy, and by exercising their option in regard to the shops to which their prescriptions shall be sent, to discourage druggists and apothecaries from vending quack or secret medicines, or from being in any way engaged in their manufacture and sale.

ART. II.—*Obligations of the public to physicians.*

*§ 1. The benefits accruing to the public, directly and indirectly, from the active and unwearied beneficence of the profession, are so numerous and important, that physicians are justly entitled to the utmost consideration and respect from the community. The public ought likewise to entertain a just appreciation of medical qualifications; to make a proper discrimination between true science and the assumptions of ignorance and empiricism; to afford every encouragement and facility for the acquisition of medical education—and no longer to allow the statute-books to exhibit the anomaly of exacting knowledge from physicians, under a liability to heavy penalties, and of making them obnoxious to punishment for resorting to the only means of obtaining it.

EXPLANATORY DECLARATIONS.

WHEREAS, Persistent misrepresentations have been and still are being made concerning certain provisions of the Code of Ethics of this Association, by which many in the community, and some even in the ranks of the profession are led to believe those provisions exclude persons from professional recognition simply because of differences of opinions or doctrines; therefore

1. *Resolved*, That clause first, of Art. IV, in the National Code of Medical Ethics, is not to be interpreted as excluding from professional fellowship, on the ground of differences in doctrine or belief, those who in other respects are entitled to be members of the regular medical profession. Neither is there any other article or clause of the said Code of Ethics that interferes with the exercise of the most perfect liberty of individual opinion and practice.

2. *Resolved*, That it constitutes a voluntary disconnection or withdrawal from the medical profession proper, to assume a name indicating to the public a sectarian, or exclusive system of practice, or to belong to an association or party antagonistic to the general medical profession.

3. *Resolved*, That there is no provision in the National Code of Medical Ethics in any wise inconsis-

tent with the broadest dictates of humanity, and that the article of the Code which relates to consultations cannot be correctly interpreted as interdicting, under any circumstances, the rendering of professional services whenever there is a pressing or immediate need of them. On the contrary, to meet the emergencies occasioned by disease or accident, and to give a helping hand to the distressed without unnecessary delay, is a duty fully enjoined on every member of the profession, both by the letter and the spirit of the entire Code.

But no such emergencies or circumstances can make it necessary or proper to enter into formal professional consultations with those who have voluntarily disconnected themselves from the regular medical profession, in the manner indicated by the preceding resolution.

N. S. DAVIS, of Chicago,
A. Y. P. GARNETT, of Washington,
H. F. CAMPBELL, of Augusta, Ga.,
AUSTIN FLINT, of New York,
J. B. MURDOCK, of Pittsburgh.

On motion of Dr. Brodie, the resolutions were unanimously adopted.

On motion of Dr. Keller, it was unanimously agreed that the resolutions be added as an explanatory addendum in all future publications of the Code.

AMERICAN MEDICAL ASSOCIATION.

FORMED IN 1846.

Next annual meeting will be held June 7th, 8th, 9th, and 10th, 1887, in Chicago, Ill. President, E. H. Gregory, M.D., St. Louis, Mo. Permanent Secretary, W. B. Atkinson, M.D., Philadelphia, Penn. Assistant Secretary, J. Nevins Hyde, M.D., Chicago, Ill. Treasurer, Richard J. Dunglison, M.D., Philadelphia, Penn. Librarian, C. H. A. Kleinschmidt, M.D., Washington, D. C. Chairman of Committee of Arrangements, Charles Gilman Smith, M.D., Chicago, Ill.

All membership dues should be sent direct to the Treasurer, RICHARD J. DUNGLISON, M.D., lock box 1274, Philadelphia, Penn.

MISCELLANEOUS.

ANCIENT IRISH MEDICAL JURISPRUDENCE.—DR. MAPOTHER, in the *Dublin Journal of Medical Science*, says that the Brehon Code of Laws, dating from the fifth century, and the oldest in Europe, deals largely with medical affairs. They refer to surgeons who lived before the second century. They carefully provide for distress—that is, taxation—for the support of the son taken from his dead mother's breast, for the incurable, for the care of the sick as to food, bedding, nursing, and a house with the wind blowing in all quarters and with a stream close by. The medical man had power to keep from the house

"fools and female scolds." The mode of restraint in case of a physician was, "Let his horse-whip and his probes be taken up. If he has not the proper number of such things, let a thread be tied about the finger next his little finger." The unqualified physician was to be fined if he operated without giving a guarantee against damages, or without giving notice that he was not qualified. The practitioner was to be quite exempt. An impartial physician was to be the judge of the mode of treatment and of the due recompense. The fees, always paid with oxen, the current coin, were most exactly proportioned to the rank of the patient.

STERILIZED HYPODERMIC SOLUTIONS.—DR. A. POEHL gives the following method in *Pharmaceutische Zeitung*: Water, which has been re-distilled from a mixture of about 2 per cent. of caustic soda and permanganate of potash (the first portions of the distillate, if showing traces of ammonia when tested by Nessler's reagent, having been rejected), is mixed with about 1 per cent. of pure chloroform. The alkaloidal salt is to be added and the solution heated in a flask, furnished with a thermometer, to a temperature of 70° to 62° C. until all traces of chloroform have been dissipated. The resulting solution is to be filtered through paper which has been folded ready for use, and afterwards been sterilized by heating to a temperature of 125° to 130° C. in an air-chamber or drying-oven, for at least one hour. Sufficient of the re-distilled water is to be poured through the filter to make the filtrate either weigh or measure accurately the desired quantity. Last, but by no means least, the solution is to be preserved in vials which have been washed with some of the same water and dried at a temperature of 125° to 130° C. or over. The cork used should also be washed in the re-distilled water, and dried in the same manner as the vials. Solutions thus prepared have been kept for months without showing signs of change.

[A still better way is to use soluble hypodermic tablets, dissolving them in clear water brought to the boiling point in a spoon.]

TO DISTINGUISH OLEOMARGARINE FROM BUTTER.—J. Horstler recommends the following procedure: A piece of oleomargarine, the size of a hazelnut, is placed in a test-tube, and the end made air-tight. Into another test-tube a like quantity of butter is treated in the same way. When both test-tubes are held in the hand the oleomargarine soon liquefies, forming a clear solution; whilst butter requires double the time for solution, and when dissolved is not so clear as the oleomargarine solution. When the tube is filled one-third with ether, the oleomargarine is easily dissolved, and does not produce any turbidity or precipitate on the addition of alcohol. Butter when treated in like manner yields a precipitate.—*Microscope*, Dec., 1886.

DETROIT BOARD OF HEALTH.—An effort is to be made to abolish the health board of Detroit, Michigan, and create a Health Commissionership endowed with full power.

NITRITE OF AMYL IN OPIUM POISONING.—Nitrite of amyl has recently given excellent results in a case of opium poisoning in which belladonna failed, and when the patient was thought to be beyond medical aid.

UNIVERSITY OF MICHIGAN.—The Board of Regents of the Michigan University has decided to ask the legislature for \$75,000 with which to build and furnish a new laboratory for the use of the four departments of physics, hygiene, microscopy and physiology.

DR. G. ADLER BLUMER, first Assistant Physician of the Utica Asylum for the Insane, has been unanimously elected Superintendent of the Asylum, to fill the vacancy caused by the death of Dr. John P. Gray. Dr. Blumer is a native of England, and was graduated from the Medical Department of the University of Pennsylvania in 1879.

THE COMMITTEE FOR COLLECTIVE INVESTIGATION.—We are in receipt of the following communication: In the session of the International Medical Congress of Copenhagen I was appointed the American member of the Committee for Collective Investigation, and permitted to select a colleague in the United States. Thus the pamphlets and circulars prepared by, or with the authority of the general Committee in London, were distributed under the names of N. S. Davis, and the undersigned. They were made returnable to my address on January 1, 1887. As I have resigned my position on the above Committee, I require the permission and privilege of notifying, through your journal, the holders of the above pamphlets that they ought to be sent to N. S. Davis, M.D., 65 Randolph Street, Chicago, Ill., instead of the undersigned. Very respectfully,

A. JACOBI, M.D.

110 W. 34th St., New York, Dec. 19, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 11, 1886, TO DECEMBER 17, 1886.

Major Jno. W. Williams, Surgeon, ordered for duty at Jackson Bks., La. S. O. 205, Div. Atlantic, Dec. 14, 1886.

Major B. F. Pope, Surgeon, relieved from duty in the office of the Surgeon-General of the Army, and will report in person to the President of the Army Medical Examining Board in New York City for duty as member and Recorder of the Board. S. O. 285, A. G. O., Dec. 9, 1886.

Pope, Benj. F., Major and Surgeon, so much of S. O. 285, A. G. O., Dec. 9, 1886, as directs him to report in person to the President of the Army Medical Examining Board, New York City, for duty as member and Recorder of the Board, is revoked. S. O. 287, A. G. O., Dec. 11, 1886.

Capt. Joseph K. Corson, Asst. Surgeon, leave of absence extended seven days. S. O. 288, A. G. O., Dec. 13, 1886.

First Lieut. Chas. C. Barrows, Asst. Surgeon, granted leave of absence for two months, to take effect when his services can be spared by his post commander. S. O. 285, A. G. O., Dec. 9, 1886.

First Lieut. Geo. F. Wilson, Asst. Surgeon, granted leave of absence for one month, with permission to apply to Hdqrs. Div. of the Missouri for an extension of twenty days, to take effect about Dec. 15, 1886. S. O. 138, Dept. Dak., Dec. 1, 1886.

First Lieut. R. R. Ball, Asst. Surgeon, ordered for duty at Ft. Riley, Kans. S. O. 125, Dept. Mo., Dec. 13, 1886.
